In every rocky desert are found two distinctive fea tures which form characteristic phenomena of the wide, barren landscape beaten upon by the fierce sun of the sub-tropics: *the so-called tropic protective crust and the intricately winding dry valleys with smooth steep sides known as wadis*

These phenomena have hitherto been regarded as separate and dissociated in cause but recent investiga tions have clearly demonstrated their close connection *and interdependence*

The term "tropic protective crust' is used to designate the thin hard coating found upon all desert rocks This coating due to the intense dry heat consists of a layer of iron and manganese oxide It may be distinguished from the rock itself by scratching with a sharp instru ment.

According to the investigations of Mr J Walther a yellow color shows a newly formed crust containing a hydrated iron oxide a red color shows an older crust which has been changed into iron oxide by loss of water and a gray tint shows the presence of manganese oxide

The colors *of the crust vary between deep black clear* gray and all shades of brown which generally shows the presence of silicic acid the darker the stone the richer being the crust in this acid

The second marked phenomenon of these deserts are the ravines cut deep in the horizontal plateaus inclosed *by lofty unscalable walls, and often ending in a steep* blind wall after long extents, measured by journeys of hours or even days

The desert east of the Nile valley beginning near Cairo is a characteristic rocky desert and affords an ad mirable as well as accessible field of observation

I INVESTIGATION OF EFFECT OF PROTECTIVE CRUST ON INTENSITY OF EROSION

In the desert a distinct difference is to be noted be tween stone exposed to direct sun and that which re ceives little or no sunshine

The first is covered with a crust which is harder than the mother stone and is severely eroded on the surface, to which fact is due the name tropic protective crust

This crust or rind is formed wherever direct sun rays fall but also creeps into tiny superficial cracks into which no rays penetrate It would thus seem to be due to the heating of the stone which favors a chemical combina tion of the stone with the iron and manganese salts of the atmosphere

Those portions of the stone lying in shadow on the other hand are not protected by a crust against super ficial erosion Hence the moisture of the night dew or an occasional rain remains longer and chemical erosion proceeds unhindered

Erosion therefore begins in the shadowed part form ing tiny cracks or projections which gradually increase inward until a cavity is formed in the side or top or the projecting portion eaten away from beneath falls of its own weight

This is called erosion from within outwards When a large piece of rock forming such a projection breaks off a protective crust is at once formed on the exposed sur face of the breach. The fallen block lying on the ground shows the protective crust on every side, but betrays inner cavities which have eroded outward so as to break through the crust, in which case the crust extends in patches from the roof of the cavity

The pendent parts shadow the bottom of the cavities formed by them and therefore accelerate the erosion But these fragments and projections owe their existence to the protective crust since this preserves them from too rapid decay

Often indeed the mother stone is entirely eroded, and only the harder crust still hangs to the rock as the roof or sidewall of a cavity

Thus we see that the term "protective' crust is accurate only in that the stone immediately underlying it is pro tected. On the contrary, the crust favors the shade erosion which is the dominating factor in the desert, since through its greater hardness and durability it allows such shadow-making portions of the rock as the roofs or walls of caves to stand longer than they otherwise would.

Since the crust favors the dominant cause concerned in the characteristic rock forms of the desert, by logical deduction it must be a significant factor in the formation of the wadis.

It is not, however, here implied that the crust is a necessary feature of erosion, since crusted and non-eroded rocks are found.

In order to discover whether there was a "weather side" in the desert I examined Egyptian architecture

In the desert itself there are too many factors con *cerned for a definite result to be reached The direction* of the wind and the hardness of the stone are determin ing factors, and moreover it is difficult to find a block of an undoubtedly synchronous breach and yet of a dif ferent orientation

But it is a well known fact that the stones employed *in Egyptian buildings show crusts after 6 000 years*

One of the best known examples of this is the dam dis covered by Schweinfurth in the Wadi Geraui at Heluan The blocks used there which have an eastern exposure are only slightly attacked on top and show a marked browness yet a distinct cavity is eroded in the soft *gypsum of every stone*

For our purpose, however the pyramids offer the best example being exposed to every point of the compass Of the pyramids at Ghiseh only the Chefren still shows a portion of the original covering near the summit The others show only eroded blocks the time of whose ex posure is undiscoverable

All four sides of the Chepen pyramid have an equally brown tint showing an equal amount of erosion The vertical summer sun therefore has strength enough to develop the crust even on the north side

This facilitates the study of the wadis since in in *vestigating the crust erosion* the orientation of the rocks may be disregarded without its becoming a serious source of error

If we look at the Sphinx we observe that on the back of the head there is a strongly marked crust and obvious erosion has begun while on the eastward looking face there is little crust and little erosion It seems to re main true that where there is little crust there is little erosion

A special form of the crust is here referred to in which on normal brown crusted rock a slag like applied crust appears in spots This is black and always raised in relief If such a stone is cut in sections there is usu ally found lying under these accretions darker stone containing lumps and hollows or else arranged in layers The hardness tests show it to consist of horn stone injections in chalk which explains the dark color since this gains in darkness as it gains in silicic acid It is not unusual for horn tone to be found in localities where fossilized wood is often found In any case we see that harder stone raised in relief lies opposite crust covered chalk

When the chalk weathers its protective crust does not completely resist the outer erosion but renews itself con stantly much like the human skin without showing definite flaking

In this process of renewal it takes material from the mother stone and occasions therefore a steady erosion from without inward

This erosion, which is naturally very slow proceeds side by side with the much more rapid and important shadow erosion

The crust does not always work continuously into the rock There are cases in which the crust breaks loose from the rock in layers—the process of desquamation In such instances the action is ascribed to solutions of salt which have filtered in and then crystallized

WADIS.

The extensive course of all wadis suggests water as the creative agent The question is whether the quantity of water now available is sufficient to have caused them or whether a greater precipitation formerly existed

For the Sinai desert a *pluvial period* seems indicated Hume concludes from marked boulder and pebble de posits that great snow fields existed in former ages He considers it certain for Sinai that now in the pebble de posits of the wadi mouths the denudation exceeds the de posit, and that therefore smaller streams now dig their beds in the pebble deposits washed down by former mighty floods

Direct conclusions as to the Nile valley cannot be drawn from this, but close observation of wadi formation gives various indications that water erosion has had a share in modeling the relief of the desert and that to a *greater extent formerly than now*

Take the Wadi Hof for example It is at once obvi ous that we find ourselves in a valley where water has been active The ground consists of rounded grains of sand If there are contiguous walls we find definite water erosion grooves, with clearly defined wave marks Here we find white eroded channels Yonder we find heaped up piles of rubbish

Now let us direct our gaze to a bank of hard chalk over which erosive masses of water have undoubtedly plowed *when some rare rainfall has sent down its* revivifying floods On this bank we find at spots where the water must flow with slight force light traces of crust while wherever the water has dry furrows with violent deluges not the slightest remnant of the brown crust remains

Thus we see that in many places the water has gained the victory in others the crust has won the day

In order to study better this conflict between crust and water I investigated the chalk banks in the branch wadis leading off from the main wadi since there in all prob ability the crust action would be greater because of the smaller quantities of water

This conjecture was verified for without exception the ground of the branch wadis showed wherever hard chalk banks were present dark crust above earlier erosion marks

In the foregoing I have sought to present a series of erosion phenomena which give an impression that the condition of the desert valleys of the localities consid ered cannot have been caused by such quantities of water as exist at present

The conflict between the water and the crust gave us the clue and showed how in the branch wadis the crust formation had the upper hand while only in the main *ravines could sufficient amounts of water collect to ef fectually oppose the crust formation*

This struggle was active when mighty floods still rushed through the valleys but slowly the waters dimin ished and the crust won the upper hand

The eroded chalk banks show positively that to-day *the crust action is greater in extent than water erosion* for the bed worn by the rain water occupies only a small part of the whole width of the wadi Moreover those parts of the broken stone coated with the brown crust are not partially washed away again as we saw them in the main wadis

If we observe upon a flat surface the formation of a wadi we are struck by the long crooked strips of vege tation which lead to small depressions and mark the course of the wadi It is in these channels that the water runs when it rains forming pools and occasioning the growth of vegetation

The roots of these plants preserve the moisture longer and therefore give rise to more rapid erosion in their neighborhood than in dry localities and thus assist the destructive action of chemical agencies later At some point a projection is formed cavities begin to be en larged and we have the commencement of a wadi

The essential thing is in my opinion the *co operative action* of vegetation and water which loosens or disin tegrates long strips of the desert and makes them more susceptible to subterranean erosion later

That water is present in the sub soil of the wadis is proved by the cisterns which are always found in the course of the valleys But their excavation is continued at the present day essentially by crust erosion and the formation of projections

But the apparent conclusion that no valleys of long ex tent can now be formed without kettle shaped cavities is not justified Let us examine more closely the erosion in the wadis We know that huge blocks fall through being hollowed out and help to widen the wadi their fragments forming the rubbish of the sloping sides On the one hand cavities will be formed on the other the valley will be cut back But since in the backward lengthening process of the wadi the stone is prepared for subsequent weathering by the influence of vegetation and subter ranean erosion the progress of the wadi in this direction will be considerably more rapid Translated for the SCIENTIFIC AMERICAN SUPPLEMENT from *Globus*

Excavations in the Ruins of Abasside Palace

ARCHÆOLOGICAL work of some interest was carried out by an expedition sent to Turkey from France and headed by M Henry Viollet He made excavations with the per mission of the Turkish government in the ruins of the celebrated Abasside palace at Simara dating from the first half of the ninth century of our era It is a unique specimen of the architecture of this period which is still very obscure The present palace was the residence of the Arab caliphs who had been expelled from Bagdad for a certain period on acount of military seditions The archæologist has now returned to Paris and made a report to the Academy on the subject.

Safety Stops for Steam Engines

Practical Suggestions for Engineers

By W H Wakeman

A SAFETY stop on a steam engine is of as much importance as a safety valve on a steam boiler. In this article most of the safety devices used in connection with the engine governor are illustrated and their action described.

A safety stop for a steam engine is any kind of a device that will stop an engine should the governing

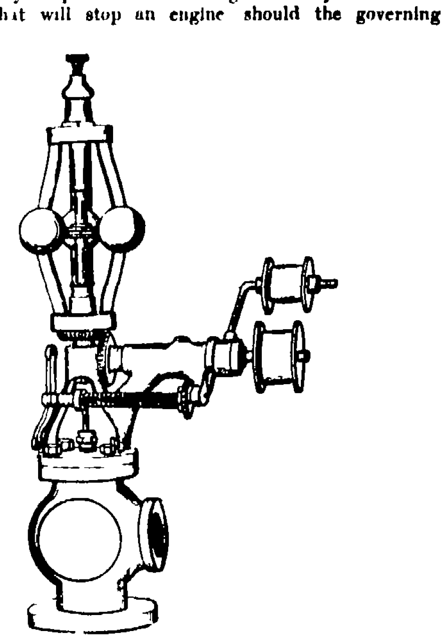

Fig 1

apparatus get out of order, and although some types of stop device will shut down an engine when the load is greater than it can carry under existing conditions, they should also be classed with the safety stop.

Fig 1 shows a simple type of safety stop. An idler travels on the top side of the belt and should the belt break or slip off the idler will fall into a lower position. This disengages the speed pawl releasing the valve which drops, shutting off steam from the engine cylinder. The packing in the stuffing box around the valve stem should be kept in good order, as it is possible to prevent prompt action of this stop should the stuffing box nut be screwed down too hard on unsuitable packing or on packing that has outlived its usefulness.

The governor shown in Fig 2 is located on the engine frame about 4 feet from the cylinder instead of directly over the steam chest. Should the governor belt break or be thrown from the pulley steam would be shut off from the cylinder. The device for opening the steam valves is similar to the Corliss gear. Steam is admitted and cut off automatically from zero to about one half stroke under normal conditions, and if more load is added the flyballs take a lower position and steam follows the piston the entire stroke providing the balls and the center weight do not fall to their lowest possible position.

If the governor belt should break or from any other cause the flyballs should move slower than usual or stop, the center weight will drop as low as possible which will cause the tripping toes on the cutoff mechanism to prevent the steam valves from opening, hence steam is not admitted to the cylinder and the engine will stop. When it is time to shut down a block is inserted, as shown at A. While this allows the center weight to go low enough to give steam to the cylinder during full stroke of the piston it does not allow the safety stop to operate. This makes it possible to handle the engine properly and not allow it to stop on either center. When starting the engine and the throttle valve is wide open, the block A is removed from the governor.

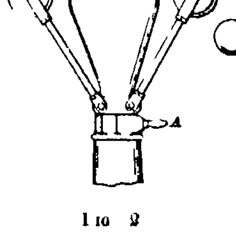

Fig 2

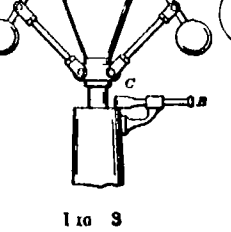

Fig 3

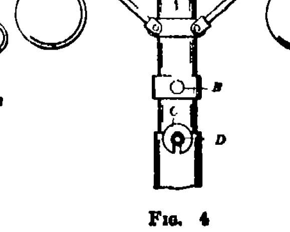

Fig. 4

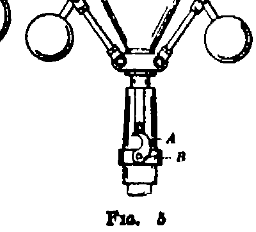

Fig. 5

Another device for blocking a governor is shown in Fig 3, which, to a certain extent, is automatic in operation. It is shown in running position. The sliding block B is held in an out position by a concealed spiral spring. Should the governor belt fail, the flyballs will stop and the center weight will fall to its lowest position. If it is desired to shut the engine down in regular service, close the throttle valve and as the speed slackens, the stop lever B is pushed inward against the spiral spring until it strikes the spindle, and is held there until the weight and collar C rests upon it. When the engine is started and the flyballs gain sufficient speed to raise the center weight, B is liberated, the spring throws it outward and the stop is set automatically.

A homemade device for blocking a governor on a Corliss engine is shown in Fig 4. The sliding sleeve A is in a position for an average load on the engine, but if the throttle valve is closed the projecting pin B falls until

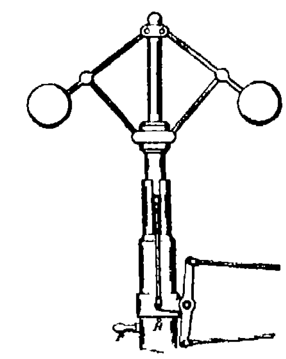

Fig 6

it rests on the thick washer C carried by the stationary pin D. This allows steam to follow the piston full stroke, and enables the engineer to stop the engine in any desired position. When the engine is started again and brought up to regular speed B rises from the washer C which is then removed from the pin D. This permits the collar B to drop low enough to prevent the steam valves from hooking on the catch blocks should the governor belt break.

An automatic device for releasing a governor after it has been blocked is shown in Fig 5. As soon as the fly balls revolve fast enough to raise the center weight the catch piece A turns one half revolution to the right on

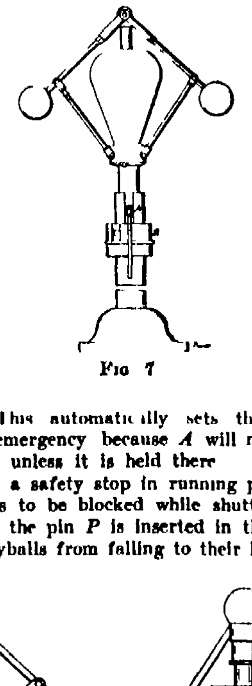

Fig 7

the pin B. This automatically sets the safety stop ready for an emergency because A will not stay in the position shown unless it is held there.

Fig 6 shows a safety stop in running position. When the governor is to be blocked while shutting down and starting again, the pin P is inserted in the hole H and prevents the flyballs from falling to their lowest position. In case the engine should stop with the pin out of the hole H, first close the throttle valve, then lift up the flyballs and put the pin in the hole H. Then unhook the reach rod and rock the wristplate to its extreme travel in both directions so that both steam valves will catch into the catch blocks, and drop the reach-rod hook into place. Steam can then be turned on and the engine started.

The governor shown in Fig 7 is in its running position with a heavy load on the engine. If more load is added the projecting pin A will rest on the movable collar B, causing steam to follow the piston full stroke. If the collar B were moved until the vertical slot C is directly under pin A, and more load is put on the engine, the center weight will fall to its lowest position, causing steam to be shut off from the cylinder.

A governor fitted with a center weight appears to be much more sensitive than if the center weight were omitted, hence it ought to operate a stop motion almost instantly. This form of governor is more sensitive while in full operation than the style shown in Fig. 6, but the former is always operated at a much higher speed, and it will run longer after the belt is removed. The effect of this action on the flyballs is partially offset by the center weight. In either case great care should be taken to have the dashpot, which usually forms a part of such governors, properly adjusted, as otherwise it may hold the flyballs up for a few seconds, when time is very valuable, and thus cause much damage.

This warning may be needed in cases in which such need is least suspected, for the following reason. An engine may nearly always carry a light load, causing the flyballs to move on a high plane, and allowing the center weight to travel through a limited vertical space. Long service under these conditions results in a very easy movement of these parts through their ordinary limits, but when moving below these limits they may not move so easily. This difference would only be noticed when the engine is started, and not then unless the engineer is especially careful to observe the details

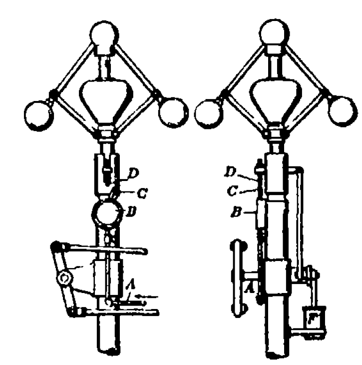

Fig 8

of operation, for the only difference is that the flyballs must be given a higher speed than if there were less friction. Even this may not exceed the highest speed attained under common conditions. After steam is shut off by closing the throttle valve, and the center weight is moving downward, it may show irregular motion, but as this cannot affect any other part, it may not attract attention.

Fig 8 shows two views of a governor equipped with a stop that is automatic in both directions. It is shown in running position. Steam from the bonnet of the throttle valve is carried through the small pipe A into the disk B where it operates on a device similar to the Bourdon spring in a steam gage, which throws C out of a vertical position as shown. Therefore the bolt D cannot rest upon it if the center weight is falling to its lowest position should the governor belt break or come off the pulley. Consequently the stop operates and steam is shut off from the cylinder.

When steam is shut off by closing the throttle valve, pressure falls in the pipe A which is piped to the steam chest or to the throttle valve under the disk; hence, the spring inside of B carries C into an upright position just in time for D to rest upon it. When the throttle valve is opened again pressure begins to rise in the pipe A, but it is not sufficient to throw the lever C over until D is lifted from it by the action of the flyballs, thus requiring no attention from the engineer. F is a dashpot which prevents the center weight from moving too rapidly.

The small pipe A carries pressure to B when the throttle valve is open, but when closed, pressure is shut off from the stop.

A peculiar governor is illustrated in Fig. 9. Centrifugal force, caused by high speed, throws the governor

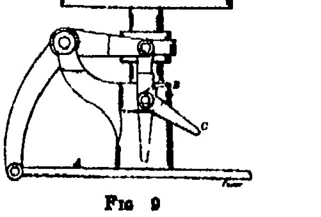

Fig 9

* Reprinted from *Power and the Engineer*

balls outward, and the bell cranks, to which they are fastened, raise the sliding sleeve which operates the long bell crank pivoted at the left-hand side of the governor This gives motion to the horizontal rod *A*, and as it is connected to the tripping devices on the valve gear, it gives a long or a short point of cutoff according to the load carried. The cam *C* is shown in mid-position When the engine is about to be shut down the long arm *C* of this cam is raised to a horizontal position by hand hence the short arm *B* stands vertically and receives the projecting part of the governor When the engine is started again the centrifugal force throws the fly balls outward, and the cam, being liberated, drops to the position shown by the dotted lines.

Every engine stop ought to be given a practical test at frequent intervals (say once each week), to prove that it is in working order For illustration take a Corliss engine with a flyball governor Close the throttle valve until there is just enough steam admitted to maintain full speed Suddenly force the flyballs down to their lowest position and keep them there for a few seconds by holding a convenient part of the governor The engine will run faster for two or three revolutions,

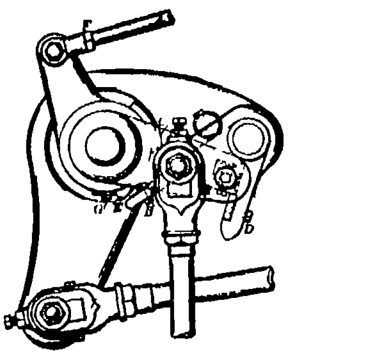

Fig 10

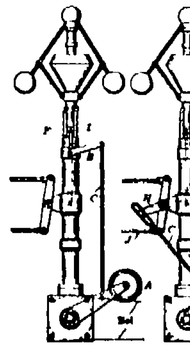
and then gradually stop, provided the adjustments are properly made If not, steam may be shut off from one end of the cylinder, and admitted to the other but this will not give excessive speed If it is not shut off at both ends, make an adjustment that will give the desired result, but do not change the comparative point of cut off, for if they are even they should not be changed, and if the condition of the valve gear in this respect is not known, an intelligent change cannot be made. It is usually possible to set the stop motion without changing the point of cutoff but on the other hand there are ways whereby both can be changed together, and it is plain that these ought to be avoided

Fig 10 illustrates this point and shows the gear for opening and closing a Corliss steam valve The reach rod *A* is adjusted so that when *B* is carried upward by the lifting arm, it will strike the knock off cam *C* and the latch *D* will be unhooked and the dashpot will close the valve If the flyballs of the governor of this engine should fall to a lower plane than at present, the reach rod *A* would be carried to the left and the safety cam *B* would move toward the right hand striking *B* and preventing *D* from hooking on Consequently the valve would not open and no steam could pass into the cylinder It is possible for the valve gear to wear until *I*



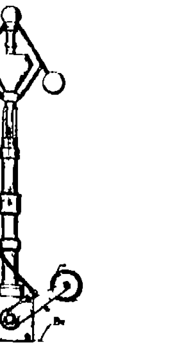


Fig 11 Fig. 12

is no longer in proper position to prevent the valve from opening A careless or thoughtless engineer will loosen the jam nut *F* and lengthen the reach rod until *E* will perform the duty for which it was designed This action causes *C* to be moved from its proper position until it no longer disengages *D* at the right moment, resulting in an uneven cutoff for the engine, assuming that it was even before The correct way is to let *F* remain as it is, and loosen nut *G* and slide *E* into proper adjustment and then screw *G* tightly down upon it

An automatic stop which needs no attention from the engineer when starting or stopping his engine is shown in Fig 11 The pulley *A* rides on the governor belt The bell-crank lever *B* is kept in the position shown by means of the long vertical rod *C* as long as the governor belt remains in place The flyballs and center weight are in position to give the longest point of cut off to the steam valves, as the projecting pin *D* rests upon *B* When the load is reduced, *D* rises, but *B* remains in position If the governor belt breaks, *A* falls, *B* is also lowered and *E* is carried toward the right, therefore *D* goes lower than shown, and steam is shut off because the steam valves do not hook on and the engine stops. An important feature of this device is that if an overload is put upon the engine it will not be shut down. On the other hand, if the governor ceases to revolve for lack of lubrication or any other cause, and the belt remains on the pulleys, steam will be admitted full stroke to the cylinder, causing excessive increase of speed.

Another stop is shown in Fig 19 The governor is

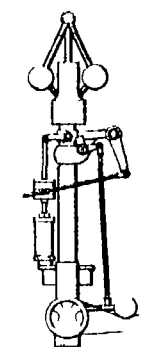

Fig 13

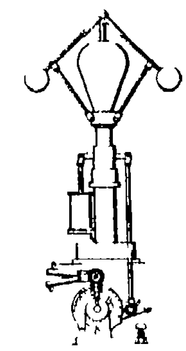

Fig 14

shown with a medium load on the engine The pulley *F* rides on the belt and during ordinary service this pulley does not change its position, consequently the slotted rod *G* is practically stationary If more load is added the center weight is lowered also the right hand end of the lever *H* the opposite end of which moves upward in the slot The lower reach rod *J* moves as indicated by the arrow If the load becomes lighter the centerweight rises and the upper reach rod is carried toward the left, shortening the cutoff The same action takes place when the governor belt breaks, because *F* falls, and the slotted rod *G* is drawn down until the end strikes the pin in the bent lever *H* the effect of which is to force the center weight upward shortening the point of cutoff until it is reduced to zero and the engine stops The collar *L* must be set high enough to allow the center weight to rise as described but no higher As the flyballs rise to operate the stop motion the pulley F and its connecting levers must be heavy

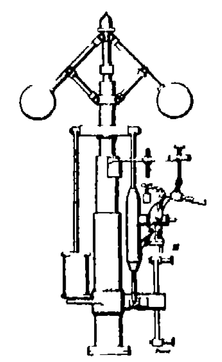

Fig 15

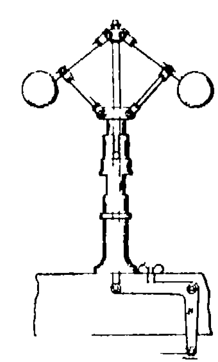

Fig 16

enough to overbalance the center weight, flyballs, etc With this gear the knock-off cams are utilized for safety cams, but only one set is required to both operations

Fig 13 represents another stop depending on an idler for its operation As long as the belt supports this idler the engine cannot be shut down by an overload but when the belt fails the cam *A* is reversed, and is no longer in a position to support the center weight of the governor, consequently when it falls as low as possible, the valves remain closed and the engine stops This device acts quickly because no load is put upon the idler and all of the mechanism connected to the idler tends to carry it downward when the belt breaks

A flyball and center weight governor attached to an ingenious device which operates the cutoff mechanism also the stop is shown in Fig 14 The main parts of this device consists of two disks designated as rear and front, both of which are hung at the center The rear disk *A* is attached directly to the governor by a vertical rod The front disk *B* operates the two reach rods Under normal conditions these disks move together and transmit the motion of the governor to the cutoff mechanism

The flyballs are shown in position for a medium load

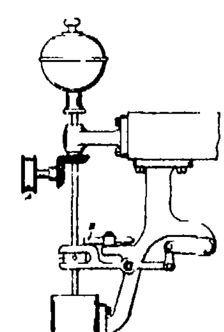

Fig 17

on the engine. If the load is reduced the balls and center weight move upward, rotating the disks from right to left. This demonstrates that if *C* and *D* are carried to the left the cutoff is shortened, therefore if they are carried far enough the steam valves will not open Increasing the load causes the center weight to fall, carrying *A* downward until the pawl *E* rests on the adjustable screw *F*, causing *E* to release the front disk which is quickly thrown to the left by a strong coil spring This action rolls the cutoff cams until they prevent the steam valves from opening But one set of cams is used to designate the point of cutoff in regular service, and to prevent the valves from opening in case of accident to the governor, without raising the center weight

To prevent the stop motion from operating when the engine is shut down under normal conditions, a pin is inserted into both disks, thus locking them together When the engine is started again this pin is thrown out automatically thus making it impossible for the engineer to leave it in place, and render the stop useless

A more complicated form of stop is shown in Fig 15 The rod *A* corresponds to the ordinary side rod on a governor, except that its length is variable and to shorten this length is the sole object of the device because this section throws the ordinary reach rods to their extreme position and steam cannot be admitted to the cylinder The enlarged part of the rod *B* is hollow and fitted with a strong spiral spring which tends to shorten the rod but the pin *C* extends into this hollow part and prevents the operation of this spring

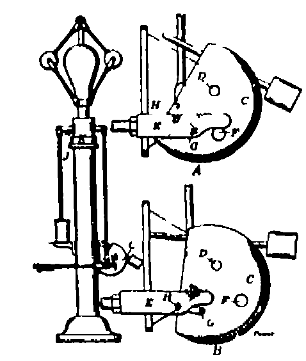

Fig 18

Suppose that the valve gear is deranged and the engine starts to "run away The flyballs rise carrying the spring supported lever *D* upward until it strikes the stationary stop *F* As *D* is depressed by this action *C* is withdrawn from *B* and the inclosed spiral spring draws the reach rod lever upward shortening the point of cutoff to zero (without carrying the flyballs higher) and as steam cannot enter the cylinder the engine stops

During ordinary service the rod *F* slides freely in the plate without interfering with the action of the governor in regulating the engine speed However if the belt runs off the flyballs drop to a lower plane and the movable part of the device is lowered until *F* rests upon *G* thus pulling *D* down as before drawing *C* outward and allowing the concealed spring in *B* to draw the reach rod lever up until the point of cutoff becomes shorter and finally is reduced to zero stopping the engine When preparing to shut down the engine in regular service, the stop is rendered inoperative by adjusting the plug *H* thus enabling the engineer to stop and start at pleas

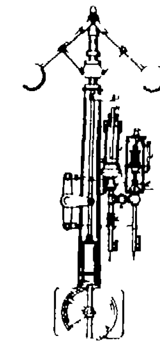

Fig 19

ure When the engine is started again the flyballs rise and liberate *D* which action throws *H* back automatically into the position shown

A very simple device for operating a stop is shown in Fig 16 As the flyballs drop the rod *A* is carried toward the right by means of the bell crank lever *B* and this prevents the steam valves from opening A slot is provided in the frame for the thumb nut *C* allowing it to move freely vertically as long as it remains in the position shown but if it is turned at right angles to this position it cannot pass through the slot While turning the thumb screw prevents the device from operating in case the governor belt breaks it is necessary to do so in order to operate the valves while starting and shutting down the engine If the thumb nut is not set in the running position the device is no longer a safety attachment

Fig 17 illustrates a governor which is set low on the engine frame The pulley *A* is driven from the crank shaft by a belt and bevel gears transmit motion to the vertical shaft, on which is mounted a pair of flyballs inclosed in an iron case *B* If this belt breaks, the flyballs come to rest, and the vertical shaft is drawn upward the revolving collar *C* moving with it, thus turning the side shaft *D* through part of a revolution This action prevents the steam valves from opening

This stop will not operate while the hand lever *E* is

in the position shown, because it prevents C from rising but when given one quarter revolution C is at liberty to rise A dashpot G prevents C from rising and falling rapidly

Another type of stop and its operating mechanism is shown in Fig 18 Two views of the tipping device are shown at A and B A shows the position taken with a light load on the engine The half-circular plate C is carried by a short shaft The reach rod F rests upon the pin I and is held there by gravity also by action of the link The pin G is set into the reach rod and H is a similar pin set into the plate C Therefore the stress upon the rod in the direction of the arrow will hold E more firmly on the pin H

If the governor belt breaks, J is lowered into the slot in the moveable collar K and the action is further illustrated by B The plate C has turned toward the left until the pin H is lower than pin F, causing the link to reverse its position, thus moving E toward the left twice the length of the link, which is sufficient to operate the stop

A stop operated by electricity is shown in Fig 19, used in connection with a Corliss governor, but it is suitable for several other types of valve gear Steam at boiler pressure is admitted to the angle valve A, which is closed under normal conditions When the crank-shaft speed exceeds the limit for which this stop is set, a special governing device closes the electric circuit B and the armature C releases the lever D This act allows steam to open A, when it passes through check valve E into the vertical cylinder F, causing the piston G to rise and the rod H to lift J until the collar K prevents it from going higher, thus raising the flyballs to their highest position, and rolling the knock-off cams on the valve gear so far around that they prevent the steam valves from opening

When D is replaced, A is closed, and by opening the drip L all pressure is released from F, thus allowing the piston G to resume the position shown, when the stop motion is ready for service. Then the throttle valve is closed, the steam valves hooked up, and the engine is ready to start

The Exploitation and Culture of India Rubber Plants

Business Aspects of the Question

The success of India rubber culture or even of the exploitation of wild plants is not always certain It depends upon a great number of conditions which have not received the attention which they deserve The problem is one of great complexity The India rubber plant is not a single species but there are many plants native in various parts of the globe from which India rubber can be obtained and every tropical region has its special indigenous plants Can all of these be exploited or cultivated profitably or should one be selected for cultivation everywhere Would it be better to abandon the collection of wild rubber and to cultivate new indigenous or foreign species? Many African colonists do not hesitate to reply that the cultivation and even the rational exploitation of the native rubber vines should be abandoned and replaced by the cultivation of the Brazilian species *Hevea* and *Manihot Glaziovii* which they regard as superior in many respects to the African rubber tree *Funtumia elastica* (*Kickxia elastica*) In Java and British India the cultivation of the *Ficus elastica* is gradually being replaced by that of the *Hevea* which has been planted largely in the Federated Malay States and the Straits Settlements Mons E de Wildeman the curator of the botanical garden of Brussels, who discusses these questions in *La Nature* approves the extension of the culture of the *Hevea* but not the abandonment of the culture and exploitation of suitable indigenous plants He supports this view with regard to Africa, at least by the following considerations:

Tropical Africa produces a great variety of India rubber plants including vines which contain rubber in their stems, roots or both; herbs which contain rubber in their roots or tubers only and trees from which rubber can be obtained by means of incisions in the bark In all of these three groups we find productive rubber plants which have been exploited by the natives, in some cases long before the period of European colonization No one of these plants can be cultivated everywhere for the different species require different conditions of life Hence the choice of a species must be made carefully and no species foreign to the region even if indigenous to the continent should be planted extensively before preliminary experiments have been made not with a few plants but with several hundreds at least The plants behave very differently according as they are cultivated singly with great care or planted closely in large numbers The dense plantations are subject to diseases and require many precautions

The plant then should be suitable to the region and consequently it is desirable to propagate the native species In Africa in particular certain vines known to be extremely productive should be cultivated

Another important question is that of labor If the cultivation of the *Hevea* is profitable in the Malay States and Straits Settlements it might be thought that it would be equally profitable in Africa where the climatic conditions are very similar In Africa however we do not have the same class of laborers The coolies of Java and Ceylon are unquestionably much more competent than the African negroes with rare exceptions The production of India rubber from the *Hevea* requires not only the comparatively simple work of cultivation but the very delicate operation of tapping or bleeding In Asia this operation is performed with a minute care which cannot be expected from African negroes, unskilled in work of this sort and averse to regular work of any kind The very life of the plantations would be jeopardized by putting them in the hands of unskilled workers. Hence, until the natives have become more civilized it would be better to allow them to treat the indigenous rubber plants as they have done for many years, meanwhile establishing, in suitable places where laborers are abundant and can be watched experimental plantations, which may have a great influence on the economical future of the region

In the Belgian Congo extensive cultivation of the *Hevea* is being earnestly advocated, although no commercial company has yet undertaken this culture on a large scale. The sanguine expectations are based on the few successful results obtained in experimental plantations but the economic value of the cultivation of any particular species of India rubber plant can not be definitely fixed without observations extended over from 3 000 to 5,000 trees. This does not mean that it is necessary to abandon the cultivation of the *Hevea* in Africa and every other region where it is not indigenous Extensive cultivation should be commenced however, with the native vines and the *Funtumia* When favorable results have been obtained from many large plantations of *Hevea* we can judge whether it is necessary or desirable to substitute the Brazilian plant entirely for the native species It appears probable that the native plants will maintain their superiority Every tropical colony and indeed, every country and every natural division of a country should remain its indigenous products

Another important question concerns the method of extracting the latex from which India rubber is obtained We do not yet understand the utility of the latex to the plant Is this liquid which contains various useful substances a waste product of no further use to the plant? Is it a means of defense against enemies or does it contain ingredients which again enter into the life of the plant? There is probably some truth in each of these hypotheses At all events, the removal of the latex always causes a disturbance in the life of the plant, diminishing its vitality and power of resistance to disease In all intensive cultivation, diseases are constantly becoming more virulent and the pathology of plants is becoming a more important science to the agriculturist

Numerous experiments made in the Straits Settlements and the Malay States, appear to prove that the only practical method of exploiting the *Hevea* is by means of the "half herring bone" system of incision deepened daily or every other day In this manner all the bark of the trunk is removed in a time which varies with the skill of the workmen The bark is gradually renewed but a time arrives when only a very small portion of the original bark remains The operation is then recommenced on the new bark which is usually four years old The primitive bark is generally seven years old when the first incisions are made The cultivation of the *Hevea* has not continued long enough to make it certain that this method can be pursued indefinitely without destroying the plantation For this reason it appears more advisable to employ the rather brutal process which is still used by the natives of many tropical regions, and which consists in felling the tree at once It is an error to suppose that this barbarous method necessarily destroys the rubber plantation or forest If the natives are allowed to fell every rubber tree they find the number of productive trees will certainly diminish, but if the trees to be felled are selected with care or even if the natives are given a free hand without being urged to excessive production the young growth will, after a certain number of years, form a productive plantation Rubber vines also should be cut off, instead of being tapped

The idea of extracting rubber from the bark of the *Funtumia* by a mechanical process appears to be due to Prof Warburg of Berlin This method has been abandoned in some districts It has recently been taken up experimentally with excellent results in French Africa. With the *Funtumia* then regulated felling and mechanical extraction of the rubber from the bark appear capable of furnishing a maximum quantity of rubber and also of insuring the maintenance of the plantation by natural growth

We know that India rubber can be obtained by mechanical processes from all three groups of African rubber plants, herbs, vines and the *Funtumia* tree and for tropical Africa in present conditions this method appears preferable to any other

Still another question of very great importance concerns the capital required in the cultivation and exploitation of rubber plants in the Malayan Peninsula A hectare (2½ acres) planted with *Hevea* trees is worth $4,600, even before the plants are old enough to be incised The same land a few years ago was worth only $100 In presence of such fluctuations of value the economic conditions of cultivation are totally changed, and another argument is advanced in favor of the exploitation of native species, which requires much smaller capital Mons Brenier says that this excessive increase in the price of India rubber plantations reacts in favor of the wild rubber of Brazil and Africa It should be noted here that the Brazilian rubber producing States are not only seeking to exploit the natural forests more rationally, but are also encouraging the formation of plantations of the *Hevea* which should succeed on its native soil better than elsewhere.

It is certain that the world has room for extensive plantations of rubber trees and that immense quantities of rubber can be produced and used to advantage; but it is equally certain that a day of overproduction will come sooner or later If all the young plantations now in existence shall in a few years produce as abundantly as the old plantations, overproduction is inevitable and near The constant developments in industrial chemistry will increase the employment of regenerated and inferior rubber, perhaps of substitutes for rubber, and this will naturally lower the price The date of this overproduction does not appear so near when we note that a large proportion of the trees now planted especially in Eastern Asia, are unproductive, owing to errors in cultivation and in selection of plants and soil Mons Brenier proves that the competition which is bound to come will leave in existence only those plantations which have been established in the best cultural and commercial conditions, and have received the greatest care in selection of plants, cultivation collection and preparation of rubber, in the prevention of disease and in the maintenance of a force of competent workmen In a word, the successful companies will be those which treat their trees most scientifically such as the larger companies of the Malayan Peninsula, each of which maintains its private staff of chemists, botanists, mycologists, etc

An attentive examination of the numerous problems presented by the cultivation of rubber plants only serves to show the depth of our ignorance in regard to the history, life and proper cultivation of these plants Every country which is directly interested in the production of rubber should give serious attention to the study of local production and should establish botanical and chemical laboratories, working in harmony with the experimental plantations Holland has long followed this excellent plan and some English colonies have also founded laboratories Within a few years Germany has established experimental plantations and laboratories in several colonies, and schools of research and instruction, devoted especially to rubber culture, have been opened in Berlin This example will probably be followed in England The complex problem of the rubber industry can only be solved by constant harmonious co-operation between men of science and men of practice. The solution will not be obtained in a short time—*La Nature*

What Men Do with Their Dead

To many persons, death is incomprehensible Even civilized men shudder at the sight of the dead face of a man whose mental powers have won their admiration Death inspires still deeper awe in primitive peoples, who regard it as the work of supernatural powers, invoked by sorcery If a beetle hums or a moth flutters about the corpse the insect is believed to harbor the soul that has left the body The methods of disposing of the dead are based on these beliefs These methods will be copiously illustrated at the approaching International Hygiene Exhibition in Dresden The following notes are quoted from *Hygieia* the journal of the exhibition

The dead person may be regarded as a friend or as a foe, and the treatment of the corpse varies accordingly Almost all races, even the most primitive, render some services to the dead, if only for the sake of performing a duty and escaping post mortem vengeance The Tasmanians believe that the souls of the dead migrate to planets hence they deposit corpses in hollow trees This practice suggests the origin of the coffin It is often considered essential for the dead man to rest in his native soil Hence migrating tribes have carried some of the home soil with them in their wanderings, for filling graves.

These are some of the friendly offices to the dead. When the spirit of the deceased is feared as an enemy, the treatment of the body is very different. In many cases it is left lying in the house of death, which is then tightly closed and shunned with superstitious awe. The idea of separating the dead from the living is expressed still more clearly by the practice of fettering the corpse before burial. In this way the possibility of return to life is supposed to be prevented The practice of cremation is partly based on this fear of the dead man's return. The ashes or unconsumed bones are usually inclosed in a suitable vessel. The custom of exposing the corpse to be devoured by wild beasts and birds is still practised by the Parsees. It indicates a high degree of contempt and aversion. The body is rendered quite harmless and the mental powers of the deceased are compelled to seek refuge in the sharers of the feast. The disposal of the dead serves to illustrate the general law that the apparently hygienic precautions of primitive races are founded on fear of demons and sorcerers. This is true, to some extent, of the art of medicine in general.

Shearing Sheep by Machinery

How Frenchmen Have Improved an American Invention

SOME agricultural operations which can be accom plished rapidly and perfectly by machinery are still performed almost everywhere by hand, with very primi tive tools. The machines devised for such work are, in general, employed only in large establishments, as they are too costly for small farmers and are otherwise unsuited to their needs. Some machines, however, are moved from farm to farm, so that they may serve all the farmers of a district. In France, this expedient appears to have been adopted first in the case of distilling apparatus Itinerant threshing machines and sawmills are now common

A similar method has lately been adopted for shearing sheep and the work which formerly occupied weeks can now be accomplished in one day by a portable apparatus Machine tools driven by a crank and flexible transmission, have long been employed for shearing sheep and clipping horses This device requires two men for each animal shorn, one man turn ing the crank while the other applies the shears or the clipper but it expedites the work, clipping a horse in one hour and shearing a sheep in five minutes, and it spares the animal the wounds which are frequently in flicted by hand shears An electric motor can ad vantageously be substituted for the man who turns the crank

A great advance has been made by the introduction of an explosion motor capable of operating several ma chines at once A wagon maker at Gaissy in Cham pagne has constructed a traveling sheep-shearing es

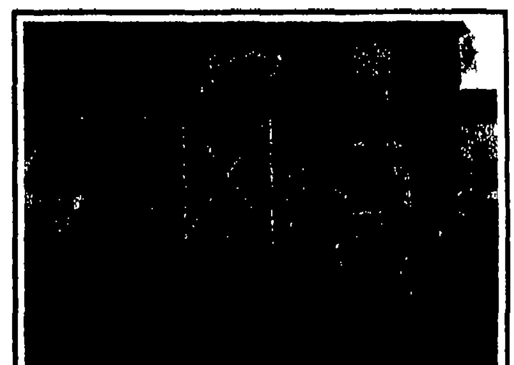

FIG 1—A SHEEP SHEARING CAR

tablishment equipped with 4, 6 or even 10 shearing machines, driven by a single motor The apparatus has been employed with success on the flocks of Champagne and it attracted much attention at a recent agricultural exhibition It is mounted on an ordinary four wheeled platform truck

A small gasoline motor, of 5 horse power, drives a horizontal shaft, to which each of the shearing ma chines is connected by the flexible transmission de scribed below The car is furnished with benches on which the sheep are placed and with a removable canvas roof

The shearing machines are arranged in pairs, to right and left of the driving shaft, to which each machine is connected by an arm composed of three segments joined in such a manner that it can be moved freely in any direction. Two of these segments are tubular and contain an endless cord which passes over a grooved wheel on the driving shaft, and a second grooved wheel, carried by the shearing machine The transmission is illustrated by Fig 2 The tubular segment D and E are suspended from one end of the solid rod B which carries a counterpoise C at its other end The tubes D and E are connected to the rod B to each other and to the shearing machine T by the universal joints F G H When the particular shearing machine shown in the illustration is not in use the weight of the counterpoise C causes the rod B to stand nearly vertical in which position it releases the clutch which connects the grooved wheel P with the driving shaft and allows this wheel to stand idle though the shaft, driven by the belt R may be rotat ing and operating the other machines In order to bring the machine T to the sheep's fleece it is necessary to pull it downward depressing the rod B to a posi

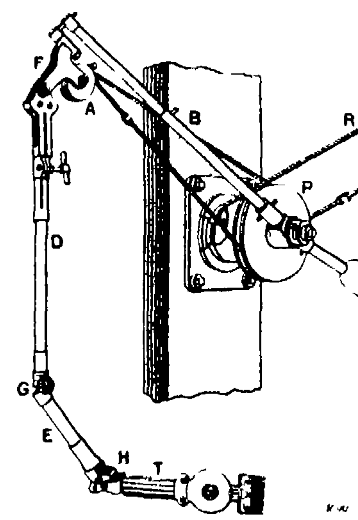

FIG 2—THE FLEXIBLE TRANSMISSION

tion in which it clutches the wheel P to the driving shaft The endless cord passes over two guide wheels I at the first joint F and over two smaller guide wheels at each of the joints G and H

The shearing machine is illustrated by Fig 3 The two parts of the endless cord, after traversing the tubular handle of the implement are guided by two small wheels G H to a large grooved wheel A pin placed eccentrically on the face of this wheel, engages with a fork on one end of a lever the other end of which is attached to the toothed blade P Hence the rotation of the wheel gives a reciprocating motion to the toothed blade which slides over a fixed comb as in an ordinary clipper

The shearing car shown in Fig 1 carries six shear ing machines and a set of machine tools for sharpen ing blades and other purposes As each machine can shear a sheep in 5 minutes 720 sheep can be sheared in a day of 10 hours—*La Nature*

The Interior of the Earth

THE interior of the earth is scarcely more accessible than the stars to direct experimentation and is less known through valid indirect evidence Some information is given by earthquake shocks which though local in origin shake the whole earth By collating the records of seis mographs in various places it has been learned that the velocity of the earthquake wave is 3 or 4 miles per second in the upper strata of the earth and more than 10 miles per second in the central nucleus The earth as a whole may be compared to a great spherical bell which when struck makes only two or three complete vibrations per hour As the note emitted by a piano string depends on its length, thickness and tension, so the note of the earth bell and the velocities of waves in its different parts give some indication of the state of the concentric strata of which the earth is composed

The information thus obtained is very incomplete and scientists have endeavored to fill its voids by means of various plausible hypotheses A review of our present knowledge of the earth recently presented to a French scientific society contains two remarks of especial interest concerning the variations of gravity and pressure in the earth's interior

If a shaft were sunk vertically to the center of the earth and an object, suspended from a spring balance were lowered down the shaft the weight of the object, as indicated by the dial of the balance, would at first in crease, as the descending object approached the deeper and denser strata After passing a certain depth, how ever the weight would begin to diminish, and it would continue to diminish to the center of the earth, where its value would be zero, because the object would there be equally attracted in every direction.

The pressure increases enormously with increasing depth below the earth's surface It must be about 900 000 atmospheres at a depth of 400 miles (1/10 the earth's rad ius), 4,000 000 atmospheres at 2 000 miles (half the ra dius) and more than 100 000 000 atmospheres at the center At such pressures the materials of the earth, though heated above their melting points, are probably quasi solid and as rigid as glass or steel Hence the velocity of propagation of vibrations must exceed the velocity of sound in ordinary solids such as cast iron, in which it is 20 000 feet per second

Directed Wireless Telegraphy

THE Bellini-Tosi system of directed wireless telegraphy is now in practical use on land and sea, according to a letter addressed to *La Nature* by the inventors and has

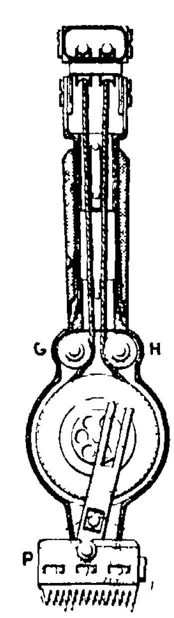

FIG 3—THE SHEARING MACHINE

given entire satisfaction At Boulogne France, the system has been in continuous operation since January 1910 It works perfectly and has rendered great service to navigation The station uses a wave length of 300 meters (984 feet) and a range of 300 kilometers (186 miles) On shipboard a special application of the system is made so that the position of the vessel can be determined in foggy weather by means of the coast wireless stations The position is thus found as accurately as it can be deter mined by the ordinary usual methods in clear weather

TABLE OF CONTENTS

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending March 7, 1911,

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents]

An English Water Dynamometer for Absorbing 1 OOO Brake Horse power

By Frank C Perkins

The accompanying illustration shows the construc tion and method of operation of a 21 inch water dynamometer of the Froude type now in service in a testing department of a shop at Worcester Eng land and capable of absorbing 1,000 brake horse-power at 700 revolutions per minute

This machine was designed for the purpose of de termining with absolute accuracy the power de veloped by an engine or motor in an expeditious and practical manner and is capable of regulation so that the power put into it at any speed can be absorbed from the minimum to the maximum capacity of the dynamometer

The dynamometer consists primarily of a turbine or rotator revolving within a casing which is mounted on friction rollers and connected to a water supply so as to enable the casing to run full of water when the machine is in use The rotor is fixed to the shaft which projects on either side of the casing and to which the engine or motor to be tested is coupled Engines or motors of either direction of rotation can thus be proved on the one machine

Each disk face of the rotator is formed with a semi-elliptical annular channel divided into a number of compartments by means of ob iq ıe vanes The corresponding faces of the casing are also formed with similar channels divided in the same way The channels on the rotator and the casing thus form two complete annular channels of elliptical cross section each channel being divided as previously stated into compartments by means of the oblique vanes

The water in each annular channel is rotated con tinuously by the centrifugal force imparted to it by the rotator and it passes from one compartment into the next and so on An extremely high speed of rotation of the water is obtained and the power or energy p t into he dynamometer is by this means converted into heat which passes in the water leaving the machine.

The motion of the water causes the rotator to re-act on the casing and tends to turn it on the friction rollers. This is prevented by means of an extension or arm, working between stops at the end of which are the balance weights and the counterbalance by which is measured the actual power put into the dynamometer

In order to reduce the power absorbed by the dyna mometer when required thin metallic shields are provided which are interposed between the faces of the rotator and the casing, thereby cutting off a por tion of the effective area of the annular channels In h s manner the power may be reduced from the maximum down to about one thirtieth of tl at an ount

The friction rollers supporting the asi g are ad justable, so that the dynamometer shaft may be read ly brought in line with that of the engine or motor under test.

The horse-power absorbed by the dynamometer = brake horse power of engine or motor $\dfrac{W \times N}{K}$

when

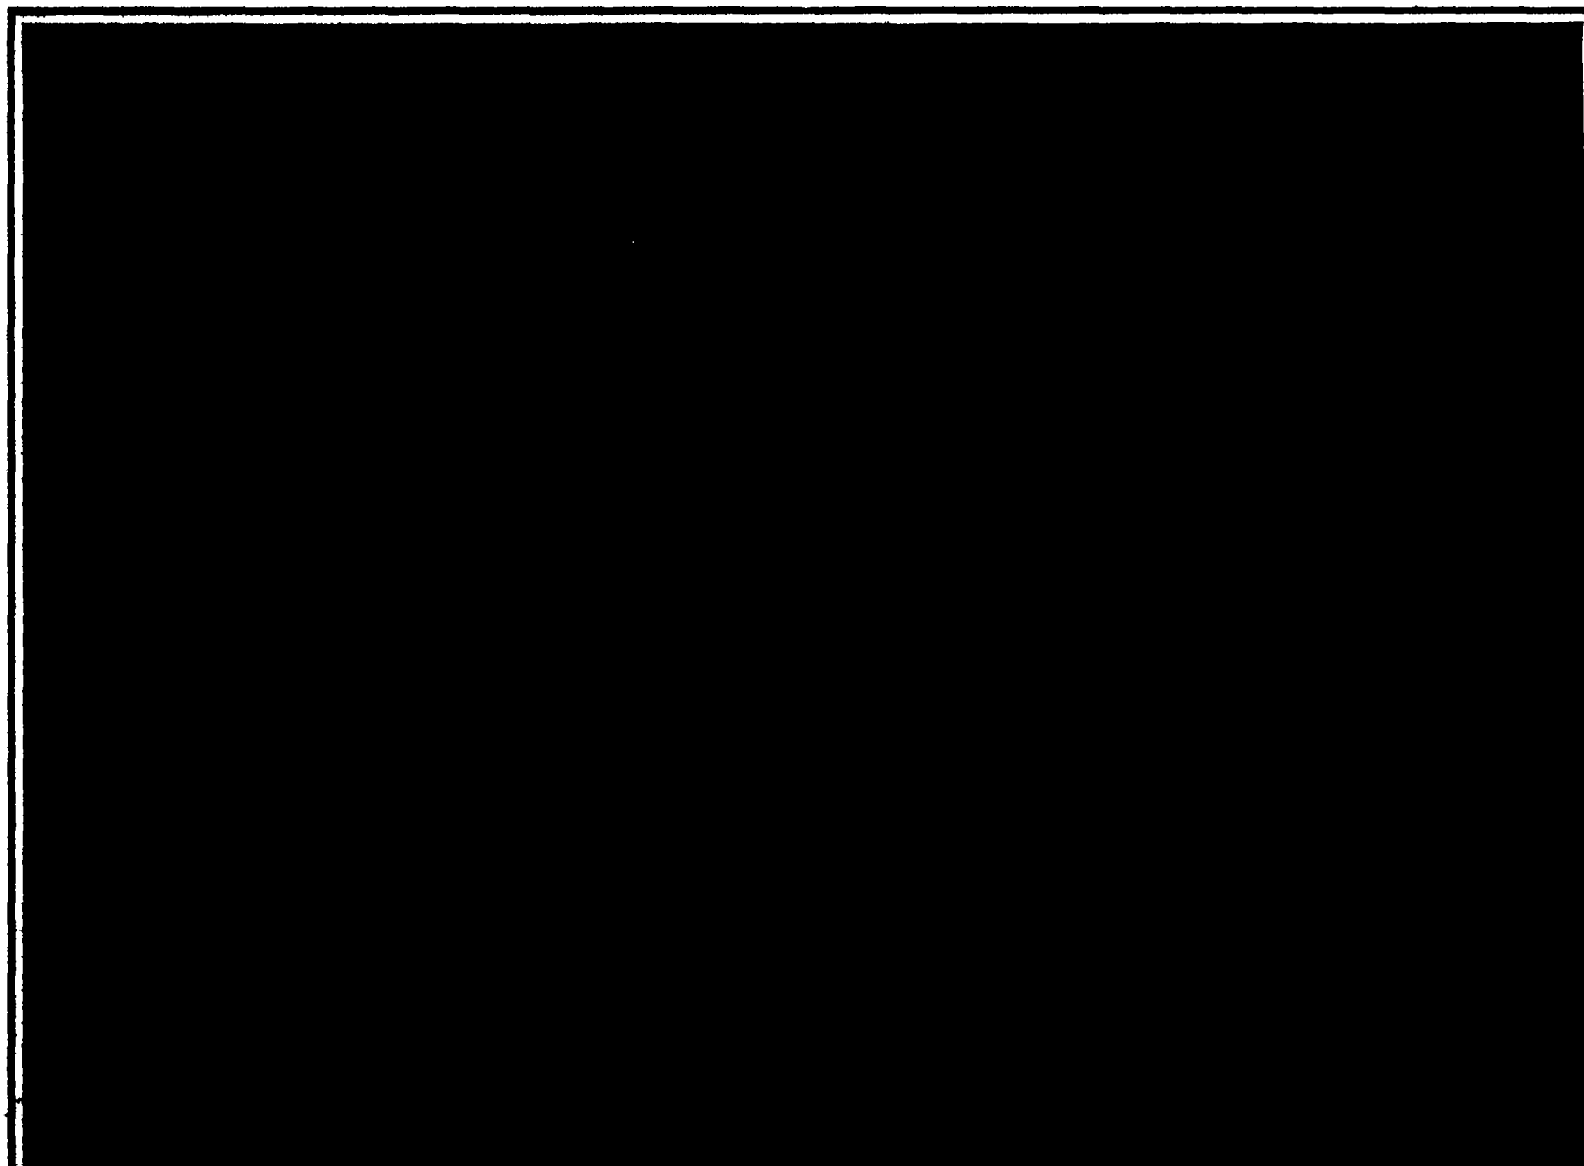
W = The effective weight in po nds at the end of the dyna nometer arm

N = Revol ions per minute

K = The constant for ea h machine and is de-rived from $\dfrac{33\,000}{\pi \times 2L}$ as in the Prony brake formula where L equals the radius or the length of the arm

The quantity of water used = 1 89 gallons per horse-power per hour as can be obtained from the following calculation

$$\text{Gallons per hour} = \frac{\text{H P} \times 33\,000 \times 60}{778 \times 10 \text{ Temp difference between water at inlet and outlet.}}$$



21 INCH FROUDE WATER DYNAMOMETER AT WORCESTER ENGLAND CAPABLE OF ABSORBIN 000 BRAKE HORSE POWER AT 700 REVOLUTIONS PER MINUTE

Handling Passengers on a Rapid Transit Railroad*

Construction of a Rapid Transit Line as Illustrated by the Hudson and Manhattan Railroad

By J Vipond Davies

Passenger transportation has developed the most complex problem which is to-day presented to the engineer for solution The immense increase of population particularly with reference to the concentration in cities has produced new and grave conditions which have to be cared for by a careful study of individual cases as each case requires absolutely new and independent treatment With the steam railroads the problem of handling passenger traffic remains very much as it formerly did except that with the extension of cities into their suburban districts the local traffic has become so much heavier that the distribution of passengers from the terminal destination introduces a new and serious problem The number of persons who desire an all-the-year-round residence in the country districts and who conduct business within the cities is becoming yearly greater and is only made possible by improved transit facilities being provided This condition has also become a considerable factor in increasing the taxable values of suburban real estate and in developing real estate in the suburban districts of the great cities London and New York offer the best illustrations of this condition as in each of these cities there is a small district of limited area in which the bulk of the business is transacted and a huge territory radiating in every direction where the business people have their residences The state line between New York and New Jersey is a fictitious division and eliminating all consideration of the boundary line between these two states there is a district tributary to New York city which has a total population of over 6 500 000 persons In a community of this character the nearer one gets to the center of the city the more dense becomes the traffic the need for increased transit facilities greater and the possibility of movement slower all on account of the great concentration and the interference of cross-streams of travel Every one is familiar with the fact that for reasonably short distances within this zone of density one can reach his destination quite as quickly by walking as by using a surface car As one gets farther from the center of a large city and approaches the country the traffic thins out proportionally with the density of the population and at the same time the possible speed of transportation becomes greater The latest figures available indicate that the total movement of passenger traffic within the metropolitan district of New York aggregates very close to 2 000 000 000 passengers a year on all lines which is equivalent to 308 rides per capita per annum and the movement of passengers within the Borough of Manhattan averages over 400 rides per capita per annum In order to get more rapid service for passenger traffic it has become necessary in New York to move the means of transportation from the surface of the streets where there is interference with every other class of vehicular and pedestrian travel As a city grows to the size which is now known as a city of the first class these conditions arise the necessities become similar and gradually the large cities are forced into doing what New York is doing at the present time viz to install transit lines either above or below the surface so that rapid transit service may be carried on without interference with other transportation and thereby obtain a greater measure of rapidity and safety in the service In the city of London this condition arose many years ago earlier possibly than would be the case in most American cities on account of the narrow streets and the consequent tremendous surface congestion With broad avenues or streets the period of congestion is postponed so that the necessity for transit lines either above or below the surface is not reached at quite as early a period in the growth of a city Our great cities are not willing to develop elevated railroad lines anywhere near their hearts on account of obstruction to light and air the further and serious obstruction to other traffic and what is by no means the least objection the great nuisance of increased noise so detrimental to the nervous systems of people who must hear the roar of the traffic At the same time in many of the American cities elevated railroad lines are deliberately and it seems foolishly installed in the suburban districts purely on the ground of the cheapness with which they can be constructed or in order to obtain what is called rapid transit service at a reasonable cost in districts sparsely populated This has been deliberately done with the present Rapid Transit Subway in the city of New York where in the northern portions of the city the subway emerges onto an elevated structure and runs over long sections of steel viaducts To a considerable extent the same has been done in Philadelphia If any such structures are necessary and are hereafter built, they should be carefully designed and constructed so as to eliminate all noise arising from an exposed light steel structure This may be accomplished without any great addition in first cost and with only slightly increased obstruction upon the surface of the ground

The title which has been adopted in this country for transportation other than on the surface has an unfortunate adaptation as it involves a good deal of service which is by no means rapid transit The service to which these or any lines of public transportation are applied is affected materially first by the density of the population and second by the local conditions At the same time it is readily understood and appreciated that the service is the heaviest at certain hours of the day and lightest at other hours and curiously enough it seems that on most lines the traffic curves correspond very closely that is to say granting a certain total daily service given by any line of railroad whether on the surface on ferries crossing the rivers on an underground or steam railroad line which does a local transportation business within our populous areas the curves of traffic per hour are very similar varying of course according to the total movement per diem These curves reach their summit or peak in the morning hours in the movement toward the heart of the city between 7 and 9 o clock and reach the corresponding peak for the evening outward bound movement between 4 30 and 6 30 o clock The Public Service Commission has rather happily designated these movements as workwards and homewards respectively The morning peak in one direction workwards toward New York reaches its maximum between 8 and 9 o clock 7½ per cent in the direction of heavy flow and in the opposite direction simultaneously 1½ per cent of the entire total traffic in both directions per twenty-four hours while the homeward peak in the evening—the heaviest and controlling movement—reaches its maximum between 5 and 6 o clock, when the outward movement is 10 7 per cent and the simultaneous reverse movement 2½ per cent of the entire total traffic in both directions for the day The movement during the middle of the day is very much less while the movement after midnight is extremely light, and no railroad operates suburban trains at a profit during the wee small hours of the night but only on account of its general obligation to the public

The Hudson and Manhattan Railroad Company was organized as a private enterprise and as an interstate railroad to handle a proposition which is new and unlike any other in New York city or elsewhere As every one is well aware, the steam railroads handling New York traffic terminate for the most part on the west bank of the Hudson River whereas the destination of the passengers is almost entirely within the city of New York Similarly the street railroads have their termini at various points along the Hudson River front and a very large portion of the traffic is carried from points in New Jersey to these termini for ferriage across the Hudson River to New York city The Hudson and Manhattan Railroad differs therefore from the ordinary rapid transit railroad in that it is a terminus in the city of New York for the steam railroads terminating in the State of New Jersey and is a collecting agency in the city of New York for passengers using the steam or surface roads from Jersey City and Hoboken to the suburban districts in New Jersey The layout of this railroad is now so well known that it is unnecessary to elaborate upon it except to draw attention to the fact the road has in New York both an uptown and a downtown terminus The former is located in the shopping district and is convenient to places of amusement, hotels and the residential district, and the latter is in the heart of the financial and business district For a road having the short mileage of the Hudson and Manhattan Railroad the traffic concentration is very great, in fact, as great as on any railroad in the city of New York and in studying the proposition of construction and operation it has been necessary to consider carefully the very great concentration of traffic and consequently to arrange all the details of construction and equipment for easy prompt and efficient handling of the public

There is no one who will disagree seriously with the statement that the public taken *en masse* is like a flock of sheep, extremely difficult to direct or handle and that it will at all times move in what it considers the lines of least resistance consequently the public moving as a mass is a very serious problem to be considered by those designing or equipping a transportation line The treatment of such a proposition must be done with a clear knowledge of the fact that one is dealing not with individuals but with masses or crowds and while the individuals composing the mass have sense and can be reasoned with and managed, the mass is unreasoning and often unreasonable, consequently nothing can be omitted in the design and equipment of a transportation line which will assist and direct a crowd so that it can have no possible choice in the matter of what it will or will not do Only by perfect arrangements in this respect can the railroad and its operating officials obtain the best results for the traveling public To obtain best results has been the constant effort of those who have had to do with the development of the Hudson and Manhattan Railroad

The original inception of the present system was a tunnel between the foot of 15th Street, Jersey City, and the foot of Morton Street, New York which had been started many years ago The company had undergone several reorganizations, and the property was finally acquired by the present holders at a foreclosure sale The property then consisted of a section of a tunnel of considerably larger internal diameter than the present tunnels driven from the New Jersey shore toward New York It was designed and partially constructed with the idea of being a terminus to be used jointly by the Erie and Lackawanna railroads, and while the construction of this short section made history in engineering considering that the promoter was really not an engineer at all, the use and operation of it were utterly impossible The portion of tunnel constructed was 18 feet internal diameter unnecessarily large for the ordinary street railroad or suburban railroad car but too small for two cars to pass and yet the tunnel was designed for a standard steam railroad car for which it was unsuitable In the first financing it was most essential to get a tunnel under the river to demonstrate the feasibility of its construction and after the long history of failure which had attended the early days of the Hudson River Tunnel Company it was desirable to establish the fact that such a railroad could be built and operated A plan was therefore prepared by which it was contemplated that the tunnel would be carried to the New York shore of the same diameter as the portion driven from the New Jersey shore and within this tunnel it was proposed to operate very narrow cars, somewhat along the lines of the cars first operated in the City and South London Railroad tunnel in London The tunnel was to be equipped with double tracks and operated as a double-track railroad in order that it might be of some service to the public and at the same time prove the feasibility of its construction and operation This plan also contemplated adhering to the original location of the road which provided for a terminal on the surface about midway between the Erie and Lackawanna Railroad stations in Jersey City It was proposed to divert the street railway cars to this terminus making it necessary to transfer passengers across a platform from the street railway cars to the narrow tunnels cars and *vice versa* In New York it was planned to have the narrow tunnel cars come to a depressed station at Christopher and Greenwich streets making the terminus at that location adjacent to a surface car line in New York Such an operated tunnel would have simply been a connecting link between the street railroads in Jersey City and Hoboken and the street railways in New York. It was very easily proved that such a proposition operating narrow cars as individual units would not be sufficient in capacity or rapid enough to handle the traffic and could not earn sufficient money to pay the interest on even the comparatively small capitalization necessary to complete, equip, and put in operation the doubletrack railroad in the single tube The next step was to complete a second tunnel with similar termini making a double-track railroad, through which could be operated standard street railway cars. Such a proposition would not be feasible as no one operating a tunnel railroad of this character would agree to operate it with anything but cars of steel and fireproof construction With the use of such cars no speed could have been attained except by coupling the cars and forming trains The undertaking proceeded on this general idea, but it was planned to construct the street railroad cars of steel and to couple them into trains and operate such trains through the tunnels with a full system of signals. The second tunnel was designed not only to take street cars, but also larger cars, if later on it were found desirable to equip the tunnels with larger cars for regular suburban service It was found that the termini as contemplated were poorly located for convenience of public service and quite inadequate and insufficient for practical use in handling a volume of business large enough to insure getting returns from the capital necessary, and considering that a public utility is primarily for the public use, it was decided not to spare any expense and to overcome all difficulties so as to make the project of the greatest service to the public. The terminus in

* Proceedings of the Engineers' Club of Philadelphia

New Jersey was the first one changed, and the location adopted was at the Lackawanna Railroad terminus in Hoboken, where all the surface and trolley lines of the Public Service Corporation of New Jersey from the north end of Hudson County terminate and where the Lackawanna Railroad brings a large suburban traffic over its lines. When the first tunnel was connected under the river to New York application was made to the Rapid Transit Railroad Commission for authority to change the location of the terminus in New York, for which the earlier franchise had been obtained to a point where it would be of real service to the public as well as an objective point for operation The result was the location of the terminus at Sixth Avenue and Thirty third Street.

Such is the brief history of the development of the Hudson and Manhattan Railroad and it may be of interest to present various points which have been carefully studied, considered and adapted for its particular business and special needs whereby the company has endeavored to carry out arrangements which place this road it is believed ahead of all others that have been installed in combining convenience and ease of operation with the least possible friction and discomfort to the traveler, and with the greatest possible efficiency and economical handling of traffic

Capacity—The first essential in the study of this railroad was to decide definitely on the capacity for transportation that could be furnished during the hour of maximum travel as this factor is the basis for regulating everything that comes after The dimensions of the property which could be acquired for stations either downtown in New York or at Hoboken where it was necessary to locate upon private property and not under the public streets fixed the greatest length of train that could be accommodated at 400 feet The curvature of the railroad as laid out particularly the short curves (radius 90 feet) entering and leaving the Church Street terminal made it necessary that the cars should be as short as possible and the truck centers so spaced as to reduce the overhang of the cars on curves to a minimum The cars in the Rapid Transit Subway in New York are 52 feet long but this length proved to be too great for the Hudson tunnels as an eight car train would be in excess of the maximum length of train that could be accommodated on a tangent in the stations After considerable study the length of car determined was 48 feet 3 inches when coupled with distance between truck centers 33 feet. All clearances in the tunnels and approaches had therefore to be figured in relation to this particular size of car The clearances in the tunnels allow for a car of the same width as the original subway cars (8 feet 10½ inches) which makes a roomy car satisfactory for passenger use The height of the car which does not affect the comfort of passengers was of necessity made low on account of the clearances The length of train determined upon was eight cars a total length of 386 feet A speed curve diagram was then calculated on the fixed characteristics of the railroad the train weights, and on the assumption that motor equipment would be installed on the cars to operate at a maximum speed of 45 miles per hour on level tangent The speed is reduced for station and junction controls on curves and of course on grades It was figured that station stops would be thirty seconds Experiments with the air brakes determined the safe braking distance on various grades throughout the tunnels at which the cars loaded and operated at the calculated theoretical speeds could be properly controlled The safe braking distance determined the spacing of signals and as the signal system is the double overlap type (that is to say, the position of a given signal ahead is indicated to an approaching train at two signal stations previous) the spacing of signals throughout the tunnels provides for the closest possible operation permissible under ninety seconds headway with eight-car trains The railroad is being operated on this interval successfully and regularly The train load and the minimum train interval indicate that it is possible to operate any portion of the road to the extent of carrying 32 000 passengers in one direction in one hour All the remaining factors entering into the design of a railroad operated for passenger service depend therefore on this one essential prime factor—maximum capacity

Stations—As in almost every road laid out, the general location of stations is one of the easiest matters to decide upon The questions involved are what points offer the greatest facility for the collection and distribution of passengers and how frequently stations should be located In this particular case the solution was even more simple than usual A terminus downtown in the heart of the business district was essential, and its general location had to be within quite narrow limits. The exact location was fixed by the property which could be acquired near Broadway, between Fulton and Cortlandt streets. The short length of, and the physical conditions on, the downtown line led to the conclusion that there would be no station but the terminal, and as arrangements had already been made with the Pennsylvania Railroad for a connection and for interchange of business, the first station in Jersey City was obviously under the station and tracks of the Pennsylvania Railroad. At Hoboken arrangements previous to this had been made for the occupancy of the under surface of property of the Public Service Corporation at the point where its trolley system terminates near the ferry and fortunately this location was adjacent to the Delaware Lackawanna and Western Railroad station so the use of this private property fixed the station at this point The tunnels extending from Hoboken to the Pennsylvania station pass under the property and yard of the Erie Railroad so a station was located at Pavonia Avenue for the interchange of passengers with the Erie Railroad and also with the trolley cars of the Public Service Corporation These points practically control all the local street railroad business of Jersey City and Hoboken as well as the great bulk of the steam railroad business coming to New York

In New York city uptown the local conditions make it necessary to have stations at close intervals to give proper facilities to the public and to connect with the intersecting street railway lines elevated railroad lines etc It was undesirable to locate stations even for local business closer than 1 200 to 1 500 feet which makes but a short distance for passengers to walk to or from intervening points and if the stations were located closer than 1 200 feet the trains could not gain sufficient speed between stations to give adequate service In the case of Hudson and Manhattan Railroad the stations except on Sixth Avenue are few and at long intervals The distance from Church Street to the Pennsylvania station is 1 2 miles from Hoboken to Christopher Street 2 01 miles and from the Pennsylvania station to Hoboken with only one intermediate stop—Erie Station—is 1 75 miles consequently very fast service can be given

Having decided upon the general location of the stations the next point was to determine upon a design for stations with a view of providing every facility and convenience for the traveling public When a railroad has to provide facilities for handling a concentrated travel of 32 000 passengers per hour in one direction and when that volume of traffic is likely to have one point as its destination as for instance Church Street Terminal New York and to a less extent the terminal at Hoboken then the design of the station is all important and it is particularly important with respect to regulating the length of time of station stops so as not to hamper operation and interfere with the regular maintenance of the prescribed train interval Some years ago it was thought necessary by railroad men to have at a station a large number of tracks where trains could stand a considerable time while being unloaded and loaded The conditions of suburban rapid transit service have necessitated a radical change from this old theory A steam railroad train made up of coaches equipped with platforms and steps at the ends by which passengers must leave and enter can only unload and load even in the most rapid suburban service at the rate of approximately 30 passengers per minute per car For steam railroad trains with cars having a seating capacity of about 60 passengers and no necessity whatever for making a short station stop this rate of handling passengers is still permissible but with rapid transit service, where it is not unusual to have a total of 115 passengers per car, this rate would be impossible Cars equipped with end doors at the level of the station platform as in the older types of elevated and subway cars permit the movement of only one person through a car door at one time It requires sixty seconds to unload a car of this type and if the train is then reloaded at the same point it requires thirty seconds to take on say one-half a car load As the movement in the contrary direction is never as heavy as the movement in the maximum direction and as the loading process cannot be begun until the unloading is completed it is obvious that this interval would be prohibitory under conditions of maximum service Further than this the fact of having a single platform from which to unload and load passengers simultaneously introduces a congestion on the platform which delays materially this movement and lengthens the necessary station stop Even the movement on street cars in or out is only at the rate of 50 passengers per minute through end openings and if one end is closed as in some of the modern cars of the pay-as-you-enter type when operated at terminals it is not unusual for passengers to enter at a rate of only 17 or 18 persons per minute and consequently to get a car loaded at such a slow rate as this interferes materially with the capacity of the road

At the Hoboken Terminal the Public Service Corporation has lately completed a terminal station, which is a new departure and ideal for handling efficiently these types of cars The station is inclosed and every passenger must buy a ticket and put it into a chopping box before entering the station the conductor has only to collect fares from passengers who get on after the car has left the terminal station In street service passengers usually get on or off in small numbers at any place other than terminals, and so if these terminal points are cared for, there is little difficulty in handling the passengers.

The result of numerous observations of all possible combinations shows clearly that the essential requirement of all station design for handling large crowds at terminals is to separate the movement of passengers so that cars are unloaded from one side and loaded from the other This does not necessarily apply at local stations where passengers are comparatively few and well distributed the movement can be made within the allowable thirty second station stop and with comparatively little inconvenience to the public The Church Street terminal (New York) Hoboken terminal and the stations now being constructed at Thirty third Street and Broadway New York and at Summit Avenue Jersey City therefore are arranged with platforms at the level of the car floor and with provision for loading trains from a platform on one side and unloading onto a platform on the opposite side

The next point to be considered in designing the station is the arrangement for handling passengers between trains and public thoroughfares without conflict In the movement It is most essential in any railroad proposition to control the movement of passengers as far as possible in the right hand direction and so far as possible to deliver the flow of passengers in one direction at points where they will not come in contact or conflict with the passengers moving in the opposite direction One of the most unfortunate features in an underground system is the necessity for taking passengers from station platforms below the level of the street and distributing them at the street surface and this necessitates in the cases of slight elevation stairs or ramps and in cases of great elevation escalators or elevators The movement of passengers in a straight passage either on a level or on a reasonable incline of 10 or 12 per cent is very rapid and when the movement is approximately in one direction it amounts to 40 persons per foot of width of passage per minute Consequently a comparatively narrow passage will accommodate a large number of people in a short period of time As soon as such a movement reaches a stair case however the rapidity is immediately reduced as the step taken by the passengers is shortened from about 30 inches to approximately 12 inches so that while the passenger may take the physical step as rapidly as when walking on a level surface the actual forward movement is perceptibly slower On broad staircases moving in one direction only and upward the number of passengers per minute averages 15 per foot of width whereas the maximum counted on any staircase under these conditions is 24 per minute If moving downward the average per minute under similar conditions is 13 and the maximum is 18 These conditions have to be taken into serious account when the necessity for staircases arises It is equally obvious that wherever conditions permit ramps should be provided instead of stairs as the accommodation provided by a ramp is very much greater and the use of a ramp is materially easier for the passenger

In the development of Church Street terminal where the concentration of people is likely to be excessive there could be no choice in the use of staircases for handling passengers from the platforms to the concourse level but the height of the concourse above the platforms was made as small as was possible allowing proper clearances for the trains The alternate platforms in this station are for loading the others for unloading so that the loading platform serves two trains while the central unloading platform serves two tracks the exterior platform is for unloading and of course serves but one track The arrangement of staircases from the unloading platforms is tandem on the centers of platforms and the direction is outward from the center of the platform There are six staircases to each platform three on each side of the center line of the platform—so that the distance from the exit door of a car to the nearest staircase is very short These staircases discharge passengers at the concourse floor in a direction pointing south to Cortlandt Street or north to Fulton Street thus delivering passengers on the concourse floor in the direction they desire to proceed On the other hand the staircases to the loading platforms lead from central points on the concourse floor to points along the train platforms and are so arranged that each loading platform has two pairs which enables the operating department to group the chopping boxes at the top of each of the two pairs of staircases and thus reduce during the slack hours the expense of ticket choppers ticket examiners guards etc Up to the present time no more efficient arrangements have been invented for examining and canceling tickets than the old barriers and chopping boxes The arrangement of stairs delivers passengers coming to trains at four points on the loading platforms more or less equally spaced and provides an equal distribution in the train loading At the Church Street terminal the space is sufficient to permit of distributing passengers on the concourse floor so that under the worst conditions of the maximum traffic there will be no congestion on this floor and the extremely broad ramps to Cortlandt and Fulton Streets and wide staircases to Dey Street provide free ingress and egress to and from the concourse floor.

(To be continued)

Cement Sidewalk Paving*

Simple Directions for Laying It

By Albert Moyer, Assn Am. Soc C E., M Natl Cement Users' Association

Cement sidewalk paving is a manufacturing industry whereby cement stone slabs are framed in place on the job Laying of this description has various uses Its principal use is a permanent path for pedestrians Among the other uses are driveways for vehicles, a floor wearing surface for buildings platforms in the stations of transportation lines wharf coverings cellar floors, curb and gutters The principal objects to be accomplished in manufacturing these cement stone slabs for the above named purposes are permanency durability and neatness

To accomplish permanency it is necessary that these slabs remain hard tough and in the original position for the average life of good construction work To achieve this object, correct methods of manufacture must be employed which will avoid settlement cracks, upheaval by frost and roots of trees crumbling due to work having been laid in freezing weather contraction cracks expansion cracks separation of top from base and disintegration

To avoid settlement cracks it is necessary thoroughly to ram the ground after excavating for foundation After drainage foundation has been put in place this should be thoroughly and evenly tamped so as to avoid any uneven strain The thickness of the slab should be governed by the factor of safety necessary to provide for the weight that is likely to be placed on any one slab It is estimated that a number of persons can be so crowded together as to cause a weight of from 100 to 150 pounds per square foot As the strength of the slab is not always governed by its thickness, maximum strength is obtained by properly proportioning the aggregates so that maximum density results.

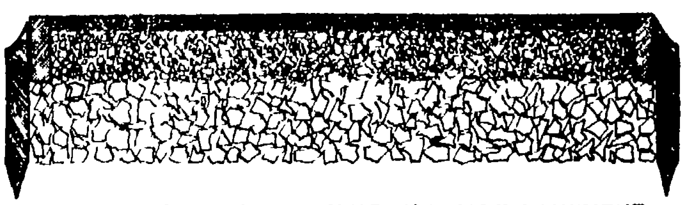


FIG 1 SECTION OF A CEMENT SIDEWALK PAVEMENT

To avoid upheaval by frost, a proper drainage foundation must be provided, such foundation to be carried to a sufficient depth so as to provide for perfect drainage; a drainage foundation is of use only in the event that it thoroughly drains Such a foundation is often placed so that it not only fails to acomplish the purpose for which it was intended, but practically defeats that object by causing an accumulation of water which in freezing upheaves the pavement A drainage foundation should have an outlet which has a fall of about ¼" or over to the foot If there is no natural outlet for such drainage, blind drain leaders should be provided at points along the walk where they are necessary These leaders should be formed of similar material as the drain itself with, possibly the addition of a porous drain tile leading into holes filled with cinders or crushed stone which will allow the surrounding earth to absorb the accumulated water

Upheaval by tree roots can very easily be avoided by cutting out any roots which will run under the pavement less than a depth of six inches under bottom of drainage foundation

Portland cement concrete expands and contracts in practically the same ratio as steel; it is therefore necessary to cut joints which will allow for this expansion or contraction The concrete must be cut entirely through with a cleaver, or other instrument, from ⅛" to ¼" wide, the blocks thus formed not to exceed 6 square. I am fully aware that very excellent work has been done, the blocks being as large as from 12 to 14 ; that good results were obtained with such large slabs is due more to favorable circumstances than to correct method. By figuring the expansion and contraction per degree between the heat of summer and the cold of winter, it will be found that we are only within the region of safety when the slabs do not exceed 6 with an ⅛" joint between each slab.

Expansion cracks are not due so much to the expansion of the cement stone slabs as to the expansion of other material bearing against these slabs; it is therefore advisable to cut the concrete away from the manholes, iron posts, etc., leaving about the same space in the joints as between the slabs themselves This space may be readily waterproofed by using felt paper painted with a good waterproof paint.

In the past it has been a very common practice to allow the base to set hard before laying the top coat; it is unnecessary at the present date to dwell on this subject; we all know that it is utterly wrong There are, however, other causes which prevent the top coat from adhering permanently to the base the principal cause being carelessness in allowing men to walk over the base carrying with them dust and dirt, also failure to protect the base, allowing the surface of the base to be exposed to the rays of the sun and thus dry the surface prematurely, at the same time allowing dust and dirt to blow over the surface, coating the concrete so that the top when placed fails to adhere permanently It is also absolutely necessary that the top be cut directly over the cuts in the base; otherwise the top coat will crack along the line of the joint in the base.

The principal causes of disintegration and chalky top surface are insufficient mixing, drying out before ultimate crystallization of cement, and bad material used. Start right and good results naturally follow To avoid disintegration material should be carefully selected. This selected material must be thoroughly incorporated and

FIG 2—CONCRETE MIXING PLANT SHOWING CONCRETE BOARD TOOLS ETC NECESSARY FOR MIXING CONCRETE BY HAND

FIG. 4—SPREADING THE CEMENT OVER THE SAND

mixed into a plastic mass with sufficient water to bring about ultimate crystallization of the cement. Being thus mixed it should be immediately placed upon a cinder or broken stone foundation which has to be *soaked with water*, thoroughly and evenly tamped and then protected from drying out before final setting. Cement needs water not only when mixed, but after being placed and tamped and it requires water until ultimate crystallization has taken place. If any portion of the concrete is robbed of the amount of water necessary to bring about this result, the concrete is weakened to that extent.

It is important that the best material be used in the manufacture of Portland cement sidewalks. Poor material makes poor walks and costs just about as much.

Having selected the best materials obtainable, by far the most important operation is that of *mixing*. The methods employed in mixing by hand as well as by machinery depend largely upon the character of the aggregates used. It is now being almost universally recognized that the small aggregates properly graded in size make the densest, strongest and best concrete for sidewalk paving. Mix a concrete made of gravel, three-quarter inch hard limestone traprock or other hard tough stone and good coarse sand, by first mixing the cement and sand dry.

Following is the best procedure for hand mixing graphically described. (Written by Percy H. Wilson and Clifford W. Gaylord.)

The permanency of the pavement depends on careful and thorough mixing.

Showing the Quantities of Materials and the Resulting Amount of Concrete for Two-bag Batch, Using Natural Mixture of Bank Sand and Gravel

Kind of Concrete Mixture.	Proportions by Parts: Cement.	Sand.	Stone or Gravel.	Two Bag Batch: Materials: Cement, Bags.	Sand, Cubic Feet.	Stone or Gravel Cu. Ft.	Concrete Cubic Feet.	Size of Measuring Boxes Inside Measurements: Sand.	Stone or Gravel.	Water in Gallons for Medium Wet Mixture.
1 2 4 concrete	1	2	4	2	3¾	7½	8½	2 × 2 1 ½	2 4 11½	
1 2½ 5 concrete	1	2½	5	2	4⅔	9½	10½	2 × 2½ 11½	2 × 11½	1
1 3 6 concrete	1	3	6	2	5⅝	11½	12	2 × 3 11½	3 4 11½	8½

Showing the Quantities of Materials and the Resulting Amount of Concrete for Two-bag Batch.

Kind of Concrete Mixture	Proportions by Parts: Cement.	Natural Mixture of Sand and Gravel.	Two Bag Batch for Natural Mixtures of Bank Sand and Gravel: Materials: Cement Bags.	Natural Mixture of Sand and Gravel Cubic Feet.	Concrete, Cubic Feet.	Size of Measuring Boxes: Mixture of Sand and Gravel		Water in Gallons for Medium Wet Mixture.
1 2 4 concrete		4	2	[illegible]	8½	2 4	11½	10
1 2½ 5 concrete		5	2	9½	9½	2 × 5	1	9
1 3 concrete	1		2	11½	2	3 × 4	11½	13½

With the proper materials selected the next step is to mix properly and with dispatch. On large jobs it is more economical to mix concrete by machine, but for small jobs using even as much as several hundred cubic yards of concrete it is much cheaper and more expedient to mix by hand. This is of course especially true when only two or three men are available and the work is often in

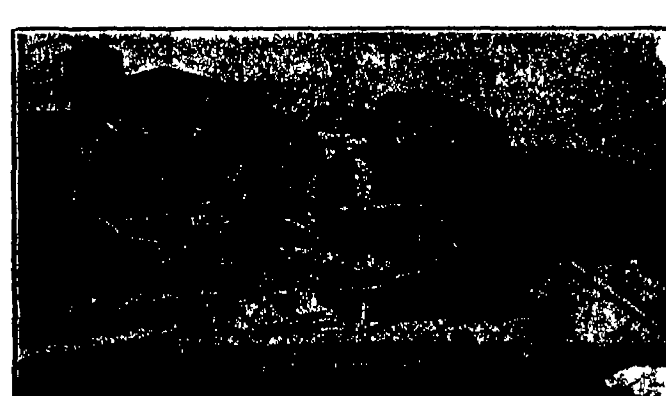

FIG 12.—PLACING THE CONCRETE WITH WHEELBARROWS

terrupted There are many ways of "hand mixing" all having the same good results The way described here we believe to be the one best calculated to obtain good results with a minimum of labor In this description and the accompanying illustrations, we have taken as a basis a Two Bag Batch

A concrete board for two men should be 9 feet × 10 feet Make it out of 1 inch boards, 10 feet long surfaced on one side using five 2 inch × 4-inch × 9 foot cleats to hold them together If 1 inch × 6 inch tongue and groove roofers can be obtained they will do very nicely if fairly free from knots The object of the surface boards is to make the shoveling easy The boards are so laid as to enable the shoveling to be done with and not against, the cracks between the boards The boards must be drawn up close in nailing so that no cement grout will run through while mixing Knot holes may be closed by nailing a strip across them on the under side of the board It is a good precaution against losing cement grout to nail a 2 inch × 2 inch or 2 inch × 4-inch piece around the outer edge of the board Often 2 inch planks are used in making concrete boards, but these are unnecessarily heavy and very cumbersome to move

Placing the Concrete Board—The concrete board is a manufacturing plant and the advantages of its location should be carefully considered Generally it is best placed as close as possible to the place in which the concrete is to be deposited but 'local conditions must govern this point Pick a place giving plenty of room near the storage piles of sand and stone (or pebbles) Block up your concrete board level so that the cement grout will not run off on one side and so that the board will not sag in the middle under the weight of the concrete

Do not use any old boards that are handy for the wheelbarrow runs Make a good run smooth, and at least 20 inches wide if much above the ground It is surprising how this one feature will lighten and quicken the work

List of tools and plant to be used in mixing giving sizes, quantities etc

Concrete board for two bag batch 9 × 10 in size *

Nine pieces ⅞" × 12" × 10 surfaced one side and two edges (any width of plank may be used 12 is specified only for convenience) 5 pieces 2" × 4" × 9 rough 2 pieces 2" × 2" × 10 rough 2 pieces 2" × 2" × 9 rough

Concrete board for four bag batch 12 × 10 in size:

Twelve pieces ⅞ × 12 × 10 surfaced one side and edges (any width of plank may be used 12 is specified only for convenience) 5 pieces 2" × 4" × 12 rough 2 pieces 2 × 2' × 10 rough; 2 pieces 2 × 2" × 12 rough

Runs—2" 2½ or 3" plank 10" or 12 wide

Measuring boxes for sand and stone or gravel

For two bag batch 1:2 4 mixture:

Four pieces 1" × 11½" × 2 rough 2 pieces 1" × 11½" × 4 rough 2 pieces 1" × 11½" × 6 rough

Note—The 2 pieces 4 long and the 2 pieces 6 long have an extra foot in length at each end to be made into a handle as shown in Fig 2

For two-bag batch 1:3:6 mixture

Two pieces 1" × 11½" × 2; 2 pieces 1" × 11½ × 3 2 pieces 1 × 11½ × 5 2 pieces 1 × 11½" × 6

Note—The 2 pieces 5 long and the 2 pieces 6' long have an extra foot in length at each end to be made into a handle as shown in Fig 2

For four bag batch:

Double cubic contents of boxes and order lumber accordingly

Shovels—No 3 square point

Wheelbarrows—At least two necessary for quick work; sheet iron body preferred

Rake

Water barrel

Water buckets Two gallon size

Tamper 4" × 4" × 2 6" with handles nailed to it as shown in Fig 2

Sand Screen—Made by nailing a piece of ¼" mesh wire screen 2½" × 5 in size to a frame of 2" × 4"

With the mixing board placed and the "runs" made the concrete plant is ready

First load your sand in wheelbarrows from the sand pile wheel on to the 'board and fill the sand measuring box which is placed about two feet from one of the 10-foot sides of the board When the sand box is filled lift it off and spread the sand over the board in a layer three inches or four inches thick as shown in Fig 4 Take the two bags of cement and place the contents as evenly as possible over the sand. (See Fig 4.) With the two men Fig 5 start mixing the sand and cement, each man turning over the half on his side. Starting at his feet and shoveling away from him, each man takes a full shovel load turning the shovel over on their own side. In turning the shovel, do not simply dump the sand and cement near the edge of the concrete board, but shake the materials off the end and sides of the shovel, so that the sand and cement are mixed as they fall This is a great assistance in mixing these materials In this way the material is shoveled from one side of the board to the other as shown in Figs 5 and 6 Fig 5 shows the first turning, and Fig 6 the second turning

The sand and cement should now be well mixed and ready for the stone and water After the last turning spread the sand and cement out carefully, place the gravel or stone measuring box inside it as shown in Fig 7, and fill from the gravel pile. Lift off the box and shovel the gravel on top of the sand and cement, spreading it as evenly as possible With some experience equally good results can be obtained by placing the gravel measuring box on top of the carefully leveled sand and cement mixture and filling it thus placing the gravel on top without an extra shoveling This method is shown in Fig 8 Add about three-fourths the required amount of water using a bucket and dashing the water over the gravel on top of the pile as evenly as possible (See Fig 9) Be careful not to let too much water get near the edges of the pile, as it will run off taking some cement with it. This caution, however does not apply to a properly constructed mixing board as the cement and water cannot get away Starting the same as with the sand and cement turn the materials over in much the same way, except that, instead of shaking the materials off the end of the shovel the whole shovel load is dumped and dragged back toward the mixer with the square point of the shovel This mixes the gravel with the sand and cement the wet gravel picking up the sand and cement as it rolls over when dragged back by the shovel (See Fig 10) Add water to the dry spots as the mixing goes on until all the required water has been used Turn the mass back again as was done with the sand and cement With experienced laborers the concrete would be well mixed after three such turnings; but if it shows streaky or dry spots it must be turned again After the final turning shovel into a compact pile The concrete is now ready for placing (See Fig 11)

Number of Men—For the above operation only two men are required although more can be used to advantage If three men are available let two of them mix as described above and the third man supply the water, help mix the concrete by raking over the dry or unmixed spots as the two mixers turn the concrete, help load the wheelbarrows with sand and stone or gravel, etc Fig 5 shows a third man on the board In this illustration he is helping mix the sand and cement by raking it—a most effective practice

When the day's work is done, carefully clean all the tools especially the concrete board Remove with a shovel all the loose cement, sand, and stone. Then scrub the board with a broom and water If this is not done, small particles of stone are glued to the board by the cement and render shoveling the next day most difficult

We again wish to call attention to the fact that there are several ways of mixing concrete by hand just as effective in their results as the ways mentioned here. But every man of experience in mixing has one way which he thinks is more effective and easier than any other

Machine mixing should be accomplished much the same as it is in Germany the mortar mixed dry then the stone added then the whole mass mixed dry; this entire mass is then run into another mixer and there mixed wet This result can be fairly well accomplished by using a mixer which has knives and rakes, which does the same thing as turning and raking in the hand mixed process; understand, I am advocating this method only for concrete made up of small size aggregates, that is, all passing a ¾" mesh.

Dry concrete, even though thoroughly tamped, seldom gives thoroughly satisfactory results

The object to be accomplished in laying a base for a sidewalk is uniform strength. The concrete to be of such consistency as will enable the workmen to place the top coat over the base during the same day and before the base has finally set. If the concrete is very wet, such as poured concrete, a scum forms on the top surface which interferes with the proper adhesion of the top coat to the base. Therefore, a happy medium should be found bringing about proper consistency which may be thoroughly and uniformly tamped. This can only be judged by the eye on the mixing board and is a matter which necessarily has to be left to experience.

The concrete should not be made so wet that it will quake under the tamping iron, unless steel strips are used for the joints or laid in alternate blocks; it should be sufficiently wet, however, so that some moisture rises to the surface under the tamping The proportion of water necessary will vary according to the climatic and other surrounding conditions The proper consistency can only be judged by the eye on the mixing board; no accurate specifications can possibly bring about uniform and desirable results. This is a matter which necessarily has to be left to experience. The tamping should be vigorous and uniform.

One of the causes of bad workmanship is due to the concrete either in the top or the base, having prematurely dried This is avoided by keeping the concrete covered to protect it from wind and the rays of the sun If the concrete is anywhere near boilers or steam pipes, see to it that the concrete is wet continuously for from twenty-four to thirty six hours; after this period sprinkle two or three times a day for a couple of weeks, or such length of additional time as economy will permit. Sidewalk paving slabs are acted on from both sides; and being comparatively thin are more sensitive than mass concrete therefore need greater protection. The writer has seen instances where workmanship as far as selection of materials, mixing, placing and tamping were thorough and excellent; but, nevertheless, bad results were obtained This was particularly true of a pavement laid over waterproofing The atmosphere absorbed the moisture from the top and the top absorbed the moisture from the base The base had nothing wet under it from which to get water could not supply sufficient moisture to the top to offset the action of the dry air and the result was a top of chalky consistency Had the base been made very wet and the top covered with wet sand, no such results would have been produced

Durability relates principally to the wearing surface; there is no reason why a cement slab should not wear longer than the ordinary natural stones; for, in forming these slabs we have the advantage of selecting the toughest and strongest stones Cement itself is tougher and stronger than most of the products of nature The texture of the surface has a good deal to do with efficiency A scum or skin of neat cement on the surface soon wears through, causing an ugly and blotchy pavement. There is no reason why a slab of cement stone cannot be manufactured which would wear for a hundred or more years; it might wear down to the extent of half an inch or an inch or more, and still preserve the same texture, This is perfectly feasible by making a slab of one piece no top coat whatever an even smooth top carefully jointed composed of small selected aggregates and in proportions which result in maximum density I have seen one or two pavements of this character notably the one around the Hotel Astor New York which is in 9" slabs entirely around the building expansion joints cut at regular intervals and so arranged as to form an architectural design The concrete was composed of three quarter inch traprock and sand The surface was floated off and smoothed down with a trowel; it was not troweled to such an extent as to bring any neat cement to the surface This pavement will wear for two hundred years or more and as it wears down the same texture is preserved

The usual troweled surface is slippery It is subject to all manner of diseases, such as hair cracks, crazing peeling etc and is only beautiful before the disease sets in A monolithic slab leveled off and smoothed to an even surface in which flint, quartz pebbles or crushed granite show through, such as some of our granolithic sidewalks can be thoroughly tamped and then floated so that the above desirable results are economically obtained Another method is to use three-quarter inch hard stone and quarry screenings or sand, making a monolithic slab straight edge off tamp uniformly smooth down to an even surface with float and trowel cut joints, carefully mark joints with a good jointer round the edges, and after final set is reached but before the surface has begun to dry scrub with a steel brush such as is used in cleaning boilers; play a hose on the surface just ahead of the brush and scrub the surface vigorously This removes the neat cement from the exposed surfaces of all the aggregates, does not disturb the aggregates, and gives a most beautiful, natural and genuine finish, similar to natural granite; you therefore have a pavement which is honest and genuinely clear through and is obviously so

The object of a top coat is durability, at the same time properly serving the purpose for which it is intended that of foot traffic A slippery sidewalk is a menace to humanity

In order to obtain durability neatness and good service, the top should be worked to a flat surface with a straight edge and smoothed down evenly with a float After the surface water has been absorbed and just as the top is hardening, it should be slightly troweled, but not enough to bring the neat cement to the surface, at the same time being careful to get an even surface avoiding float and trowel marks.

Neatness is obtained by the texture produced as described above, by carefully marking the joints and rounding the edges. Be careful not to use too much water so that an excess of water rises to the top, carrying with it particles of neat cement. This causes hair cracks, crazing, streaks and efflorescence. Another disease is occasioned by an accumulation of water in any one or more places which will cause what has been commonly known as water cracks, which are not open cracks, but surface cracks, and look like dark blotches. In discussing this

*For convenience the signs ' for feet and " for inches have been used in describing tools and plant in tables.

subject of neatness, observation would indicate that the thought uppermost in the mind of most sidewalk paving contractors had been that of forming an artificial top of veneer over the rougher concrete Do not use lamp black, it is the worse form of poor imitation Sidewalk paving construction, like all other forms of engineering, is only permanently and lastingly good if honest and genuine We will sum up the foregoing into the following suggested specifications:

SPECIFICATION SUGGESTIONS.

Sidewalks in cold climates where frost occurs should consist of a foundation of coarse cinders, broken stone brick bats, or other porous material, the concrete to be laid on this foundation Do not lay concrete in freezing weather

Excavate to a sufficient depth so as to provide for perfect drainage ram and tamp the ground thoroughly and evenly provide clean large cinders, broken stone or brick bats, any of which should be collected on an inch mesh place these to within the needed distance of the top of the established grade of the pavement (a sufficient number of inches to provide for the thickness of slab necessary to give adequate strength for the character of the work it is to perform) tamp this drainage foundation well and evenly thoroughly wet to saturation the cinders, stone or broken brick place in position wooden forms in a manner necessary to accurately outline the top and external edges of the walk the top of the form being located so as to coincide with the established grade of the walk place stakes nailed to and on the outside of forms or broad strips As an additional precaution and where necessary to accomplish the purposes of drainage, side drains should be placed every ten or twelve feet having a fall of not less than one-quarter inch to the foot, leading to some point forming an outlet for water which may accumulate This outlet should be below the frost line and it may be accomplished by a hole filled with cinders, stone or brickbats Cut out the roots of trees which lie less than a depth of six inches under the bottom of the drainage foundation

For a concrete base spread enough material to provide for the thickness of a slab which will come to within one inch of the top of the established grade; this concrete to be composed of one part Portland cement and two and a half parts sand or quarry screenings all passing one quarter inch mesh, and five parts broken stone or gravel all passing one inch mesh and collected on a quarter inch mesh; mix thoroughly

The specifications may be regulated if proportions can be obtained which will allow of a larger proportion of broken stone, at the same time giving maximum density Tamp the concrete to an even thickness cut the same into uniform squares of not over six feet square using a steel cleaver of not less than one-eighth inch and not over one quarter inch in thickness Cover the base with tarpaulins or tar paper immediately as each section is laid this as a protection against dust, dirt or premature drying Mark on the wooden forms the exact locations of these cuts After each batch of concrete is laid as required and before the base has started to harden it shall be covered with a top coat or wearing surface no dirt or dust having been allowed to accumulate on the base and the surface of the base to be wet or moist Any portion of the foundation which has been left long enough to have the appearance of setting or hardening shall be taken up and re laid before the top coat is put on

In order that the pavement may drain off readily during and after rain, the surface should be graded toward the street, having a fall of one-quarter of an inch to the foot causing the top nearest the street to be lower than the top nearest the buildings.

For wearing surface mix one part Portland cement with two parts crushed granite or other hard stone (all of which will pass through a quarter inch mesh screen) or good coarse sand mix by turning with shovels raking with a garden rake as each shovelful is turned turn twice dry and twice wet, add sufficient water to make a plastic consistency so that when floated or troweled very little water rises to the surface Spread this mortar over the concrete base to a thickness of one inch Work to a flat surface with a straight edge smooth down with float and trowel after the surface water has been absorbed be careful to get an even surface, bringing no neat cement to the surface and avoiding float and trowel marks

Cut the top surface directly over the cuts made in the base, cut entirely through top and base all around each block Finish the joints thus made with a jointer and round or bevel all edges

At the end of the day's work some careless workman often ends the work with an incline of concrete and when the work is started the next morning new concrete is spread over this incline of concrete which has set hard While a bond may result it will at best be very weak resulting during the course of a month or two in a crack at this point.

The day's work should be ended at the end of a slab A form should be staked across making a vertical joint, a piece of thick tar paper should be placed against this vertical joint and the new concrete placed against this tar paper

As an alternative and instead of using a top coat, make one slab of selected aggregates for the face and wearing surface, filling in concrete between the frames flush with the established grade Concrete must be of selected aggregates all of which will pass through a three-quarter-inch mesh sieve, hard tough stones or pebbles graded in size, proportions to be one part cement, two and a half parts crushed hard-stone screenings or coarse sand (all passing a quarter-inch mesh), and five parts crushed hard-stone or pebbles, all passing through a three-quarter-inch mesh, and all collected on a quarter-inch mesh; tamp to an even surface, prove surface with a straight edge, smooth down with float or trowel Thoroughly mix.

Do not allow any block to bear directly against any solid body, such as stone curb, building, post, manhole rim, etc. Leave the same space (about one-quarter inch) between the pavement and such fixtures as are between the blocks themselves. This applies to the base and top as designed to avoid cracks and chipping due to expansion and contraction from temperature changes This space can be conveniently provided for by the use of thick tar paper or felt, waterproofed with any of the reliable waterproof paints

When finished cover the pavement so as to protect it against the rays of the sun the wind and consequent drying raising the covering a few inches so as not to come in contact with the surfaces after the pavement has reached hard set, sprinkle frequently two or three times a day with a garden hose or a sprinkler for a week or more

SIDEWALKS.

Another method designed to insure perfect separation of slab or blocks (See Fig 13)

Place a 2 × 3-inch strip *D* parallel with the side of the walk in such position as will form square blocks of equal dimensions, not over six feet wide; brace the same with stakes but do not nail to the frame then cut a strip 2 × 3 inches, the length of which is to be the width of the blocks or distance between strip *D* and side frame *I* Place this strip so as to form a square block *C* On the inside of the strip *C* and *D* place thick tar or felt paper ¼ inch thick and 3 inches wide fill in the space thus formed (block *A*) with concrete composed of one part Portland cement two parts sand and five parts crushed stone or gravel, and mix thoroughly Tamp the concrete thoroughly to an even thickness then remove strip *C*; the tar paper will adhere to the concrete Move strip *C* to the next position skip block *B* place the thick tar or felt paper as before and proceed the same with each block laying alternately Put on the top coat before the first block made starts to set or harden and in regular order as blocks were made

CEMENT SIDEWALKS IN WARM CLIMATES WHERE FREEZING DOES NOT OCCUR.

Excavate to a depth of 4 inches below established grade of the sidewalk tamp the ground well and evenly omit the cinder or broken stone drainage foundation remainder of specification same as that for sidewalks in cold climates

DRIVEWAYS

Base should not be less than 4½ inches thick

Wearing surface should not be less than 1½ inches thick; remainder of specification same as for sidewalks

CELLAR FLOORS

Use sidewalk specification with the exception that the cellar should be waterproofed outside the sides carrying the waterproofing down outside of the wall over the top of the footings in addition lead off water by outside drainage obtained by porous drain tile covered with cinders or broken stone run around the wall just below the top of the cellar floor, leave out the drainage foundation and do not cut the concrete into blocks A two-inch to four inch thickness is sufficient

COLORING MATTER.

Do not use coloring matter unless absolutely necessary Nearly all coloring matter reduces the strength of the mortar For coloring cement work the following quantities will be found the least objectionable

QUANTITIES PER 95 POUNDS OF PORTLAND CEMENT

For a 1:2 mortar

		Pounds
Black	Excelsior carbon black	2
Black	Manganese dioxide	10
Buff	Yellow ocher	4
Blue	Ultramarine or azure blue	4
Gray	Lamp black (bone black)	½
Green	Ultramarine	5
Green	Oxide of cromium	7
Brown	Roasted iron oxide	6
Red	Red iron oxide	6 to 10
Bright red	Pompeian red	6
Yellow	Ocher	6

Mix the coloring matter thoroughly with the sand or screenings in proportions as above

CEMENT CURB AND GUTTER

The drainage foundation should be of materials as described under the head of sidewalk paving and placed so as to accomplish the object of drainage, using the methods and instructions as previously described.

Place in position the forms to receive the concrete. These forms are held in place by stakes set by the engineer at points necessary to accurately designate the line and grade of the proposed curb and gutter (See Fig 14 *A B* and *S*) For forms use 1½ to 2 inch rough planks Dimensions to be according to the height of the curb and thickness of the gutter Form *F* is movable and is held in place by iron clamps bearing against the outside of form *B* extending over the top of the curb this clamp being shaped similar to the letter C, one of the arms being fitted with a screw

Spread five or more inches of concrete mixed as described under the head of Cement Sidewalk Paving The concrete should be mixed wet so that when tamped some water will come to the surface Then place in position form *F* and fill in with concrete the same mixture between form *F* and form *B* tamp thoroughly and evenly to within one inch of the top of the curb; form *F* may be taken down immediately and moved to next position Form *B* will be found sufficient to hold the concrete curb in place without sagging Cut curb and gutter entirely through every six feet A convenient and sure method is to use a piece of quarter inch sheet iron the height and width of the curb and gutter as a division partition fasten a handle on top and shape the sheet iron the same form as the concrete base of curb and gutter (See Fig 14 *C* and *D*) Place this sheet iron division every six feet between forms *A* and *B* tamp concrete all around on both sides of the sheet iron form pull out the same immediately after form *F* is removed Fill in the cuts thus formed with dry sand mark forms *A* and *B* opposite cuts so as to accurately place the joints thus formed After each batch of concrete is laid it should immediately be covered with a top coat of wearing surface

Cover the concrete base of the curb and gutter immediately or as soon as possible after the base has been put in place with one inch of mortar mixed medium wet Materials used for this mortar and methods of mixing to be as previously described in specifications for Cement Sidewalks

Slope the gutter to meet the requirements of drainage by increasing the thickness of the top coat on the side nearest the street Work to an even surface with a straight edge laid parallel with the curb and shifted from form *B* to form *A* The upper face corner of the curb and angle between the curb and gutter should be rounded with a radius of 1 to 1½ inches After getting a good surface float with plasterers float until a smooth, even surface is obtained This surface should be wet or very moist. Dust this surface while it is still wet with granite dust and Portland cement mixed half and half dusting to take place before the surface water has been absorbed Immediately smooth down with a trowel Do not let too great an interval elapse between floating and troweling Use a curved trowel for top corners of the curb and angles between the curb and gutter After troweling finish with a soft brush, an ordinary hearth brush or whitewash brush will do If the top is too dry sprinkle with water The brush will take out the trowel marks and give an even texture and color to the finished work Cut the top coat directly over the cuts made in the concrete base leveling the edges of the cuts with a jointer

Protection is most important and is fully covered by instructions previously described under head of Sidewalk Paving

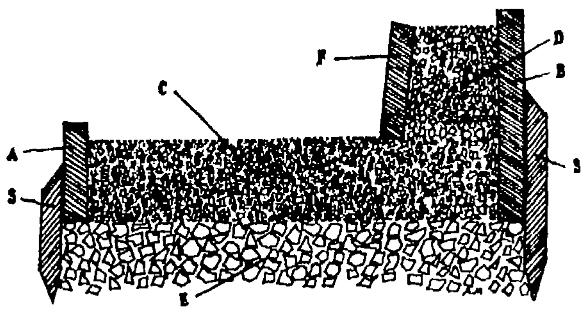

FIG 14 CONCRETE CURB AND GUTTER SHOWING DRAINAGE FOUNDATION AND CONCRETE BASE (TOP COAT NOT SHOWN)

A—Plank 1½ inch x 6 inches length as required
B—Plank 1½ inch x 13 inches length as required
C—Concrete base for gutter and under part
D—Concrete base for curb
E—Drainage foundation
F—Plank 1½ inch x 7 inches length as required
S—Stakes nailed to forms *A* and *B*

A Catskin Carriage Robe

HAVE you ever seen a catskin carriage robe with the skins in their natural colors? If not, you would be as much surprised at its beauty as the writer was when a young nephew who was visiting me from the country brought his robe out for admiration It was really beautiful but it seemed also remarkable as the handiwork of a boy not yet seventeen He had bagged the cats of all the neighborhood killed them and tanned the skins But the lining was still more remarkable It was of blanket like material and this boy had himself taken the wool as it came from the sheep washed it dyed it spun it into yarn put the yarn on a loom and had woven it into the cloth, thus alone completing the production of the cloth lining His father had a small woolen mill driven by a water wheel and covering a floor space of probably 40 × 60 In these days, when the large factories specialize labor so that different persons perform the different steps in the production of a cloth, it seemed remarkable that the boy should have, single handed converted the raw material into the beautiful finished article.

A Few Shop Jobs on an Old Car

Hints for the Handy Man with Tools

By Herbert L Towle

Aside from repairing actual breakages which are not covered in this article the work of overhauling an old car concerns itself first, with making good the wear due to use second with altering or modernizing certain features such for example as the ignition system to bring them up to date and third, with an intermediate class of repairs necessitated by such things as sagging of the frame or axles or bends in the steering connections which cause the front wheels to run out of line In most cases of wear or distortion the proper remedy suggests itself at once to the experienced shop man In many cases however the severity of automobile service is such as to require much more careful treatment than would be necessary with other classes of machinery A few typical instances are noted in the following paragraphs

MAKING A STEERING GEAR SNUG

The steering gear is usually the first part of a car to show wear owing to the violent shocks it must endure and the necessarily limited sizes of the various bearings A common fault in old cars is loosening up of the bolts holding the casing at the base of the steering column to the frame Unless the steering column is well braced to the dash or toe board the slightest looseness in these bolts will cause the steering column to shake and the bolt holes to wear large Tightening up the bolts is but a temporary make shift. The only permanent remedy is to ream the holes true and fair to the next larger size and put in bolts that are a tapping fit in the holes It may even be worth while to make special bolts for the purpose from annealed tool steel A better remedy where it can be applied is to brace the steering column This requires that the dash or toe board itself shall be rigid A simple method is to make a brass casting to fit the dash or toe board having a cored hole a quarter of an inch larger than the steering column After being put in place this casting is heated and babbitt metal is run in to fill the space around the column If the outside of the column turns thin paper must be wrapped around it to give clearance and the babbitt bearing must be 4 or 5 inches long and provided with a grease cup

In case the steering knuckles are worn loose on their pivot bolts renewal is easy if the knuckles are bushed If however there are no bushings the knuckles may be counterbored and case hardened bushings driven in These bushings of course should be case hardened inside only and copper plated and wrapped with asbestos before baking to prevent their outer surfaces from absorbing carbon The same treatment may be applied to the ends of the front cross link or the holes may simply be reamed true and pins made and case hardened to fit them If new pins are made they should be provided with oil covers or better small greasecups and able to bronze Quite possibly the crank pins of the engine under consideration are oiled by splash from above through holes drilled in the upper half of the connecting rod big ends If so the repair man has a good opportunity to prolong the usefulness of the next set of bushings by leaving the upper half entirely plain and feeding the oil from beneath by means of copper or steel scoops sweated into the bottom caps of the rods These scoops should be about one-quarter of an inch inside diameter and shaped to dip squarely into the oil Short oil grooves should lead crosswise from the oil hole in the center of the bushing but these grooves should extend no more than half way to the edge of the bushing so that the oil will not be able to escape from the bearing without doing its part of the work In handling connecting rods with scoops fitted care must be taken not to bend the end of the scoop by an accidental blow as this would defeat the object of the scoop and result in a cut bearing The reason for leaving the upper half of the bushing plain is that under pressure oil squeezes out from a bearing instead of working into it and grooves in the pressure side would permit the oil to escape at the very moment when it was most needed

SAGGED FRAME

A motor car frame is after all nothing but a spring, and it sags more or less according to the load. In time the shocks of travel may produce a permanent set in the side members, to compensate for which the motor and gear case should be lined up anew It is a good plan when doing this to load the frame in some manner to about its normal load If the sag

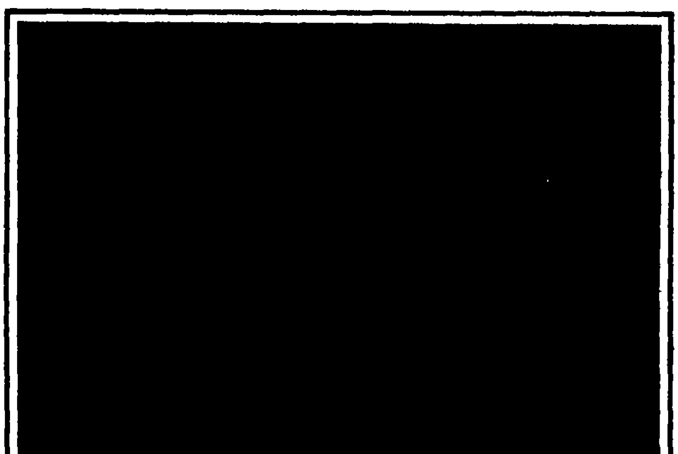
ROUNDING UP AN OLD CRANK-SHAFT

is small it can usually be corrected by putting liners under the rear feet of the engine and the front feet of the gear box Exact alignment is unnecessary if the clutch and gear box are connected by a short shaft having universal joints at both ends If however there is only one universal or none at all, fairly exact alignment is necessary An approximate test is had by opening all the compression cocks and turning the crank slowly with the clutch engaged to show whether or not there is binding at any point.

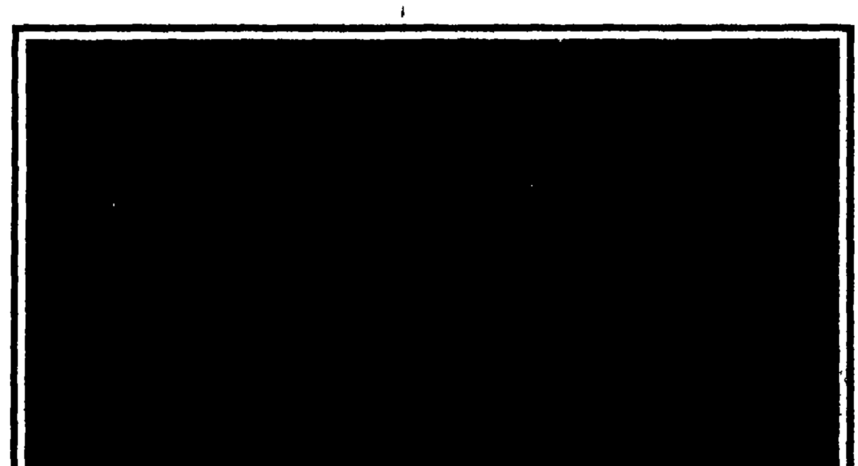
If the frame has sagged so much that liners used as above will not correct the trouble it is best to apply truss rods underneath the frame The manner of doing this will depend on the room available for attaching the ends of the truss rods and for placing the two struts According to the size of the car the truss rods may be from ⅜ inch to ½ inch in diameter and the struts may be from 4 inches to 6 inches high It is best to attach the ends of the truss rods beyond the spring shackles and if possible over the axles The struts may be spaced apart about one third the distance between the ends of the rods The rivets holding the ends of the rods should be spaced fore and aft and should be about 5 16 of and inch in

WEAR OF PISTONS AND CYLINDERS

The piston rings will become leaky before the pistons have ceased to be a fair fit in the cylinders consequently replacement of the rings may be the only thing needed In time however the cylinder wears barrel shaped and the piston also wears with the result of oil working up past the pistons in undue quantities till a noticeable click is produced at each explosion by the side slap of the piston When this point is reached the cylinder must be reground and a new piston turned to fit. The clearance between the piston and cylinder should be approximately one thousandth inch plus another thousandth for each inch of the piston diameter That is a 4 inch piston should have five-thousandths of an inch clear ance The top of the piston should have when cold at least double the clearance given elsewhere, on account of the expansion of the piston head when hot.



REPAIRING A CRANK CASE



GROOVING A PISTON

MAKING YOUR OWN AUTOMOBILE REPAIRS

these should feed to the center of the bearing

LEAK IN RADIATOR

A radiator may be repaired if the leak is outside, by emptying it and laying it flat so that the solder will not flow away To prevent adjacent seams from opening from the heat they may be kept cool with pads of wet waste

NEW CRANK SHAFT BUSHINGS

Die cast babbitt metal is now almost the universal material for crank shaft bushings and is far prefer-

diameter, two to four being used, according to the size of the rod A turnbuckle in the center of the rod will draw the frame straight

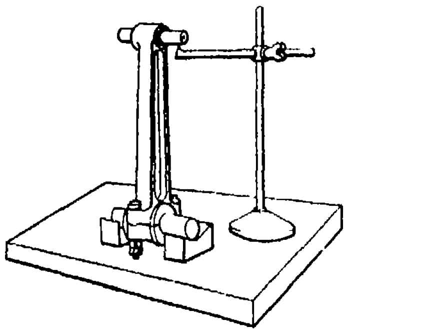
BALL BEARINGS LOOSE IN GEAR CASE

Annular ball bearings set directly into an aluminium crank case are liable in time to hammer their aluminium seatings until the outer races are distinctly loose This is avoided in some cars by setting the bearings in bronze cages, thus distributing the contact between the outside of the cage and the aluminium over a larger surface than the outer ball

race itself would afford. In case a ball bearing works loose in aluminium the best remedy is to counter bore the aluminium about ¼ inch larger each side and machine a flanged bronze ring to fit the aluminium as snugly as possible

FILLETS ON SQUARE-ENDED SHAFTS

It is quite common for the shafts in live rear axles of the floating type to engage the differential gears by having square bolts milled on the shaft ends Quite possibly the outer ends of the shafts may engage driving plates in the wheel hubs in the same manner If the car has side chain drive the differential shafts may have their inner ends formed in the same way and the outer ends may have tapered ends with hexagonal flats to hold the sprocket pinions The best modern practice is either to have the shaft enlarged so that forming a square or hexagonal of it does not reduce its section below that of the end portions of the shaft or to forge a disk on the end

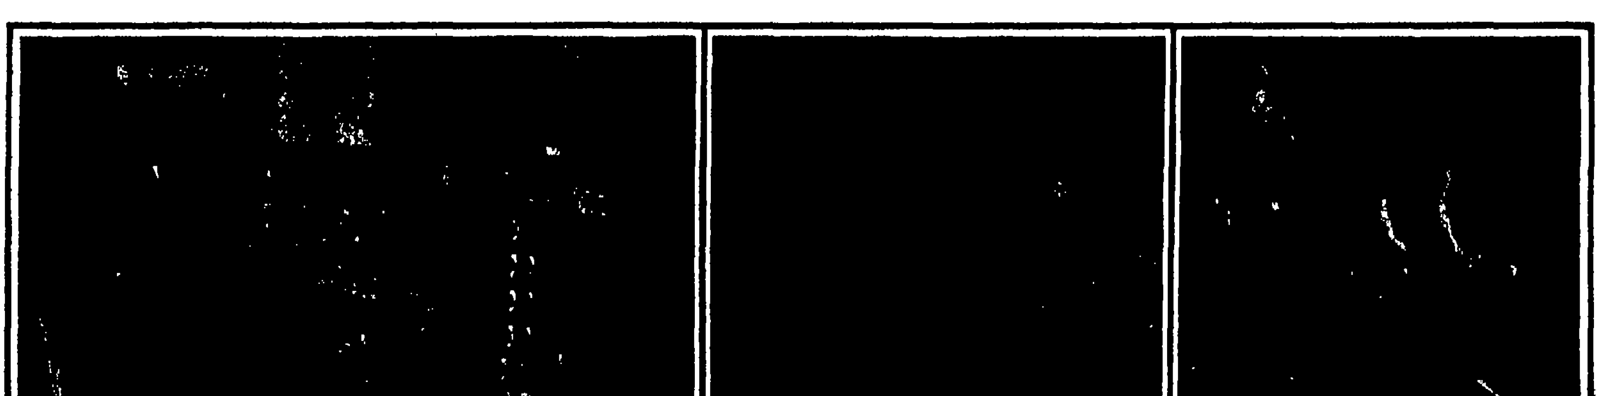


TESTING WRIST AND CRANK PIN BUSHINGS FOR PARALLELISM AFTER SCRAPING THE LATTER

of the shaft with bolt holes or clutch claws on it the purpose of either construction being to apply the driving force at a greater distance from the center of the shaft If however the shaft is not enlarged it is very important that the change from the reduced square to full circular section be gradual not abrupt An abrupt shoulder at this point concentrates the fiber stress and results in the shaft eventually breaking under strains which it would have easily endured if large fillets were provided instead of a square shoulder The same thing applies to hexagonal ends If the shaft is taken out in the course of overhauling fillets can easily be put in by means of an emery wheel

WELDING CRACKS IN ALUMINIUM CASTINGS

Until recently it was necessary either to discard a cast aluminium part belonging to the crank case or gear case in the event of its being cracked or to rivet a more or less unsightly patch over the crack to close and strengthen it. Nowadays such work is done by oxy acetylene welding The process of course cannot be described here but it consists essentially in chipping a triangular groove of the width and depth of the crack and filling this groove with molten aluminium flowed into it under the heat of the oxy acetylene blow pipe flame The same process is applicable to repairing cracked water jackets and occasionally cylinders as well as repairing damage of various sorts to wrought iron and steel Portable apparatus for this purpose may be had in the market



SOLDERING A LEAKY RADIATOR

REGRINDING A CYLINDER

REBUSHING THE BEARINGS

HOW AUTOMOBILES ARE REPAIRED

and should be a part of the equipment of every first class automobile repair shop

REFITTING THE DIFFERENTIAL

The hardest part of the differential to lubricate and the likeliest therefore to wear out soon is the spider, on which the four small bevel pinions are carried The spider is usually case-hardened the pinions may or may not be bushed Holes are usually drilled in the pinions through which oil is worked by the rolling of the teeth If however the user makes the mistake of using grease to lubricate his differential, the repairer is likely to find that the bushings of the small pinions have been cut to pieces, owing to the grease refusing to enter The journal portions of the spider are also likely to have suffered If the pinions are bushed the user is fortunate, for new bushings are easily purchased and even if the spider must be ground to true it up special bushings to fit the new diameter of the spider will not be expensive If however there are no bushings, both pinions and spider must be replaced

RERIVETING AN OLD FRAME

Most of the frames made to-day are as strong in the riveted joints as elsewhere Occasionally however one may find a frame which through long service has loosened up its joints and must be reriveted to make it sound This involves dismantling the entire car and taking the frame close to a forge as the riveting must be done hot to be secure Before riveting the holes should be reamed to make sure that they line up evenly and are the proper size for the rivets selected The frame members must be carefully cleaned after the old rivets have been cut out as dirt between the surfaces will spoil the tightness of the job.

TAKING UP PLAY IN SPARK AND THROTTLE CONNECTIONS

In few cars are the spark and throttle connections so carefully made that they don t work loose after the car has run a few thousand miles When that point is reached either the operator must depend on guess work and knack when running slowly or springs must be attached to take up the slack and exert constant pressure in one direction The latter expedient is simple and in most cases sufficient However a first-class job can be done at small expense by purchasing the ball jointed rod-ends manufactured for this purpose and sold to the trade These ends are usually made to screw over 3 16 inch rods or to screw into tubing of the same inside diameter being of the ball joint type they are flexible in any direction

OVERHAULING THE IGNITION SYSTEM

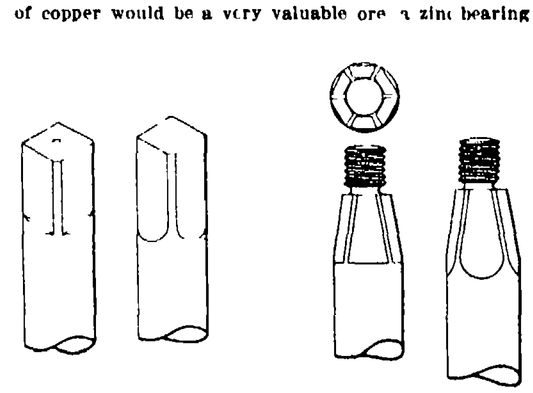
The winter is the proper time for making any changes which may be desired in the ignition system The number of reputable high tension magnetos at present available to the user is sufficient to afford little excuse for disappointment in this important item of equipment If the price of a high tension magneto is an obstacle the user can purchase at a reasonable figure a battery system of high-current economy and great reliability which produces a single spark for each ignition and requires only common dry cells as a source of current

The Outlook for the Future of Zinc Production

In making a forecast of the probable future development in the industries of the most important metals Prof J A Kemp takes up among others the case of zinc with regard to which he says

Zinc is a metal of comparatively late introduction into commerce in the large way Although known for centuries it has found its chief applications in the last sixty years There was no zinc mine in the United States until approximately the year 1860 and from the Missouri region whence we now obtain our chief supplies the really serious contributions began about 1870 Lead indeed was mined and prized long before this but the associated zinc ore was thrown one side on the dumps In the west the same experience continued until much later Zinc was a nuisance in the metallurgical treatment of lead and even the lead was sought and smelted either because of its own silver contents or because it made possible the treatment of other refractory silver ores In the metallurgical work the zinc was volatilized or slagged off and was lost Indeed one of our most serious metallurgical problems has been the successful treatment of lead zinc ores and many investigators have addressed themselves to its solution Now that anxiety is beginning to manifest itself regarding zinc supplies for the future the desire to save it is stronger than ever

Zinc however is a peculiar metal and because of the exigencies of its treatment its ores must possess greater richness and greater purity than those of other base metals Thus in the case of copper a ten per cent ore is in later days phenomenally rich and as it can be smelted in a shaft furnace the presence of iron or lime or other bases that make fusible slags is an advantage But zinc ores perhaps after preliminary roasting must be reduced and the metal must be volatilized at a high temperature from a small charge in a retort The presence of fusible bases destroys the retort and the bases are therefore debarred beyond certain small percentages Thus it happens that a forty or fifty per cent zinc ore might be valueless if contaminated by iron or lime beyond a narrow margin While almost any conceivable mineralogical aggregate that contained ten per cent of copper would be a very valuable ore a zinc bearing



BALANCED SQUARE AND HEXAGON ENDS OF SHAFTS

aggregate with four or five times as much zinc might be unsalable

In 1907 the United States was the chief producer of zinc among the nations but as a rule Germany leads followed by this country and Belgium in the order named In late years our output has varied from 26 to 30 per cent of the total As a rule Germany is 2 to 4 per cent in excess of us and Belgium is 4 to 5 per cent less

In America Missouri is the chief source of zinc Its production from the mines was in 1908 approximately one half the output of the entire United States New Jersey follows with somewhat over one quarter the total while all the rest are much smaller

The Missouri ores as thus far produced have been obtained from comparatively shallow depths They extend lengthwise and sometimes laterally to greater dimensions than vertically While it is not beyond the possibilities that lower lying deposits may be discovered since zinc ores are found in Arkansas in strata of lower geological position anticipations of this reserve have not as yet been demonstrated on a large scale

In New Jersey the future is best forecast of all For thirty or forty years there is no occasion of anxiety Yet thirty or forty years pass quickly and then we must prepare to look for other sources To make the zinc blende of the Rocky Mountain region available an increase in price is practically necessary otherwise the metal can not stand the freight charges There is zinc ore in the west but to what extent we cannot well say It has been avoided rather than sought in most of our mines Yet we do note symptoms of attention to it In Butte Montana efforts are being made to concentrate it Shipments of oxidized ores have been made from New Mexico for some years past Until recently large amounts of peculiar appearance seem to have been overlooked at Leadville Colorado They promise to be an important resource A government commission has reported upon the occurrence of the metal in British Columbia in the hopes of utilizing the ores From Mexico too, we learn of explorations for zinc Conditions are changing in the case of this metal.

and more and more of it is certain to be brought from remoter localities But when we look a long way ahead say for a century we cannot feel free from anxiety The condition of mind is even more prominent in Europe than in America. The waning of the famous old mines near Aix la Chappelle, and the apprehensions felt regarding other sources have lead to a world wide search Zinc ores for example now reach Hamburg from the Pacific shore of Siberia, and as other discoveries are made additional points remote from present smelting centers are likely to be shippers, provided that transportation is by water Nevertheless, all these new conditions call for advances in price, and before many years zinc bids fair to take the upward course

Modern Scientific Research*

Its Object and Methods

By Sir William A Tilden, F R S

Research is a word much used in newspapers and in public discussions nowadays but few people outside purely scientific circles have any clear idea as to its meaning Of course the dictionary tells us that it signifies a searching again or a careful search but the question then arises What is the object of the search and are there any rules to guide?

The object may be purely visionary as was the object of the early chemists and alchemists whose operations extending through the dark centuries of the Middle Ages left behind practically nothing but an extensive though barren literature the witness of the credulity and ignorance of those times The lesson to be derived from the whole of this strange history is one which needs to be continually revived and set in the new light of modern discovery and invention The lesson is simply that until men began to observe and interrogate nature for the sake of learning her ways and without concentrating their attention on the expectations of useful applications of such knowledge little or no progress was made In other words until a sufficient foundation of pure science has been successfully laid there can be no applied science Real progress comes from the pursuit of knowledge for its own sake

I say again this truth needs to be continually reiterated for there are still too many people who think that the true and only business of science is to find out useful things and who regard all the rest as waste of time

The first qualification for research is undoubtedly that kind of inspired curiosity which can never be eradicated and which we know by many examples is not defeated by such obstacles as poverty or ill health or pressure of other necessary occupations Another qualification is some knowledge of the subject chosen for inquiry As to this latter qualification considerable differences of opinion have been expressed Priestley whose statue stands near the Town Hall in Birmingham and many of the chemists of his time had very little preparatory instruction but some of them made discoveries of fundamental importance Priestley seems to have been of opinion that very little preparation is necessary and the discoveries which might result from experiment were regarded by him as largely the result of chance and to be compared with the game which might fall to the gun of a sportsman in a new country and whether fur or feather cannot be foretold But though this might have been partly true in Priestley's time it is certainly very far from true in our day when the accumulation of knowledge however imperfect is still immense

Every great discovery is the culmination of a long series of discoveries each of which is a necessary step and ignorance of these preliminaries stands in the way of advance

It will be worth while to examine a few cases by way of illustration No better example can be found than the establishment of the great principle in chemistry commonly called the periodic law According to this law the properties of the elements and of their compounds stand in a definite relation to their atomic weights

Modern views concerning the constitution of gases afford another illustration of the way in which the possession of one kind of knowledge leads to more knowledge Forty years ago students were led to believe that there were two kinds of gases namely on the one hand those which by the action of cold or pressure or both together could be liquefied and on the other hand some half dozen which could not be reduced to the liquid state This was attributed to some fundamental difference of constitution in the two kinds of gas

If we look for an example drawn from the domain of biology there is the doctrine of evolution now universally accepted which is based on the results of the patient collection of facts by Darwin and Wallace But those facts would perhaps not have been collected and they would certainly have been without meaning but for the results of the study of comparative anatomy by previous generations of naturalists and palæontologists as well as the recognition of the great doctrine of uniformitarianism in geology proclaimed and established by Lyell

The examples cited will not appeal to the practical man in the same way as some instance taken from a direct application of science to business or practical affairs If it is really necessary to consider a case of that sort nothing could be better than the *dynamo* which as a transformer of energy comes into prominent daily use in connection with lighting traction and as a general motive agent The detailed history of the evolution of the dynamo would be a long story and on this occasion it is only necessary to point out one or two facts For the fundamental principles involved we must go back to Benjamin Franklin and Galvani and Volta, all in the eighteenth century and later to 1831 when Faraday discovered the generation of induced currents by moving a conductor in a magnetic field But doubtless the experiments made by Franklin with the kite by Galvani on frogs legs and by Volta and Faraday with bits of wire were by the people of their day looked upon with a mixture of amusement and contempt just as some people even at the present time are apt to exclaim Who cares whether there is oxygen in the sun?

It is obvious then that whatever may have been possible in Priestley's time the wholly unrestricted person cannot expect to meet with much success in these days in the discovery of new facts and although the exceptional man may acquire in a very short time some knowledge of a special part of a subject he is in perpetual danger of falling into great mistakes It seems to me that a considerable amount of knowledge skill and experience is an indispensable equipment for anyone who enters seriously into the practice of scientific research Not that these qualifications alone serve as inducements to such a career for it would be quite easy to point to examples of learned people who have added nothing new to the branch of knowledge with which they are best acquainted This is not necessarily due to indolence nor to ignorance of the methods of research but is merely the result of peculiarity of temperament which lacks that divine curiosity which alone supplies the stimulus

I am speaking now only of real scientific research the inquiry into the secrets of nature not of the occupation of those who have only practical ends in view

Looking back over the great principles of natural science we see that in every case they have been established by the efforts of the amateur and by amateur I mean all who have undertaken the work for the pure love of it This includes not only men of independent position like Cavendish Lyell and Darwin but a large number of men who have held the office of professor or teacher but who in this country at any rate are neither paid to do such work nor required by the conditions of their appointments to undertake it So far as I know there is but one institution in this country in which the professors are not required to teach but only to press forward into the unknown and that is the Royal Institution in London But the character which that famous place has assumed during the last hundred years is not that with which it began its career It was started at the end of the eighteenth century by Count Rumford with purely utilitarian purposes in view namely for teaching the applications of new discoveries in science to the improvement of arts and manufactures and to facilitating the means of procuring the comforts and conveniences of life and while retaining that character and those pretensions it soon came to the verge of collapse But Davy's lectures and discoveries changed all that and Faraday's genius consecrated the laboratories for all time to the service of pure science

Let us review very briefly the great principles on which physical science is based

First of course there are the fundamental principles of the conservation of matter and of energy the latter finally established on a quantitative basis by Joule in 1843 There is the principle of uniformitarianism introduced into geology by Lyell now extended so as to include not only the phenomena of this earth but of the whole cosmos such extension being mainly due to the use of the spectroscope by Kirschoff and Bunsen and only a little later by Huggins The principle embodied in the so-called periodic law of the elements already referred to has led to a general belief in the evolution of matter from one primary material and physicists and chemists are vying with each other in the endeavor to gain evidence as to the details of the process I need scarcely say that the principle of evolution as applied to living beings is associated indissolubly with the names of Darwin and Wallace

Notwithstanding the discovery of radium and its allies and the discoveries by J J Thomson as to the disintegration of atoms into corpuscles a thousand or more times smaller all ordinary chemistry is built up on the conception of atoms introduced by John Dalton just a hundred years ago The consolidation of this theory has proceeded as a consequence of the discoveries begun in 1872 by Wislicenus developed by van t Hoff and Le Bel in 1874 and confirmed by an army of other workers down to the present day We now not only suppose it probable that atoms are placed within a molecule in definite positions relatively to one another but in a great many cases their order and arrangement in space can be positively traced

Suppose all these great laws and principles never to have been discovered—science and its applications would not exist and the world would have remained in about the same condition as it was in two hundred years ago Railways electric light and traction telegraphs dyes explosives antiseptics anæsthetics and many other drugs metals such as sodium aluminium magnesium tantalum and even modern steel would be unknown

But these things are merely the results of the recognition development and application of the principles already indicated as fundamental and the immediate corollaries from them And so it seems that there are two fields for research which are equally necessary to civilization and progress In the one the worker watches the operations of nature and puts questions in the form of experiments solely with the desire to find out her ways in the other attention is given only to those laws facts and phenomena which can be made serviceable to man There is much more public anxiety in regard to the last and considering how entirely ignorant are most people about the principles of physical and natural science this is not greatly to be wondered at

Some people are under the impression that there is an art of scientific discovery which can be communicated from one person to another That is not my belief I think the history of scientific discovery shows that each successful pioneer has invented methods for himself or has at least known how to select from the tools ready to his hand And with regard to personal qualifications I do not think it possible to create that combination of mental powers which is called insight Hence I have very grave doubts about the advisability of spending time and energy in trying to evoke and cultivate the capacity for research in all students in colleges and universities If this were possible we ought to see greater results in those cases in which it has already been tried The judicious teacher will of course be careful to avoid any appearance of indifference toward ardor and enthusiasm whenever they appear and he should ever be on the lookout for indications of the kind of capacity which alone repays cultivation and give it all the encouragement in his power But the clamor which has of late been raised as to the supposed desirability of extending instruction in the principles and methods of research, down to the very beginners, indicates to my mind a lack of judgment on the part of some of the agitators It seems to be forgotten that in every branch of experimental science and especially of applied science there is a great deal to learn and it is necessary that at the end of his career as a student a young man should be able to *do* things practically and usefully The theory of music and the laws of harmony are very desirable for the musician but if he is to be a performer he must devote the greater part of his time to practice on his instrument, whether piano or violin The case of the student of science is analogous and if he does not devote a good deal of time to learning the technic of his business he will not be ready for research or anything else At the present time too many students who can write at length on theoretical questions of a most recondite character and who boast that they have been engaged in research under eminent teachers, are yet incapable of choosing a subject for

* Presidential address delivered to the Vesey Club Sutton Coldfield England

themselves or of handling successfully a subject found for them by their teachers or someone else.

With the object of testing the influence exercised by methods of education in science on the development of the faculty of research I have lately had the curiosity to compare the results indicated by the lists of doctors of science of the University of London Up to 1886 this degree was awarded on the results of a very severe examination From 1887 onwards it has been obtainable only on the production of a thesis supposed to embody the ideas and the work of the candidate on some subject selected by himself The examiners are at liberty to impose an examination with the object of assuring themselves of the candidate s knowledge of his subject but as a matter of practice the examination has been reduced to a mere formality It was expected that this change of system would be followed by indications of much greater fertility in the fields of research Owing to the completeness with which chemical literature is indexed I have been able to make a comparison between the number and character of original papers published by the chemists in these two lists within the ten years following graduation in each case I have not been able to make so strict a comparison among the physicists owing to the distribution of their work through so many media of publication but I have been led by a careful survey to the same conclusions as in the case of chemists In both classes the *Examinees* and the *Researchers* if they may be so distinguished there are cases in which the doctor after taking his degree has done no original work—or at any rate none that was fit for publication—and his name does not appear in the literature of his science On the other hand both lists contain famous names I will only mention in passing that the names of Larmor and Lodge appear among the examined On the whole I see no indications that the procedure by thesis has had any effect whatever on the character of the graduates If anything the list of examined is of somewhat higher quality than the list of graduates by dissertation for there are nine out of fifty four who have become Fellows of the Royal Society while among the others there are only eight out of fifty nine who can write themselves F R S

In the latter list there may be one or two who may achieve this distinction hereafter but there are no indications that in the long run the amount and quality of the contributions made to science by the graduates who are supposed to have been trained to research will surpass those of the men who had to face the ordeal of examination

Does this not seem to justify my original contention that the researcher is born not a product of educational manufacture and that his disposition to research will survive all sorts of adverse conditions including those which are by some people supposed to be inherent in examination?

I feel convinced that most of the great discoveries of the future will be made as in the past by the inspired amateur working usually alone and often on apparently insignificant beginnings and with results which may not at first receive any attention from the world

It is however necessary in these days to provide for some form of co-operation in research partly for the reason that the cost of some kinds of investigation is quite beyond the means of most private persons and partly because of the unfortunate separation which still prevails chiefly in this country between science and industry

First then science may justly look for assistance from the State In England this is given in a grudging way Parliament allots £4 000 to the whole range of the physical and natural sciences The fund is administered by the Royal Society and the biggest slices out of it are taken in the form of contributions to the expenses of expeditions Then there is the National Physical Laboratory with an expenditure of about £25 000 a year of which £7 000 comes from the treasury This seems to be all that comes directly from the National purse but science is endowed to a certain extent by her friends This assistance is represented by the equipment of certain schools and colleges by the Guilds of London and by the small research funds of the Chemical Society and the British Association

Something more systematic is however wanted and I feel strongly that some of the rather large funds given in the form of scholarships to young students could be more advantageously used if applied to the maintenance of proved investigators to make them independent of the necessity to earn a living by teaching or other professional work I recognize however, the difficulties which would attend any such scheme In the first place discoveries cannot be made to order An able industrious, and conscientious man might work for many years without producing definite results and a few cases of that kind would destroy or shake public confidence. It would also be necessary to provide incomes large enough to retain the services of the most able men

With regard to the application of science to industry I think our manufacturers have made some progress during the last thirty years But they still suffer from delusions The mistake most commonly made arises out of a misapprehension of the methods powers and promises of science It still seems to be too often supposed that a scientific man called into hurried consultation can at once overcome a difficulty in a manufacturing process or can devise an improvement which if adopted would represent many thousands of pounds profit to someone If this were so scientific men would be better off than they usually are What is wanted is a general recognition of the principle that improvements can be expected only as the result of the use of scientific methods which are simply the methods of reason applied to the materials provided by experience

What every manufacturer wants is to begin with a scientific education if not for himself then for his sons or successors so that those who are at the head of affairs may understand fully the problems before them and in what direction to look for help towards improvement Failing this he will be dependent on the services of paid assistants and those services cannot be expected to produce the desired results unless they are paid for on a liberal scale In this country there has not hitherto been sufficient attraction to draw into the field of technology a due share of the best brains of the nation The prospect of ultimately reaching a salary of two or three hundred a year at the utmost is not sufficient to induce a young man of first rate ability to spend several years of his life and a thousand pounds or so of capital in scientific and technical studies and so the supply of the highest class of scientific assistance is at present far from what it ought to be

But suppose conditions to improve a question arises as to the best way of turning such assistance to account

A suggestion has lately been made that a new society should be formed to be constituted of trade committees associated with experts in various divisions of science to carry on experiments confidently in the interests of the manufacturers who become members of the society It seems to me that any suggestion is better than none if it results in the closer association of industry and science but I think this particular proposal would not be found to work in practice The requirements of different industries are too numerous and complicated to be met by an arrangement so simple for each committee would find itself occupied with so many different problems that nothing would be accomplished unless indeed the staff were very large In my judgment each manufacturer must endeavor to work out his own salvation Moreover the experience of the German manufacturer and to some extent also of the American shows that it can be done effectively The most famous example known to me is the case of the great Badische color works at Ludwigshafen on the Rhine There is a factory which employs some 5 000 men and which pays and has always paid 25 to 30 per cent or more on its ordinary capital The great feature of its organization is to be seen in the direct association of manufacture with research conducted by a staff of highly skilled scientific men

In England arrangements so complete are unknown and the number of highly qualified chemists and physicists employed in works 's very small I say nothing about engineers with whom I am not so well acquainted but the greater number of the chemists are merely testers doing routine work and because such men receiving the wages of a clerk have not been able to advance the industries with which they are connected their employers have in too many cases in the past come to the conclusion that science is of no use In the meantime many things have happened The neglect of organic chemistry in England forty years ago led to the complete removal of the coal tar dye industry to Germany where since that time has sprung up the equally important manufacture of synthetic drugs The saccharin the antipyrin the artificial perfumes consumed in England are not made here and it now looks as if the fixation of atmospheric nitrogen in the form of nitrate so important from the agricultural and industrial points of view was going to be taken possession of by Germany and America acting together England being left out

Such things have been said over and over again for the last thirty years or more and I am not aware that such statements have been shown to be fundamentally mistaken nor has there ever been any public explanation of the indifference displayed

The link between science and industry must be established by the masters of industry themselves I do not believe in the efficacy of much of the technical instruction which is talked about and I fear that much money is being wasted in the attempt to imitate industrial operations in schools and colleges What is wanted is the highest and most complete kind of instruction in pure science following a good general education conducted on such lines that the fittest only are passed forward to the university or scientific school Young people educated in this way form the material which should be utilized by the manufacturer But he must not expect that a man so prepared is going to earn his salary the first year or two He has got to learn his business and must have facilities for doing this or such talent as he has cannot be turned to account and this can only be done by taking him into the works This is a subject on which a great deal might and should be said but such a discussion is not suited to the present occasion

In conclusion I may perhaps be allowed to give a few minutes to a glance at the future—not that I can pretend to descry very much

We must remember that there is no finality in physical science The farther we go the wider does the horizon before us become but every discovery of a new fact or principle gives us a new instrument to help on to higher things Hence we may reasonably suppose that wonderful as the past has been the future will be more wonderful still

Here I will venture to draw a distinction between invention and discovery and to invention there is probably no limit It may be said to consist in making new combinations and permutations in the elements of knowledge already acquired Among the inventions which have affected the condition of man kind those which are concerned in locomotion stand first It may truly be said that life is lengthened not only by years but by opportunities and from this point of view quick traveling provided by steam and electricity is a great advantage It would be unwise to utter any predictions as to what may hereafter be done with big ships and aeroplanes only the old fashioned type of nervous system—already shrinking from the increased noise and bustle of the town —shudders at the thought that neither distant valley nor mountain top from the tropic to the pole can now be expected to provide an asylum where peace secure from intrusion is to be found

In Samuel Butler s Erewhon a remarkable book published about forty years ago a country was pictured in which moral delinquency was treated with sympathy and condolence while bodily disease of all kinds was held to be a crime and was punished by fine or imprisonment I suppose it will take a good many generations to reach that condition of enlightenment but the time cannot be far off when the propagation of infectious disease will in all civilized countries be abolished

The habitability of the planet Mars has of late been a subject of much revived discussion The possibility or probability of the existence of intelligent beings in other parts of the universe long a subject of debate is a question of profound interest but whether communication with them from the earth can ever be established who can tell?

But as to discovery in physical science as already said the horizon widens as we go on but it seems not improbable that there is a limit set though as yet very far off by the capacity of the human intellect Nature s ways used to be thought simple but now we know that she is not only mysterious but complex However there is every reason to expect that great strides are possible even in the immediate future The sort of problems which remain to be solved are represented by such questions as the following What is the cause and nature of gravitation and other sorts of attraction? What is the difference between positive and negative electricity and what is the relation of electricity to matter? What is the nature of chemical affinity and is it really electrical? What is the constitution of the elements and is the transmutation of metals a dream or a physical possibility?

The penetration into final causes seems as we proceed to be further and further out of our reach The problems of life and mind are up to the present inaccessible to man in his present state and notwithstanding the hopes and beliefs of some physiologists it is safe to say that they will remain so for a long time to come if not always

And even in regard to common matter and the physical forces all we know about them is derived from the perception of phenomena through the agency of our senses Now the senses sight hearing and the rest have been evolved not to provide the means of surveying nature but for the protection and advantage of the body to which they belong It is possible therefore that the human view of phenomena is only a partial and imperfect view at any rate the world which is open to the sense perception of a man must be very different from that which is perceived by many animals with their highly specialized senses such as the scent of the dog the sight of the carrier pigeon and perhaps other senses for which we have no name

In its ultimate nature said Herbert Spencer matter is as absolutely incomprehensible as space and time Whatever supposition we frame leaves us nothing but a choice between opposite absurdities.

The World's Daily Weather Maps

Systems Used in Various Countries

If you should wish to know just what the weather was doing on a particular morning at a particular spot on the land surface of the globe the chances are about two in five that you could satisfy your curiosity by visiting a meteorological library and consulting its files of daily weather maps

The accompanying diagram (Fig 1) shows approximately the area of the earth s surface that these maps now cover Nearly every civilized country including the larger European colonies now publishes at least one daily weather map based on telegraphic reports A few countries publish several maps i e maps are issued at several points within their respective territories Thus (including maps published in the daily newspapers) the United States Weather Bureau issues daily maps at about one hundred places in this country Germany publishes about twenty maps the most important of which is that issued at the Deutsche Seewarte in Hamburg India publishes three maps Most countries however issue a map at one place only viz the headquarters of the national weather service

The area represented by the map is not in most cases limited to a single country This is notably true in the case of the European maps the majority of which cover the whole of Europe The Egyptian map includes stations in Italy Greece Tripoli etc The maps of the United States Weather Bureau overlap with those of Canada

In point of workmanship the lithographic map published daily at Washington stands unrivaled while the handsome maps issued by Japan and Argentina compete for second place It would be invidious to specify the publications standing at the other end of the scale Suffice it to say that several extremely crude productions of this sort are issued abroad but in these cases the wonder is that they are issued at all considering the very meager funds and limited staffs the meteorological services in question have at their command

Besides the maps based on telegraphic reports and issued a few hours after the observations that they collate are taken there are several highly interesting synoptic maps the data for which are collected by a slower method and which generally appear months or even years after the date to which they refer The most notable publication of this character was a daily chart of the Northern Hemisphere published from 1877 to 1887 by the United States Signal Service —the predecessor of the Weather Bureau Several series of maps have been published for the North Atlantic Ocean and the adjacent continental areas

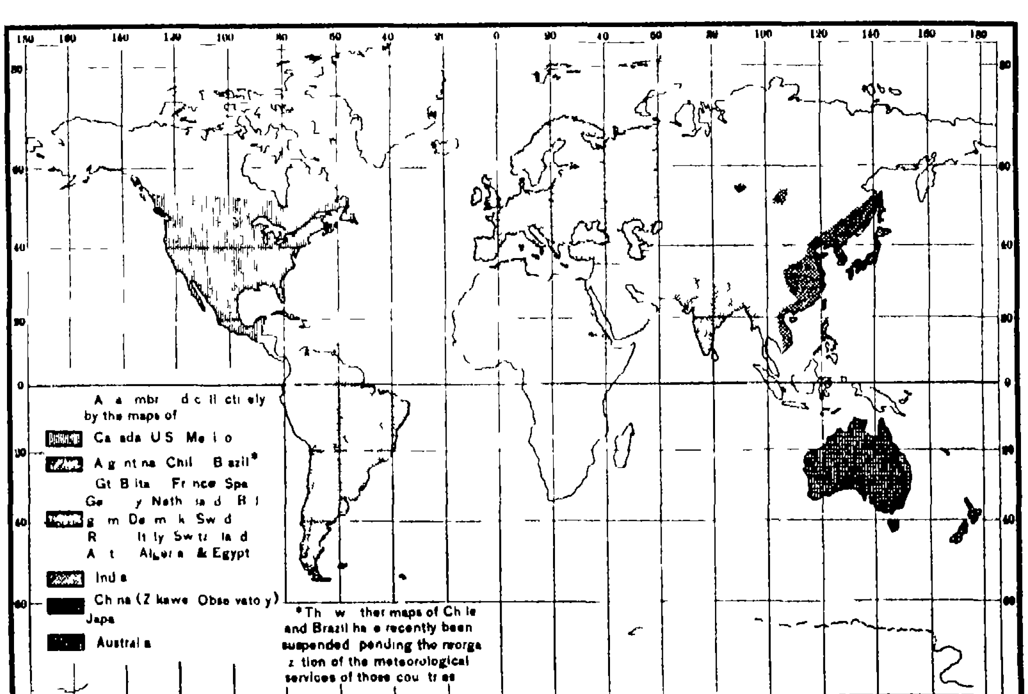


FIG 1—LAND AREAS EMBRACED IN THE DAILY WEATHER MAPS OF THE WORLD

Within a few hours after the time of observation weather maps based on telegraphic reports are published for the regions indicated by the shaded areas.

and two of these still appear viz the Cartes Synoptiques Journalières begun by Hoffmeyer in 1873, and now issued jointly by the Deutsche Seewarte and the Danish Meteorological Institute and the Internationaler Dekadenbericht published by the Deutsche Seewarte These maps of the ocean are based on the meteorological logs of vessels as well as the reports of land stations A specimen map from the Dekadenbericht is shown in Fig 2 This publication presents a somewhat sketchy picture of the weather over a wide area of land and water and appears with remarkable promptitude i e only a few weeks after the period to which it refers

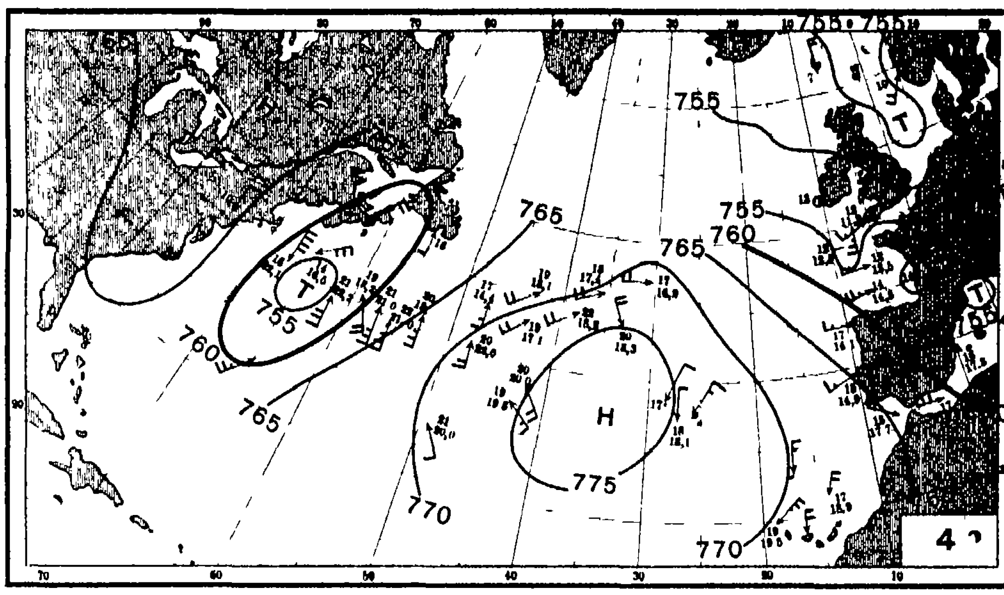

FIG 2—WEATHER MAP OF JUNE 4th 1910 8 A M

The point of the arrow shows where the observation was taken The arrow flies with the wind The tails of the arrow show the force of the wind on the half Beaufort scale The air temperature is shown in whole degrees (Centigrade) water temperature to tenths of a degree The curved lines are isobars or lines of equal barometric pressure Areas of high pressure are marked H (*hoch*) of low pressure T (*tief*) (From the Internationaler Dekadenbericht.)

The ordinary daily weather maps although primarily devoted to the weather prevailing over the land tend to spread out more and more over the adjacent oceans This expansion is made possible by the utilization of reports from islands—such as Iceland and the Azores—and to a limited extent of wireless reports from ships Observations of the latter class (i e wireless reports) are regularly shown on the English daily weather map but it must be admitted do not as yet add much to the value of the publication

In contrast to the European maps those published in the United States are based on strictly simultaneous observations They show the weather prevailing all over the country at 8 a. m Eastern Time In Europe the telegraphic observations are made partly on standard time and partly on local time and the hour of observation thus fails to coincide by two hours and more in extreme cases. However, in Western Europe including the British Isles the observations are nearly synchronous.

The problem of collecting the observations promptly enough for use on the charts, and in forecasting, has been a difficult one in all countries. It is solved most successfully in the United States, where the Weather Bureau is given priority by the telegraph companies at the time its reports are being despatched, and where the process is further facilitated by the use of an ingenious circuit system i e., the observations are assembled at a few points and at the same time are copied off at each station on a circuit as they pass over the wire this means a wonderfully rapid interchange of observations among the stations and enables the Bureau to publish its map simultaneously at many points throughout the United States In Europe national boundary lines—and the indisposition of the authorities in charge of the telegraph systems which are generally operated by the government to give special consideration to meteorological business—are serious obstacles to rapid transmission. In all countries the reports are sent in cipher A uniform code is used for this purpose in Europe

The history of daily telegraphic weather maps extends back about sixty years A few tentative undertakings of this kind were carried out both in Europe and America about 1850 but the first map that was destined to be a permanent enterprise was the French Bulletin Internationale" begun by Leverrier in 1863 and this has continued without interruption to the present day The continuous series of United States weather maps began with Professor Abbe s maps issued at Cincinnati in 1870 and soon after taken over by the Signal Service in Washington

The first published daily weather maps of the British Meteorological Office began in 1872

Proposed Department or Bureau of Public Health

The Secretary of Agriculture while in hearty accord with the general proposition to provide better facilities for work in the interest of the public health expresses himself as opposed to any plan which will remove from the Department of Agriculture the inspection work involved in the enforcement of the food and drugs act and the meat-inspection law to say nothing of certain plans which would take away the biological and entomological work of the Department. To remove from the Department of Agriculture the meat inspection and veterinary work, says the Secretary, 'would I believe be a great detriment to the work of this department and to the agricultural and live stock interests, without any corresponding gain in efficiency or advantage to the public, and would result in increased expenditures rather than in economy For example, the field work for the eradication of diseases of animals is carried on mostly during the summer, while the work of slaughterhouses is heaviest during the winter, and it is thus found to be practicable and economical to shift men from one to another of these branches as the needs of the service require.' The Secretary thinks it would be an expensive mistake to take away from the Department of Agriculture work which it is performing satisfactorily, and which it can perform better and more economically than any other agency

New Physical Apparatus*

Simple Instruments for the Laboratory

A VACUUM TUBE OSCILLOSCOPE.

Gehrke has shown that in a vacuum tube containing nitrogen the negative glow occupies a space exactly proportional to the strength of the electric current which produces it. Desselhorst has found that this luminosity is practically instantaneous, its beginning and ending coinciding exactly with the closing and opening of the circuit. The Berlin firm of Boas has constructed a vacuum tube oscilloscope which is very well adapted for the observation of the phenomena of currents of high frequency. The arrangement of apparatus is indicated in the first diagram (Fig 1). *A* represents the primary oscillatory circuit, in which the capacity is furnished by the Leyden jar C_1 and the self induction by the interchangeable coil P_1. A sparking coil can be bridged over the gap *F*. The secondary circuit shown at *B*, contains a variable capacity C_2 and an interchangeable inductance coil P_2. The secondary circuit is influenced more or less powerfully by the primary circuit, according to the distance between the coils P_1 and P_2. The character of the oscillation in either circuit can be studied by means

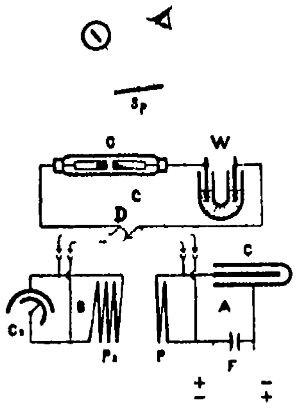

Fig 1

of the apparatus *C* which contains the vacuum tube *G* and which is bridged across either of the coils *P* and P_2 by means of the high tension commutator *D*. A water resistance *W* is connected in series with the vacuum tube in order to reduce the consumption of current. The tube *G* is observed by means of a two faced mirror *Sp* which is rotated by an electric motor at a speed which may attain 7 800 revolutions per minute. The observer sees in the rotating mirror two undulating lines of light the form of which correspond exactly to the momentary periodicity and general character of the electric current.

THE THEORY OF GRATING INVERSION

It appears from the experiments of Hertz that a grating formed of parallel wires is most transparent for electromagnetic waves when it is in the position shown at *A* in the second diagram (Fig 2) with the wires perpendicular to the electrical vector *E* of the waves, and parallel to the magnetic vector *M*. This phenomenon is known as the Hertz effect.

On the other hand the researches of Du Bois and Rubens appears to prove that a fine wire grating is most transparent for very short waves that is the waves of the visible spectrum when it is in the position *B* with the wires parallel to the electric and perpendicular to the magnetic vector. This phenomenon is called the Du Bois effect.

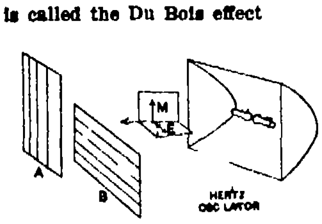

Fig 2

The wave length at which the Du Bois effect is replaced by the Hertz effect is called the point of inversion and is determined chiefly according to Du Bois, by the material of which the grating is composed. The results obtained by Du Bois however, are partly contradicted by the experiments of Braun who pulverized platinum wires on glass thus producing as he claimed exceedingly fine gratings which in all cases showed a well marked Hertz effect.

Schaefer and Reiche have published, in a recent number of the *Annalen der Physik*, the results of a theoretical investigation which indicate that Braun's observations were probably correct and that the Hertz effect is always produced when the diameter of the wires of the grating is small in comparison with the wave length. Hence it is desirable to repeat and extend the experiments of Du Bois and Rubens.

* Prometheus.

HIGH VOLTAGE INDICATOR

A simple method of determining whether a wire carries a current of high voltage or not consists in connecting the wire to earth through a Geissler tube in the manner indicated in Fig 3. The presence of a

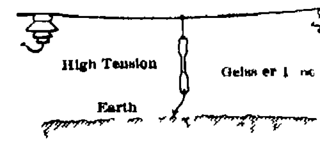

Fig 3

high voltage current is immediately indicated by the glowing of the rarefied gas in the tube. Owing to the high resistance of the vacuum tube no earth worth speaking of is produced by this method. A recent number of the *Elektrotechnische Zeitschrift* describes an indicator based on this principle and intended for stationary use. Fig 4 shows the indicator which is operated by turning up the handle *A* and thus placing the portion *B* which contains the Geissler tube in connection with the terminal *D* which is connected with the high tension circuit. The tube is observed through a little window at *C*. The axis of the movable arm and consequently the other end of the tube are connected with the earth. Fig 5 shows a similar apparatus devised for permanent use in which the tube is attached to the other parts by spring clamps.

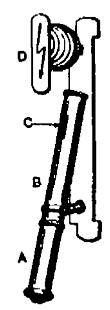

Fig 4

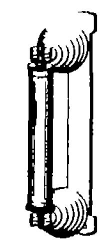

Fig 5

THE ROTAMETER

The accurate measurement of the velocity of flow of gases offers great difficulty in many experimental researches. A novel instrument for measuring this velocity has lately appeared in the market. The left hand (Fig 6) illustrates the principle of the apparatus which is called the rotameter. The gas flows upward through a slightly tapering glass tube *a*. The supply pipe is provided with a stop cock *c* and a cotton wool filter inclosed in a capsule *b*. The ascending stream of gas lifts a hollow indicator *e* to a height which varies with the velocity of the current and at the same time sets the indicator into rapid rotation about its vertical axis whence the name rotameter. The rotation prevents adhesion of the indicator to the wall of the tube. The flow in liters per second is given directly and very accurately by the portion of the indicator in respect to a scale etched on the glass tube. The scale is graduated empirically and a different scale is required for each gas.

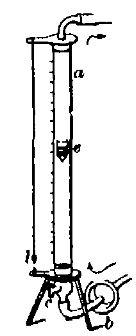

Fig 6

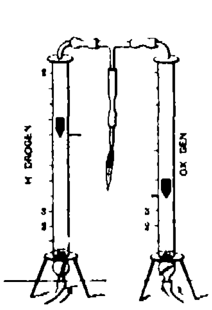

Fig 7

Two or more gases can be mixed in any desired proportions, easily and accurately with the aid of a corresponding number of rotameters. For example hydrogen and oxygen can be mixed in the proportions required to form water by joining the outlet pipes of two rotameters, the inlet pipes of which are connected with cylinders of compressed hydrogen and oxygen respectively and adjusting the stop cocks until the whirling indicators show that the flow of hydrogen is double that of oxygen. This arrangement of apparatus is illustrated by Fig 7.

THE KERR EFFECT IN GLASS

In 1875 Kerr discovered that double refraction is exhibited by dielectrics subjected by electric stress. The meaning of this statement is illustrated by the accompanying (Fig 8). A horizontal glass tube *a* the ends of which are closed by plane sheets of glass is filled with a transparent non-conducting liquid (carbon disulphide for example) in which two horizontal plates of metal *b* and *c* are immersed. By connecting these plates with the poles of an electric influence machine *d* or a galvanic battery of high electromotive force an electric field is created between the plates the lines of force running vertically in the direction of the arrows. In these conditions polarized light which traverses the tube lengthwise is found to move with different velocities according to the direction of the plane of polarization. In carbon disulphide for example light which is polarized in a vertical plane parallel to the lines of force travels more rapidly than light polarized in a horizontal plane. (The electric oscillations of light waves are perpendicular to the plane of polarization and are therefore horizontal

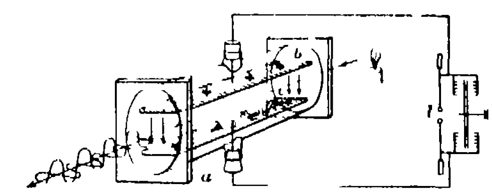

Fig 8

in the first case and vertical in the second.) As the index of refraction of a substance is the ratio of the velocity of light in that substance to the velocity of light in air we have here two indices of refraction and hence the phenomenon is called electric double refraction. The difference between the indices of refraction of light polarized respectively parallel and perpendicular to the lines of force when the fall of potential is one volt per centimeter is called the Kerr constant. The Kerr constant for carbon disulphide was measured in 1883 by Prof Quincke who obtained the value 32×10^{8}. A slightly different value 30.42×10^{8} has been found recently by Dr Tauern. An accurate knowledge of the Kerr constant is valuable as it enables high electrostatic potential differences to be measured by an optical method. Tauern's experiments have also confirmed the correctness of Kerr's observation of double refraction in glass subject to uniform electric stress. The value of the Kerr constant increases with the proportion of lead in the glass.

ELECTROMETER WITH VARIABLE RANGE AND SENSITIVENESS

Measurements with the galvanometer are made much more convenient by the possibility of diminishing the sensitiveness of the instrument ten fold one-hundredfold or one-thousandfold by the use of parallel circuits or shunts having resistances equal respectively to 1/9 1/99 or 1/999 the resistance of the galvanometer. Fig 10 shows how any given current

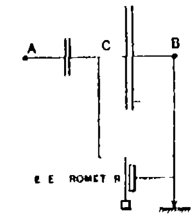

Fig 9

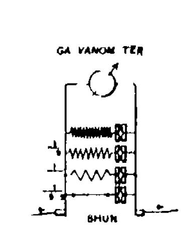

Fig 10

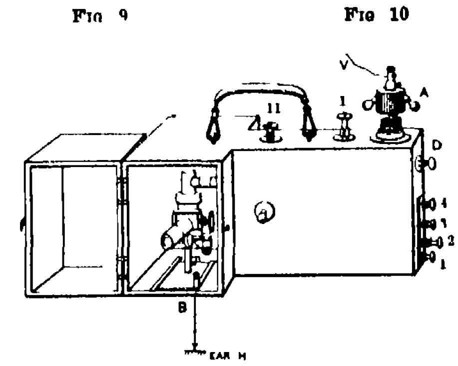

Fig 11

strength can thus be measured by means of a single galvanometer and a series of shunts

The need of a similar method of varying the sensitiveness of the electrometer is obvious Dieckmann has devised a portable inclosed electrometer which can be used with twenty one different grades of sensitiveness for measuring potentials from two volts to twenty five thousand volts (Fig 11) The principle of the apparatus is illustrated by the diagram (Fig 9) Let us suppose that it is required to measure the difference of potential between the points A and B Between these points two well insulating condensers free from residual charge are inserted in series The wire C connecting these two condensers possesses a potential which approximates more closely to that of the earth the greater the capacity of the condenser inserted between this wire and the earth, or the point B, compared with the capacity of the condenser between C and A Between the wire C and the earth is inserted the electrometer the capacity of the instrument itself being added to that of the condenser between C and B in estimating the degree of sensitiveness

Fig 11 shows a Lutz chord electrometer with microscope reading on the left and the above described potential reducer on the right The object whose potential V is to be measured is connected with the terminal A By means of the buttons I and II various condensers corresponding to that between A and C in Fig 9 can be inserted while the buttons 1 2 3 4 control the insertion of a number of other condensers, corresponding to that between C and B in Fig. 9 D is a button by means of which all parts of the interior of the apparatus with the exception of the terminal A can be simultaneously connected with the earth By drawing out the buttons in various combinations a great variety of grades of sensitiveness can be produced The condensers are all of cylindrical form and contain no dielectric except air As the Lutz electrometer does not require to be protected absolutely from vibration this apparatus can be used everywhere, even on overland journeys and on board ship, for the measurement of differences of potential ranging from two volts to twenty five thousand volts to within less than one per cent.

Illuminating Engineering*

Its Value to the Commercial Man

By William T Serrill

The writer has heard the opinion expressed that illuminating engineering is an abstruse technical science with only an indirect or remote bearing on practical questions and consequently that the commercial man of the electrical or gas interests can derive little of benefit from the study of this science or from attendance at the meetings of the Illuminating Engineering Society The object of this paper is to show that the opinion here described is erroneous

For the present purpose the subject may be divided into three classes namely First the design and development of lighting units secondly the determination of the light distribution and of other characteristics of the available units and thirdly the application of the available units to the spaces to be lighted as determined by the illumination requirements

It is evident that the commercial man is dependent upon the illuminating engineer for the design and development of the electric and gas lamps which he has available to offer to the public The physical and chemical principles underlying both of these forms of illuminants are abstruse and each has reached its present efficient form through invention and research on the part of scientific men The commercial man may well say It is not necessary for me to master these scientific principles I accept with thanks and put on the market the latest products of such invention if I am free to criticise and to state what my experience as a salesman indicates is required by the public and if the engineers meet these requirements I am satisfied

It may be admitted that the commercial man need not master the principles underlying the design of lighting units but the statement just put into his mouth shows how essential is a constant co-operation and exchange of opinion between the commercial man and the laboratory man The latter is to a large extent dependent upon the former for a knowledge of the public taste and of the extent to which the public purse will be opened to its gratification In addition the commercial man will understand the requirements demanded by the various kinds of buildings and of occupations as affecting such points as the size of the unit the distribution of light from it its color its daylight appearance etc The association together of these two classes of men at the sectional annual meetings of this society cannot fail to be of benefit to the art of illumination If on this point it may seem to the commercial man that he imparts more than he receives he should realize that it is in a good cause and will result in the production of more efficient units better adapted to the requirements of the consuming public

It is evident that the commercial man having at his command an assortment of lighting units in his effort to sell them must be possessed with a thorough knowledge of the salient characteristics of each of the units For this knowledge he is dependent upon the illuminating engineer The illuminating engineering laboratory with which the writer is connected has furnished or is now engaged in preparing information regarding the gas lamps that are being sold as follows

Light distribution curves of lamps and globes luminous efficiencies of lamps globes and mantles minimum distance from the ceiling it is safe to hang the lamps safe distance under awnings for outdoor lamps windproof qualities of outdoor lamps relative emission of radiant heat from gas and electric lamps relative intrinsic brilliancy of lamps fitted with assorted glassware proper heights of lamps of various types suitable for various purposes reflective efficiencies at various angles of various lights with standard wall papers absorption coefficients of glassware ignition devices color values of the light from various lamps strength of mantles adaptability of lamps to various gases and pressures loss of efficiency during service of lamps and mantles examination of lamp structure and suggestions for remedy of structural defects

Knowledge of the kind indicated in the above list is essential to the commercial man in his effort to sell and to meet the competition of other forms of illuminants Here there is reached another point which emphasizes the importance of the commercial man attending the metings of the Illuminating Engineering Society At the meetings he learns how to interpret and utilize the data furnished by the laboratories The subjects contained in the above list are of the sort that are considered and discussed at the meetings Any salesman listening to and taking part in the discussions thereby improves his efficiency by increasing his knowledge of the thing he sells

Having considered the laboratory end of illuminating engineering and having shown the value to the commercial man of his participation in the discussion of subjects connected with that branch it is well now to approach the third division that of applied illuminating engineering

In considering this subject one is met at the outset by the startling fact that the application of lighting units to interiors is and from the nature of conditions must be made by the commercial man In any city the electric light company and the gas company through their canvassing departments handle such work There is to be sure the consulting illuminating engineer who may plan a fraction of it but it remains true that the great bulk of lighting installation work is carried on by the gas and electric interests In the stress of competition these interests actively canvass and thus secure the work

Now canvassing for light is like other canvassing essentially commercial work It is organized and carried on for a direct and immediate commercial purpose and it must be directed by a commercial head The atmosphere of a department where canvassing is carried on should be charged with the commercial spirit Engineering departments from the nature of their duties do not develop among their employees the selling instinct The writer does not mean to imply that an engineering education is not helpful to a salesman or to any one in charge of a selling department The point he wishes here to make is that a canvassing department to be successful should be organized as such and should devote its energies exclusively to that purpose

In canvassing for light the conditions are such that generally the character of the installation must be determined by the canvasser during his visit to the consumer's premises and frequently in the consumer's presence The stress of competition and the sensibilities of the consumer generally combine to make the element of time an all important factor The prospective customer says "Here is an interior Can you light it satisfactorily? Can you improve on its present lighting? How much money can we save by installing your system?" In order to secure the work at all the canvasser must be prepared to give an immediate answer to these questions, and, in so doing he is determining the character of the installation his company will make in case it gets the order In other words the canvasser is doing the applied illuminating engineering The fact that the orders so taken may be given to an engineering department to install, and that in this way the plans of the canvasser may be checked, and corrected if mistaken, is not to the point. Occasionally such a change might be made, but many cases of this kind would seriously affect the business

Having shown that practical considerations force the application of lighting units to interiors into the hands of the canvasser it should be unnecessary to furnish an additional argument toward the education of the canvasser in the principles of illumination Each company must solve for itself the problem of imparting this education upon its success will depend whether or not the interiors covered by its field of operations are properly lighted In the writer's opinion the Illuminating Engineering Society should become an active factor in the education of the lighting canvasser Especially should the local sections take an active part In these more time should be given to discussions of actual installations Such installations illustrated by diagram or photographic slide when criticised and discussed in public meeting have a high educational value Commercial men members of local sections should be encouraged to present descriptions of such installations and of interesting problems that arise in their experience

The Illuminating Engineering Society has been adversely criticised for devoting its energies too exclusively to the abstract chemical physical and physiological problems that pertain to the profession Even if the charge be true the adverse criticism is not deserved The profession of illuminating engineering is emerging from the state of infancy It is proper that the scientific principles which underlie the profession should have been mastered before the more practical phases of the subject come to the fore The society is now in position to devote more time to the latter It has been suggested that the annual sessions should consume four days two being devoted to the scientific and two to the practical branches of the profession The purely commercial phases of the sale and introduction of lamps should probably not be considered by this society

At this point some commercial man arises and protests somewhat as follows The practice of illumination is an art and the main qualification of the person who practices this art is experience combined with common sense It may be true that the art is based on scientific principles more or less abstruse but a knowledge of these principles is not essential any more than in the art of preparing food the expert cook must be acquainted with the chemical and physical changes brought about by the application of heat to animal and vegetable tissue I grant my man must be thoroughly familiar with the lighting units and the accompanying glassware and must be able to interpret the light distribution curves and other data furnished by the laboratories but when it comes to the actual application of the units to the space to be lighted judgment based on experience is the only tool he needs There may be some cases of such complication that he may need the advice of an expert illuminating engineer but they are few and far between Practical conditions in most cases prevent an ideal arrangement of the lamp these practical conditions are so numerous and so compelling as to become the dominant factors, so that the best illumination obtainable is a compromise Outlets are fixed, and it is expensive or inexpensive to change them, the ceilings are low, columns, showcases, balconies, etc. interfere these and numerous other practical consideration are such that, in the great majority of cases, the installation made by the consulting illuminating engineer, after calculating the illumination at all parts of the room, will be identical with that made by an experienced man, using nothing but his judgment as a guide."

The above remarks of our commercial friends are interesting, and contain considerable of truth, but there is in them no argument against the proposal to educate the lighting canvasser in the principles that underlie practical illumination. No one can argue that a knowledge of these principles will detract from

* A paper presented at the Fourth Annual Convention of the Illuminating Engineering Society, Baltimore, October 24th and 25th, 1910

this man's efficiency, very few will have the temerity to argue that such a knowledge will not be of positive value to him

The practice of illumination is indeed an art, but is it not also something more namely a profession? Those arts in which the processes are so simple that no knowledge of the underlying principles is needed in order to practise them are arts pure and simple In proportion as the processes become complex and involved and as the problems contain many variable quantities a knowledge of these principles becomes essential and the art merges into a profession Shining shoes and washing clothes are arts in which the processes are simple requiring on the part of the boot black and washer woman no knowledge of the chemical and physical changes involved Cooking is to a certain extent such an art but the frequently urged claim that it is practically a lost art is due to the fact that most of the cooks are 'practical cooks and that too little attention is paid to a knowledge of the underlying principles The more complex the problems involved in illumination the more numerous the practical obstacles the more essential becomes a knowledge of and a constant reference to the principles which underlie the profession of illuminating engineering

A word of re-assurance may here be advisable lest the commercial man be frightened at the vast extent of learning that is expected of him The transactions of this society as one turns them over page by page present many formidable propositions to any one who is not a trained scientist or an expert mathematician The commercial man may be comfortable in the thought that these are not for him The principles he needs are relatively simple, and such as he can easily grasp if he appreciates their importance and seriously applies himself to them He should learn how to determine the amount of illumination from the curve of the lighting unit when the units are spaced at any given distance and height and how to allow for the effects of reflection from walls and ceiling He should maintain a drawing board for his own use and should use it constantly never guessing at the result when it may be ascertained by proper calculation Most formulas that he needs in his work are given in table form for his convenience and constants are provided for his use it is not absolutely necessary that he should understand the derivation of the formulas or the laws on which the constants are based but the more he understands of them the better He should practise to think and judge of illumination in definite units—in foot-candles and to enable him to do this he should understand the use of the portable illuminometer and make constant use of this instrument in reading the actual illumination obtained by the equipments he installs There is no better way to train the judgment than this constant checking of calculations by results He should be a constant attendant at the meetings of one of the local sections of this society even although he may not follow every argument or calculation he will surely absorb from every discussion some grain of knowledge which will enable him more intelligently to meet the demands of his calling

The profession of illuminating engineering deals with an important subject fraught with grave consequences to the future of our race Conserving the most vital one of those five senses which form the connecting links between the personality of the individual and the physical world it is destined to exercise an important influence on the progress of civilization It enlists the services of the physicist the chemist the mathematician the physiologist the oculist the manufacturer the architect the artist and in this list the commercial man holds an honorable and commanding position No one two or three of the types of men here named can solve the multifarious problems of the profession It requires the services and the co-operation of them all The profession cannot afford to have any one of them hold aloof and it will prosper in proportion to the degree of co-operation and of interchange of opinion that is maintained and to the extent to which those individuals who compose each group endeavor to broaden their views by obtaining as great a knowledge as possible of the activities of the other groups The commercial man cannot afford to remain ignorant of the progress of illuminating engineering The best basis upon which to build the knowledge and experience of salesmanship in this commodity is a familiarity with the principles of illuminating engineering

Correspondence

The Star Clusters

To the Editor of SCIENTIFIC AMERICAN SUPPLEMENT

The suggestion of Mr Arthur K Bartlett in the SUPPLEMENT of the SCIENTIFIC AMERICAN of February 4th that the solar system is gravitating toward the star-cluster in the constellation of Hercules is perhaps worthy of more attention than on a superficial view is accorded to it The problem what are the laws of motion of a system of bodies subject to mutual attraction according to the law of gravitation or any other law cannot be solved by the mathematical methods which are available at present In other words the algebraic equations which define these laws cannot be obtained Even the solution with regard to two bodies is only a partial one since it rests on the hypothesis that the original tangential impulses took place in the same plane which is infinitely improbable If this solution has been attempted and accomplished on the hypothesis that the directions of these impulses crossed without intersecting one another it has not come to the writer's notice

Although we cannot solve the general problem yet according to the laws of mechanics certain principles have been established which can give us some idea of the manner of motion of the bodies under consideration These are

1 The center of gravity of a system of bodies subject to mutual attraction is stationary with regard to those bodies just as the sun is stationary with regard to the planets

2 The sum of the areas described by the radii vectores each multiplied by the respective masses of the moving bodies is constant

3 The vis viva of the system is constant

From the last principle it follows that the system can never come at rest

The second principle establishes the fact that the nearer the bodies approach one another the greater must be the velocity of their motion

The first principle necessitates that all the bodies must gravitate toward one and the same point namely toward the common center of gravity

When several thousands of bodies in their course gravitate toward one point, it would seem that at some time or other in the neighborhood of that point a cluster will be formed Granting this let us try to determine what course any one of the bodies under consideration is likely to follow

Suppose a body is moving away from the cluster then the attraction of the cluster will retard and finally reverse its motion

If at this juncture the body is affected by no tangential force in other words if it has been moving in a straight line which passes through the common center of gravity then it will return along the same line approaching the cluster with increasing velocity and finally reaching it The universe is built on so generous a plan that the body here considered may traverse the cluster without coming in collision with any of the bodies composing it no more than a comet passing through the solar system must necessarily collide with any of the planets or satellites of that system Indeed the fact that the stars which constitute a cluster can be observed individually and counted shows that the distances which separate them must be very considerable Moving as it does in a line which passes through the common center of gravity the attractive forces which affect the body in a direction perpendicular to that in which it moves will nearly balance each other So it must continue to move in a straight line passing through the cluster and then departing from it with a velocity which is retarted continually until it is exhausted and the motion of the body is reversed once more Such a body therefore will simply oscillate between two points on opposite sides of the cluster and equidistant from it

If the body which is the subject of our consideration at the time when its motion is reversed was moving in a direction which did not pass through the common center of gravity then it will describe approximately an elliptical arc and in returning it may or may not traverse the cluster

If the body does not traverse the cluster but passes by it then the cluster will operate upon it as the sun does on a comet that is swing it around and throw it back into space and the orbit of that body will be approximately a more or less elongate ellipse of which the common center of gravity will be one of the foci

If the body does traverse the cluster it will be affected by the attraction of that part of the cluster which is bounded by a sphere whose center is the common center of gravity and of whose surface the moving body is one of the points The attractive forces which the bodies outside of that sphere exert on the body under consideration will nearly neutralize each other Virtually the conditions which determine the motion of the body here considered will be the same as those which govern the motion of a body that does not enter the cluster The orbit of every body therefore that traverses the cluster and does not pass through the common center of gravity will likewise be approximately a more or less elongate ellipse having the common center of gravity for one of its foci

As to the motion of the bodies composing the cluster each body of the system in its turn will approach the common center of gravity and the cluster therefore is composed of those bodies which temporarily are in the neighborhood of that center

Of course all these conclusions are very rude approximations and the orbits of a stellar system are not pure ellipses no more than are the orbits of the planets satellites and comets of our solar system Yet it would seem that the theory here presented gives a fair idea of the interaction of a large number of bodies subject to mutual attraction Perhaps the best example of the probable motion of the bodies of a stellar system is afforded by the comets which appertain to the solar system

Although the passage of a body appertaining to a stellar system through the central cluster of that system does not necessarily involve collision with other bodies yet it does not follow that such collision does not occur from time to time On the contrary occasional collisions are not only probable but apparently necessary for the preservation of the caloric energy of the system

Perhaps every star cluster is the center of a stellar system and the furnace in which the bodies belonging to the system regain the heat which they have lost during their long excursions in space

Handling Passengers on a Rapid Transit Railroad—II*

Construction of a Rapid Transit Line as Illustrated by the Hudson and Manhattan Railroad

By J Vipond Davies

Concluded from Supplement No 1838, page 179

It is not possible in all cases to load passengers so that they will be evenly distributed throughout the train as is the case at Church Street terminal For instance at Hoboken terminal the only connection available for interchange of passengers with the Lackawanna Railroad enter the first car they come to and fill the cars at one end of a train leaving the cars at the other end practically empty To counteract this unequal train loading an entrance for passengers interchanged with the Public Service Corporation (trolley cars) was constructed as near as possible to the other end of the station and the result is a well balanced arrangement for the distribution of passengers through out the entire train Similarly at the Pennsylvania station passengers from the railroad are necessarily delivered to the Hudson and Manhattan Railroad at the extreme easterly end of the station and to counterbalance this entrances for passengers from the trolley cars and street are located at the westerly end of the station The local stations on Sixth Avenue have all been arranged with entrances and exits as near as possible to the center of the train whereas the stations at Christopher Street and Ninth Street owing to curves in the line which prevented the platform from being centered on the only available site for a stairway and entrance are arranged for end loading—Christopher Street at the westerly end and Ninth Street at the easterly

In the design and construction of the stations of the New York rapid transit subway practically all the entrances and exits consist of openings in the side walks covered by kiosks which interfere seriously with the use of the sidewalk In the development of the Hudson and Manhattan lines the Rapid Transit Commission appreciated the objections to the kiosks erected on the sidewalks and compelled the company to arrange for the entrances and exits through private property unless specifically permitted to do otherwise by the Commission In some cases arrangements were made for entrance and exit through private property on Sixth Avenue and in other cases entrances and exits were placed under the stairways leading to the elevated railway so that the erection of kiosks involved no additional obstruction on the sidewalk To make a railroad of the greatest convenience to the traveling public the stations need be clearly defined and easy of access An entrance through private property seldom affords the same convenience to the public as does an entrance direct from the public streets even at the expense of obstructions such as railings or kiosks Entrances placed directly upon the street are more in evidence and are consequently of greater value to the public so that although at first thought the obstruction to the sidewalk may be considered as pre eminent yet the general convenience of the traveling public is better served by kiosks On the other hand where it is possible to arrange stairways as was done on the Hudson and Manhattan Railroad under the stairs of the eleated railway so as to provide this convenience without additional obstruction to the sidewalks the arrangement is ideal There is however one serious drawback as in the majority of cases the stairways to the elevated railway are so narrow as to give inadequate width for proper service and wherever there is a possibility of passengers moving in opposite directions no stairway should be installed less than five feet in width and it is desirable to make them not less than six feet wide which allows ample width for two persons abreast walking in the direction of the maximum movement and one person in the direction of contrary movement The interference with the movement of passengers in the maximum direction by an opposite movement on narrow staircases is detrimental to general efficiency

Platforms should be designed to provide ample room for the free movement of passengers In the case of unloading platforms all that is necessary is to have sufficient space with ample exits so that an entire trainload of people can be easily discharged onto the platform within the limit of time fixed for the station stop and further that the entire trainload so discharged may pass out of the station before the arrival of the following train It is usually not necessary for a platform to be wider than the floor area of the car itself although there should be a widening of platforms in the vicinity of stairways or exits as there must of necessity occur a slight congestion at the points of exit from the unloading platform In the case of loading platforms the consideration is affected materially by the character of train service operated With the Hudson and Manhattan Railroad at Church Street terminal and later at the Thirty third Street terminal there are in use platforms twenty feet wide common to trains serving different routes There must therefore be ample room on the platforms for an entire trainload of people to stand for either route for which a train is destined and to distribute them selves so that they can enter the train immediately upon its arrival It is obvious that if an attempt is made to unload passengers from an arriving train onto the same platform on which passengers waiting to leave on the same train are standing the movement of passengers is seriously interfered with and the public inconvenienced since the station stop must be increased to permit loading and unloading of the trains It is very plain therefore without argument or the use of figures that the convenience of the public and the rapidity of passenger movement can be best accomplished by unloading passengers onto one platform and loading them from another It is quite material in unloading passengers that the train stands on a tangent The great objection to a train standing on a curve at a station is that passengers may be injured by stepping through the gap between the train platform and the station platform In the Rapid Transit Subway in New York as well as elsewhere this gap has been illuminated by lights underneath the edge of the platform which clearly indicate the gap and assist materially in avoiding accidents but apart from the possibility of accidents the location of a station platform on a curve with the consequent gap between the platform of the car and the station platform seriously affects the rapidity of movement of passengers either entering or leaving the train There is an instinctive pause by each individual seeing the gap the movement is much slower in consequence and the length of the station stop is materially lengthened

The arrangement of ticket offices is important in station design At first sight this seems like a matter requiring little attention but as a matter of fact it is essential in the economical operation of a rapid transit railroad and in the efficient handling of passengers. In arranging ticket offices it is vitally important to locate them so as to force passengers as far as possible to move in the right hand direction and it is also important to arrange the position and grouping of the ticket offices so that the line of passengers purchasing tickets will not be interfered with or crossed by passengers leaving the station or by those with tickets desirous of reaching the trains. Ticket offices for the sale of steam railroad tickets should be located in convenient sight of travelers but entirely out of the stream of traffic whereas for the sale of strip tickets used in rapid transit service the boxes must be located along the direct stream of movement, so that no passenger leaves his general direction and yet so grouped that while one stream of persons is purchasing tickets there is unobstructed opportunity for those persons already having tickets to pass along The arrangement of ticket windows in tandem on the same face is valueless, for the reason that those who are buying tickets at the first window must of necessity cross the stream of passengers trying to obtain tickets at the second window which invariably causes discomfort and obstruction. The Hudson and Manhattan Railroad has carried out the usual arrangement of installing one large and important ticket office at a station in which the ticket agent can keep his safe, stock of tickets and cash and in addition has provided sundry portable ticket offices which can be wheeled into line during the busy hours and moved entirely out of the way during the slack hours In all cases the arrangement of ticket offices should be such that the ticket-chopper is near to the ticket seller so that the seller may have the chopper under observation, and so that in case of necessity the ticket-chopper may assist the ticket-seller However, the distance between the two should be such as to permit a passenger, after having purchased a ticket, to pause before putting the ticket into the chopping box. One ticket-chopper usually serves two lines or streams of traffic, and the barriers should be only so wide as to allow a single file of passengers to pass on each side of the chopping box. The most convenient and desirable width for this passage is 24 inches With the ordinary stream of passengers on this road it is found that one ticket-chopper can pass through the gate in two files 108 passengers per minute. This rate of passage is too great however, except for short spurts as the chopper cannot properly examine tickets, and provision should be made for an average rate per chopper not exceeding 4 000 persons per hour An examiner who has to punch or personally scrutinise railroad tickets can only pass about 30 per minute An ordinarily competent ticket agent will sell about 2 000 rapid transit tickets per hour and make change, or for short periods may sell as many as 2,500 tickets per hour In calculating the number of selling agents or chopping boxes necessary for handling the maximum traffic these figures can be taken as a basis for speed

In connection with the stations there is one other matter to which reference should be made that is the necessity for the use of elevators or escalators at certain points in the underground railroad where the depth of the station below the surface is considerable The new plans of the Public Service Commission require them when the lift exceeds 30 feet. This is provided on the Hudson and Manhattan Railroad at the Pennsylvania station in Jersey City The capacity of an escalator is usually thought to be considerably greater than the capacity of an elevator on account of an escalator taking a continuous stream of people and moving them as they arrive without an intermission or pause which is of considerable importance as a pause however short in duration affects materially the flow of passenger movement The elevator service was installed at the Pennsylania station therefore on account of the absolute necessities of the case as it was impossible by any arrangement which could be devised to lay out an escalator service at that point and the conditions were ideal for the installation of an elevator service The company provided elevator service with the utmost appreciation of the possible congestion arising therefrom The size of the elevators was limited by the width of panel in the main bracing of the elevated station and allowed cages only 10 feet square Further the Pennsylvania Rail road Company could not without seriously affecting its own business spare the concourse floor room sufficient for more than four elevators The capacity of these elevators on the basis of allowing two square feet per person is fifty persons per lift, and as the lift of about 92 feet is continuous from bottom to top and *vice versa* it was agreed to operate at the comparatively slow speed of 300 feet per minute particularly as the actual running time of the elevators is small when compared with the total elevator interval. To facilitate the movement of passengers the scheme of dividing incoming and outgoing passengers, was used, the same as in the other stations This was done by providing openings on the front and rear of the elevator cages, receiving passengers from the Pennsylvania Railroad trains direct into the elevators from the train side and discharging passengers from the tunnels to the Pennsylvania Railroad trains on the opposite side. The gates are as nearly the full width of the elevators themselves as they could be made. It was possible to get an effective gate opening of 6 feet 3½ inches in width and to equip the elevators with a pneumatic device by which the elevator operator controls the opening and closing of the doors of the cages and elevator fronts. The result of the layout has thus far greatly exceeded the original idea of its possibilities and has more than satisfied the officers of the Pennsylvania Railroad as to capacity It is usually not desirable to attempt to fill the cages to their maximum capacity and to handle passengers most efficiently and expeditiously it is found that a load of forty persons will accomplish more than one of fifty, on account of the delay in loading the additional ten people. In this manner, the four elevators can handle passengers at the rate of sixty people per minute in one direction. On one occasion five fully loaded suburban trains of the Pennsylvania Railroad, after being stalled at Point of Rocks outside Jersey City, came into the station practically in a procession, and the passengers moved into the elevators as they arrived without the slightest congestion or undue inconvenience. An elevator of the size installed at this station is probably more efficient for the rapid handling of passengers than one of large floor space, as the service is so rapid that there is practically no pause in the flow of people.

Cars—In handling passengers, the second important point is the design of car, particularly with reference to loading and unloading, and its internal arrangement as affecting the passenger and its relation to the

* Proceedings of the Engineers Club of Philadelphia.

station. In the first place, the train service operated by the Hudson and Manhattan Railroad is essentially a short-distance service The longest continuous distance usually traveled by a passenger—from Pennsylvania station to Thirty third Street, or from Hoboken terminal to Church Street terminal—is less than four miles, consequently the time a passenger is in a car is comparatively short, and not comparable with the time taken on a railroad such as the electrified lines of the Long Island Railroad or the Interborough Rapid Transit Subway where a passenger may ride from 20 to 25 miles on a continuous trip It is a well known fact that a crowd of people desirous of traveling on a train will insist on using the first train in every case and will jam itself into a train whether there is sitting room or not notwithstanding that another train is following within ninety seconds and in spite of the fact that crowding an already overloaded train materially lengthens the time of the station stops and interferes with the headway and progress of all following trains The next following train may be running practically empty It is therefore not essential on a road such as the Hudson and Manhattan to attempt to provide the maximum seating capacity in a car but it is necessary to give the maximum seating capacity only under ordinary conditions and at ordinary hours and to give the greatest floor space for standing room and for carrying the maximum number of people in the easiest way with the least obstruction and inconvenience due to deliberate overcrowding

The Hudson and Manhattan Railroad trains are essentially moving terminals for the steam railroads a very large number of passengers carry valises and other baggage consequently the car with the greatest unobstructed floor area is the most advantageous for such service For this reason it is desirable to arrange the seats along the sides of the car without cross seats which possibly would have given but four or six seats additional per car but which would have obstructed very materially the rapid movement of passengers This arrangement gives a seating capacity of forty four persons per car A novel feature of this scheme for seating is the subdivision of seats into sections which was devised by Mr Stillwell This scheme was adopted because most of the passengers desire corner seats and for the purpose of stiffening the side trusses of the car The subdivision of seats into sections is convenient and has proved to be very popular

The use of the enameled rods in place of straps adds another convenience for passengers Enameled rods are more sanitary than leather straps and a new enameled metal loop is being tried by the Rapid Transit Subway as a substitute for leather straps.

The newspapers have so thoroughly educated the public as to the merits and demerits of side doors for cars that there is little to add here Side doors were first used in a practical way on the Hudson and Manhattan road and with complete success but to get the maximum efficiency they should be used in conjunction with platforms at the level of the car floor and with station platforms arranged for loading passengers on one side and unloading on the opposite side The cars have a clear opening of 36 inches for each end door and 41 inches for the side door With these conditions 106 people can be unloaded in twenty nine seconds or at the rate of 3 65 per second and there is not the necessity for the very wide doors which are essential where the loading and unloading is from the same side The earlier cars of the Rapid Transit Subway were arranged with only end doors having an effective opening of about 33 inches This is wider than is strictly necessary for a single line of passengers but at the same time altogether too narrow for a double line Cars more recently built and provided with side doors have an effective opening of 47 inches which permits a double line of persons outward or a single line of passengers moving out and a single line moving in at the same time but even with these wide openings the result is not as expeditious as with loading and unloading on opposite sides

The installation and operation of side doors is complicated in opening and closing as the side doors are necessarily out of sight of the guards standing at the end of the car and the doors cannot conveniently be opened and closed by men on the platform It would be a very serious burden to maintain men on every platform to operate the side doors On the Hudson and Manhattan Railroad all car doors are equipped with a pneumatic device for opening and closing and there are air-cushions on the edges of the doors No trouble whatsoever in the operation of the doors and practically no accidents of a serious nature have occurred The Rapid Transit Subway has equipped the side doors of its newer cars with mechanical devices operating with a chain and toothed gears which appear to operate satisfactorily

Generally speaking in rapid transit service the conditions are different from street railroad conditions by reason of the fact that on a street railroad passengers get on and off the cars and trains anywhere and that fares are collected in each car at the point where a passenger gets on which makes the entire distance the car travels practically a continuous station In any rapid transit or high speed line it is necessary to make definite stops at stations and to equip each station properly for the sale and collection of tickets instead of on the trains

The greatest complication in connection with a moving platform device is in making it a continuous station One of the points of advantage in a moving platform is the fact that the whole distance can be made a station practically the condition on a street railway but it is almost impossible to equip the whole length of the platform with ticket agents

The capacity of trains is regulated as before outlined by the capacity of the cars forming the trains The frequency is regulated by the time interval at which trains can be operated and is irrespective of the speed of trains which affects only the convenience of the public and the ability of a railroad to get business A railroad is a commercial enterprise and while it is constructed for public service it is primarily constructed with a view of obtaining an adequate return on the money invested To obtain this result therefore on a private or public investment it is essential to operate with the greatest efficiency and to so design a railroad that it can give maximum service

Therefore the details presented here will indicate the importance of not sparing trouble or expense in designing constructing and equipping a railroad so as to give the greatest service with the least inconvenience to the traveling public combined with maximum efficiency and economical operation The essential point with a public service corporation is to serve the public properly and this was the underlying thought of Mr McAdoo the president when at the opening of the Hudson and Manhattan Railroad he addressed the employes with words to the effect that he wanted no effort spared in the operation of the railroad to please the public

If it is conceded that a rapid transit railroad is a public utility then there is also implied a mutual obligation between those who operate the road and the public authorities who grant franchises and regulate the service to treat each other in a broad minded manner and to co operate in providing rapid transit facilities which will be of the greatest service and convenience to the traveling public

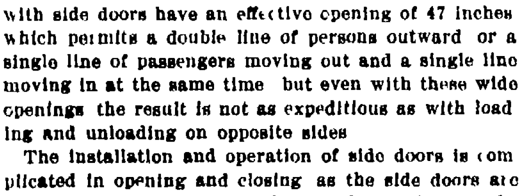
An Instructive Barogram

We are indebted to the Taylor Instrument Companies for permission to reproduce the accompanying barogram which was obtained by Mr P R Jameson F R Met S in the course of a voyage around the world The particular week s record here shown was made on shipboard between Mozambique and the coast of British East Africa i e the vessel was going nearly due north and passed through about 12 degrees of latitude during the week

While this record offers nothing of special note from a meteorologist s point of view it is in fact a perfectly normal record for the region and season in question, making allowance for the fact that the barograph had probably not been adjusted for some time and read much too low It is presented to our non meteorological readers as a pretty illustration of the very regular diurnal fluctuations of the barometer within the tropics, with the additional effect due to a rapid translocation of the instrument in latitude The ship was sailing from a region in which the barometric pressure is permanently high—viz the ridge of high pressure in the neighborhood of the Tropic of Capricorn—toward one in which it is permanently low viz the doldrums —the belt of calms near the equator between the two trade-wind belts This accounts for the progressive fall of pressure from the beginning to the end of the record The effect is however somewhat greater than would be expected from the normal distribution of pressure in this region and was possibly heightened by an accidental tilting of the trace sheet with respect to the revolving cylinder of the barograph.

If the reader will compare this barogram with one made in temperate latitudes he will be struck by the clock like regularity with which a maximum of pressure occurs at 10 A. M and a minimum at 4 P M, with secondary maxima and minima at 10 P M and 4 A. M., respectively There is an oft-quoted saying of Humboldt's to the effect that so regular is the daily rise and fall of the barometer within the tropics that the time of day may be inferred from it with considerable accuracy. The daily range averages about one-tenth of an inch of the mercurial column Day after day the history of the barometer repeats itself The monotony of the process is varied only—and at any given place this occurrence is fortunately rare—when a tropical hurricane passes near the point of observation Hence in tropical countries any departure of the instrument from its accustomed daily course is looked upon as ominous

In temperate regions the barometer has a similar double diurnal period but the periodic range is less and near the poles it is almost *nil* Moreover outside the tropics this daily oscillation is as a rule completely



AN INSTRUCTIVE BAROGRAM

masked by the passage of those widespread areas of hyperpressure and hypopressure that we call respectively, highs and lows Within the tropics these disturbances are almost unknown except for the small but intense lows known as tropical cyclones or hurricanes. Furthermore the latter are in any given region, limited to a particular season of the year and they rarely if ever, occur over the southern Indian Ocean during September the month in which the accompanying record was made

The cause of the double daily oscillation of the barometer is one of the time-honored riddles of meteorology No one has yet completely unraveled it, though of late much light has been thrown upon the subject The daily march of temperature—with a minimum in the morning and a maximum in the afternoon—would lead us to expect a *single* daily oscillation of atmospheric pressure When the air near the earth s surface is heated it expands pushes its way upward and overflows, thus diminishing the total mass of the air over the heated region and causing the barometer to fall The converse occurs when the air is cooled, and then the barometer rises This process alone would give us a daily maximum and a daily minimum of pressure twelve hours apart, instead of two maxima and two minima, at intervals of six hours such as actually occur

The explanations of this double period hitherto offered are too intricate to explain here in detail An analysis of pressure records obtained in all parts of the world has shown that the curve representing the daily march of the barometer at any place is really a composite of two curves One of these has a daily period and is evidently a local temperature effect the other which is the more regular of the two appears to depend upon the normal vibration period of the whole atmosphere a resonance effect as it is technically called The reader who desires to pursue this subject further may do so in Hann s Lehrbuch der Meteorologie (2d ed Leipzig 1906)

Fruit Disease Investigations

The investigation and study of fruit diseases have been vigorously pushed and have shown a healthy progress The destructive tumor disease of limes and other citrus fruits has been shown to be of fungus origin and attacks oranges as well as limes The new methods of spraying with sulphur compound worked out by the pathologists of the Department has been widely adopted by apple growers The investigation shows that fine fruit can be produced and protection secured against fungus disease without the injurious effect resulting from copper compound Bordeaux mixture is still being used but in the spraying of apples it has taken second place Special attention has been given to experimental work in perfecting the method of using the new sulphur sprays for the fruit spot and leaf disease As a result fruit growers who have used the new sprays have secured fine crops of the best apples they have ever grown Spraying has very largely prevented the fruit spot and leaf disease known as cedar rust or orange rust prevalent in the Blue Ridge and Allegheny mountain district from Pennsylvania to Tennessee The peach growers of Virginia West Virginia, and Georgia have been prompt to adopt the discovery of spraying with self boiled lime sulphur for brown rot and scab which has resulted in the removal of some of the factors which rendered the growing of this fruit uncertain The pear blight eradication methods have been in extensive use on the Pacific coast

Much space is given in discussing the work of the Bureau of Entomology to the important work that bureau has done during the past year in its effort to control or eradicate the gipsy moth and the brown tail moth The infested territory covers all the New England states excepting Vermont, and the Department working in co-operation with the authorities of those states has met with gratifying success Conditions there are largely improved

Mechanical Aids to the Study of Marksmanship

A German Army Officer's Invention

Lieutenant von Stegar of the German army has invented a simple apparatus which facilitates instruction in marksmanship and shows the recruit the character and extent of the error made in aiming. This apparatus which is described and illustrated in *Kriegstechnische Zeitschrift* is made in two parts. The first part (Fig 1) is a pair of sights of the point and notch type used on rifles constructed on an enlarged scale and so mounted on a tripod that it can be turned in any direction. The height of the point and the breadth of the notch are each about two inches and the point and notch are mounted on the ends of a strip of wood about three feet long which is attached to the tripod by a double joint moving with slight friction. The second part (Fig 2) is an adjustable sight hole consisting of a wooden disk with a perforation one-fifth of an inch in diameter which is attached to a tripod by a jointed arm moving with slight friction.

It has been the practice of instructors in marksmanship to employ enlarged wooden sights laid one upon the other for the purpose of showing the correct and incorrect positions of the point with respect to the notch but many unintelligent recruits cannot understand the demonstration because the sights on the rifle are not in contact, but are widely separated. Much better results can be obtained with the new apparatus. The recruit stands a pace or two behind the sight hole and looks through it at the pair of sights one pace farther forward. No target is required. By means of the adjustable sight hole the eye can be fixed in any position and the correct relative positions of the point and notch as well as any deviation therefrom can be easily demonstrated.

In the exercise in which the pupil is required to designate the point at which a rifle has been aimed by the instructor the pair of sights is placed ten paces from a disk of cardboard or canvas, with the point nearest the target. The instructor aims the sights and the recruit, standing about one pace from the notch indicates the point on the target at which he thinks the sights are aimed. This point of the target is marked with a black patch. The instructor then places the sight hole before the pair of sights so that an eye looking through the hole sees the notch bisected by the point. If the recruit has judged correctly the black patch will be seen directly above the point, but if he has judged incorrectly the patch will be seen to the right or left of the point (Fig. 4). The recruit, looking through the sight hole, can thus see his error. Or the sight hole may be so placed that the patch appears exactly over the point. In this case the error is shown by the unsymmetrical position of the point in the notch (Fig 5).

The apparatus is used in a similar way in the exercise in which the pupil is required to aim at a mark chosen by the instructor and the error is shown, as before by using the sight hole which is adjusted by the instructor. The apparatus is not intended for universal use but only as an aid in the instruction of the less intelligent and especially awkward recruits, where it saves much time and vexation and teaches accuracy of aim. The pupil sees his own error because his eye is brought to the correct position by the sight hole. Without the apparatus the instructor can only say that the gun is aimed too high, too far to the right, etc but the recruit has to take this verdict on faith and is little helped by it. The movable pair of sights might be dispensed with and the sight hole attached to the butt of the rifle but this arrangement would be less convenient and less accurate owing to the nearness of the hole to the notch.

A Handsome County Bridge

A Reinforced Concrete Bridge Connecting Asheville with West Asheville

The handsome reinforced concrete bridge represented in the illustration spans the French Broad River connecting the city of Asheville with West Asheville a thriving and energetic little city of 3 500 people. The entire construction is of reinforced concrete with a total length of 931 feet 6 inches. It is composed of two clear spans of 145 feet each with an east approach of 475 feet and a west approach of 135 feet. The distance from the top of the bridge at the center of the arc to the water at normal level is 50 feet. The structure has a 30 foot roadway with an electric car line in the center and a 12 foot 6 inch clear roadway on each side of the rail. It was designed for a capacity of three 35 ton electric cars. The total cost of the bridge was $70 000 and including right of way and incidentals $72 000. R P Johnston of Asheville N C was the engineer and C B Clarke & Company Baltimore were the contractors. The bridge was opened to the public on February 10th 1911.

The Asheville Electric Company is extending its line across the bridge to the western portion of West Asheville a distance of a little more than two miles at a cost of nearly $40 000. Large forces are at work at both ends of the line and cars are expected to be in operation by April 1st 1911.

Soil Surveys

During the year soil surveys were carried on in fifty nine different areas in twenty-six different states and as a result 32 762 square miles were covered in detailed work and 79 108 square miles of reconnoissance surveys, mainly in the Great Plains region. A total area of 359 564 square miles or 230 120 960 acres has been surveyed and mapped since active field work was begun in 1899.

It is now clear that the pioneer methods of agriculture are inadequate for the increasing needs of our growing population. There is also abundant evidence that with a thorough knowledge of the soils and the intelligent application of modern intensive methods the yields per acre of our staple crops can be increased many times.

The soil surveys are showing the vast opportunities for crop specialization in the various soils in different sections of the country. Reconnoissance surveys of the Great Plains region thus far made have furnished a large amount of valuable and accurate information not only to prospective settlers but also to those farmers who are already in the areas.

Curved Photographic Plates*

Their Advantages in Astronomical Photography

By F A Bellamy, Hon M A (Oxon), F R A S

A SHORT note on the subject of curved photographic plates may be of interest. From the earliest days in photographic astronomy one of the difficulties to be met and overcome was the curvature of the field or the rapid falling off in the definition or good focus in the images of the stars away from the center of the photographic plate It is obviously of the greatest importance for accuracy and utility for uniformly good quality definition to be obtained over as large an area on the plates as possible

To an astronomer the reduction of the aperture of the photographic lens is not permissible or at least usually very inadvisable for stellar work as the maximum aperture is required in order to reduce the time of exposure as much as possible.

Though curved plates have in the past been suggested and used with a view to overcome the want of good focus beyond a very limited area, they have never found favor with astronomers for various reasons among these being the difficulty of making them uniformly suit the area of good focus simultaneously at the center and the edges the great cost of making satisfactory plates (uniformly coating them) greater risk of breakage difficulty of measurement storage and so on When the first conference in connection with the Astrographic Survey was held in Paris in 1887 one of the subjects proposed and discussed was the use of curved plates for the survey The plan was rejected as not feasible In twenty three years knowledge has advanced and the utilization of methods and appliances—common in other branches of science—has greatly increased so that what was impossible or inconvenient years ago is now rendered more convenient and available for use

The suggestion to use curved plates has been brought up again This time from a personal acquaintance with the worker and his excellent work we may say that there is a much greater chance of the method being tried under every condition that promises success which we hope will ultimately be achieved by Dr J H Metcalf

The lens he is using is a Petzval doublet and the focal length is seven times the aperture and gives a scale of picture of 90 inches to 1 millimeter With this lens he has found by re-focusing for various parts of the plate that all parts of a 10 inch by 8 inch plate equal to an area of 5 degrees square can be brought into good focus and excellent star images obtained As the lens can do so much by merely altering the focus gradually between the center and the edges the extreme amount to be allowed for in changing the focus for these two positions is only three one-hundredths of an inch (0 8 millimeter) it seems quite possible to bend a plate temporarily by that amount without fracture

* *Knowledge*

FIG 1—THE CENTER OF THE PLATE

Two exposures were made on the same plate the left hand one with the plate curved the other with it flat

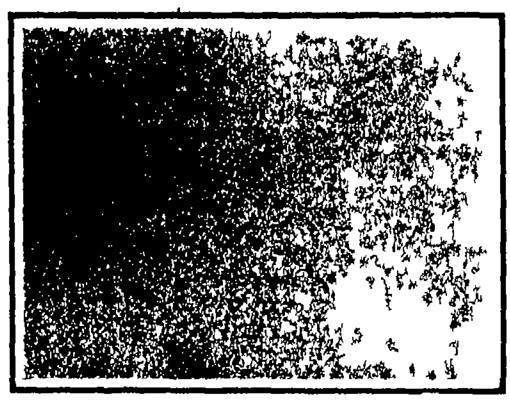

FIG 2—THE EDGE OF THE PLATE

Here there were two exposures as in Fig 1

Various methods were tried to produce the required amount of bending artificially of these the most successful as one might expect is that produced by atmospheric pressure on the outer and film side surface of the plate caused by exhaustion of the air in a closed chamber at the back of the plate

From a trial made with the 16 inch Metcalf telescope in 1910 June 29th ocular evidence can be obtained by the examination of the two sets of star images shown on the accompanying illustrations The region is that surrounding R A 19h 0m and +5 degrees and is enlarged nine times from the original plate so that 10 inches equal 1 millimeter In obtaining these two exposures the first and left hand image was taken with the plate temporarily curved and the second image shows the same star with the plate flat each exposure was of ten minutes duration In Fig 1 the center of the plate is substantially in the same focus the flat plate image being slightly the better one of the two When the outer parts of the same plate are compared a marked improvement becomes obvious with the curved plate images the bright stars showing less diffusion and naturally smaller images there being less scattering of light and the faint stars—the stars light being more compact and in focus—are distinctly improved almost invisible and diffused images become quite visible and better formed

Further plates have since been taken with that instrument to test the effect on the determination of magnitude and of position From an examination of sixty-one stars fainter than the 10 1 magnitude it was found that the flat plate lost 0 17 magnitude at 1 5 degree from the center in the curved plate the brightness increased by 0 06 magnitude No systematic error was detected

The effect on the actual positions of the stars has not yet been determined this requires careful and accurate measurement of a number of plates preferably of the same area.

For the convenience of use storage and measurement it will be a distinct gain to be able to have the plates flat rather than have to deal with plates with a permanent curvature When the temporarily curved plates are measured there are obvious advantages in having them flat in the measuring instrument.

The plate reproduced here is from the Harvard Circular No 161

Knowing Dr Metcalf's skill in practical photographic astronomy and his power to overcome difficulties we may expect still better results from his instruments

A Concrete Potato Peeler

A NOVELTY in cement construction is a concrete potato peeler It is an urn shaped reinforced concrete vessel which has a revolving disk in the bottom of the bowl driven from below through bevel gearing and designed to spin the potatoes around the inside of the bowl The rough surfaces on the disk and bowl rub off the potato skins and several sprays of water injected at the upper edge wash the potatoes clean and carry the refuse out at the bottom It peels a peck of potatoes perfectly in two minutes and while the machine is still running a door in the side is opened and the potatoes are ejected by centrifugal force into a galvanized iron receptable A motor of one-half horse-power capacity furnishes ample power and the driving pulley is proportioned to give six hundred revolutions per minute to the disk It is claimed that the machine saves twenty per cent of potato which is wasted by hand peeling to say nothing of the saving in labor and time Deep eyes and corners in irregular potatoes must of course be removed with a knife

The machine is cast upside down using mortar of a consistency which pours readily The mold is made of cast iron in several sections, and includes a collapsible core for making the bevel gear chamber below the peeling bowl After the concrete has stood in the mold for several hours and has hardened sufficiently the mold is inverted and the inner surface of the bowl is roughened with a steel brush —*Concrete Age*

CONCRETE POTATO PEELER

Work Among Southern Farmers

AS A result of the teaching of the methods of the Department for scientific farming, farmers throughout the country have increased their yields. The demonstration work among southern farmers has shown excellent results and progressive growth. Organized in 1904 for the purpose of fighting the boll weevil in Texas, this work has now extended to all the southern states. The boll weevil has been fought progressively and where the farmers have followed the instructions of the agents of the Department an average crop of cotton has been produced in spite of the weevil and statistics show that on the other hand where planters have not followed the instructions a crop failure has resulted This is conspicuously true in the alluvial sections of Texas, Louisiana, and Mississippi The methods advocated are being adopted by farmers in the boll weevil infested territory and are fast being recognized as the best means yet presented of raising a crop of cotton in spite of the boll weevil This means the restoration of confidence and credit and prevents the abandonment of farms and emigration of labor to other fields From 1904 to the present time the agents in this line of work have been increased from 1 to 450 and the demand is growing. More than 75 000 farmers are receiving direct instruction on their farms

Potash Salts: Light on an International Controversy—I*

Uses and Occurrence of Potash in the United States

By W C Phalen

INTRODUCTION

The many inquiries that have come to the Geological Survey for official information regarding American sources of potash have rendered advisable the publication of the available data on this subject Chapters on potash salts were published in the annual reports on mineral resources of the United States for 1887 and 1904 The more important statements in these summaries are here republished and expanded in the light of later observations and other information procured by the Survey geologists chemists and statisticians

Potash salts are used extensively in the United States They are essential to numerous industries that are vitally connected with the welfare of the American people—the most notable being the fertilizer industry They are used also in the manufacture of glass in certain kinds of soap in some explosive powders and in the chemical industries including the manufacture of alum cyanides bleaching powders dyestuffs and other chemicals among which are arsenite of potassium bromide of potassium chlorate of potassium permanganate and manganate of potassium nitrate of potassium and silicate of potassium

DOMESTIC POTASH INDUSTRY

Practically all the potash salts of mineral origin consumed in the American industries at present are imported from abroad chiefly from Germany There was a time in the history of the potash industry however when the United States produced a large part if not all of the potash it consumed The burning of wood and the lixiviation of the resulting ash to extract the potash though of minor importance so far as the monetary value of the product is concerned is one of the oldest of the purely chemical industries in this country Cognizance was taken of it in the census reports as early as 1850 so that data are available for comparing the condition of the industry for each decade since that year In the following table are given the quantity and value of potash produced in the United States from 1850 to 1905

Potash salts produced in the United States 1850 to 1905[1]

Census	Number of Establishments	Product		Average Price per Pound
		Quantity	Value	
		Pounds		
1850	549		$1 401 588	
1860	219		538 550	
1870	105		337 071	
1880	68	4 5 1 671	282 648	$0 061
1890	76	5 106,939	197 507	0 039
1900	[a]0	8 804 706	178,180	0 049
1905	[a]49	1 811 087	104 655	0 058

[1] Munroe C E Bull 9 Census of Manufactures Bur Census 1905 p 18

[a] Includes establishments engaged primarily in the manufacture of other products

According to C E Munroe the figures given above show a constant decrease in the total value of the potash produced in this country since 1850 and a steady decrease in the quantity of the product since 1890

This seems quite reasonable in consideration of the destruction of the forests during recent years and the resulting decrease in the quantity of ashes readily available for the manufacture of potash also in consideration of the decrease in the native fertility of the soil with which has come an inclination to return potash to the soil as it occurs in the ashes rather than to extract and market it and also in consideration of the cheapening of soda or hard soaps and increased facilities for bringing them to agricultural communities whereby the temptation to extract potash from ashes for the manufacture of potash or soft soaps is lessened These causes combined with the comparative cheapness of foreign potash, tend to destroy the domestic industry The data given in the above table indicate that the industry is a waning one and that it may come to be of so slight importance as not to warrant separate consideration in subsequent censuses, unless other causes recently set in operation shall revive it in another form."

IMPORTATION OF POTASH SALTS

The potash industry has not been revived in the United States thus far and the great bulk of the potash salts now used are imported. The following table shows the magnitude of the importation of potash salts for the years 1900 1905 and 1910

Imports of potash salts for the calendar years 1900 1905, and 1910, in pounds.[1]

(Figures from Bureau of Statistics.)

	1900		1905		1910	
	Quantity	Value	Quantity	Value	Quantity	Value

[1] This table is based on total imports for the calendar year not, as nearly all the import tables in this volume on imports for consumption for the calendar year

[2] These figures are for the fiscal years

THE CHEMICAL MANUFACTURES IN THE UNITED STATES DEPENDENT ON IMPORTED POTASH SALTS

Potash

Under the head of potash are included potassium carbonate and caustic potash Potassium carbonate is made from potassium chloride by the LeBlanc process in the same way as soda ash from salt, but the ammonia process can not be employed because the acid carbonate of potassium ($KHCO_3$) is soluble in ammoniacal solutions and does not precipitate The material is sold in the trade under the name potash or pearlash and is used chiefly in the glass industry in the manufacture of caustic potash and in the manufacture of chromates of potassium A considerable quantity is bought by soap makers and causticized the solution being used for soft soaps

Caustic potash (KOH) is made in the same way as caustic soda It is much more deliquescent than the corresponding sodium compound and is generally made where it is to be used In soap making it was formerly customary to saponify the fat with caustic potash and then to add common salt. An interchange between the potassium and sodium took place the result being a hard sodium soap But as soda is now cheaper than potash and yields a hard soap directly potash soaps are used only for special purposes

The consumption of potash or pearlash in the glass industry of the United States at the census of 1890 was 2 644 978 pounds valued at $135 047 and at the census of 1900 4 406 211 pounds valued at $186 047 The percentages of increase in quantity and value are respectively 73 and 38 The quantity of potash used in the soap industry at the census of 1905 was 4 453 800 pounds valued at $191 933 but this does not include the potash produced and consumed in the same establishments in the manufacture of soft soap Glass and soap making are two of the industries in which the largest quantities of potash as such are used

The following table shows the imports of potash and ashes for three years—1904 1905 and 1910

Imports of potash and ashes 1904 1905 and 1910

Year Ending June 30	Imports of Bicarbonate of Potash		Imports of Carbonate of Potash			
			Crude or Black Salts		Refined	
	Quantity	Value	Quantity	Value	Quantity	Value
	Pounds		Pounds		Pounds	
1904	96,769	$4,778	8,193,873	$294 896	18,596,306	$397 104

1905	5,269 604	217 041	32,818	2,537	60,718
1910	8,785,491	308,606	141 480	11 096	60,380

Alums.

In the manufacture of potash alum ($K_2SO_4.Al_2(SO_4)_3.24H_2O$) large quantities of potassium sulphate are used. On the addition of the potassium sulphate to the sulphate of alumina, the potash alum crystallises out in extremely pure form Alum is extensively used in the dyeing industry as a mordant and by paper makers and leather dressers. A small quantity is used in medicine. The following table gives the quantity and value of potash alum manufactured in the United States at the censuses of 1900 and 1905 The figures for 1910 are not yet available

Potash alum manufactured in the United States, 1900 and 1905

	Quantity	Value.
	Pounds.	
1900	14 200,393	$315,004
1905	10,807 154	156 448

Cyanides and Derived Compounds

The class of cyanides comprises potassium cyanide or white prussiate of potash sodium cyanide and other simple cyanides including cyan-salt," a mixture of potassium and sodium cyanides, potassium ferrocyanide (yellow prussiate of potash) potassium ferricyanide (red prussiate of potash), there are also the cyanates and ammonium and potassium sulphocyanates etc

Potassium cyanide (KCN) is generally made by fusing potassium ferrocyanide with potassium carbonate until the evolution of gas ceases The following is the reaction

$K_4Fe(CN)_6 + K_2CO_3 = 5KCN + KCNO + CO_2 + Fe$

The metallic iron that is produced sinks to the bottom of the crucible and the fused mixture of cyanide and cyanate is run off The addition of powdered charcoal reduces part of the cyanate to cyanide The product thus prepared is pure enough for many purposes The commercial salt always contains cyanate and carbonate and is sold in various grades depending on the purpose for which it is to be used The best quality contains about 98 to 99 per cent KCN but ordinary grades contain only 65 to 70 per cent It is a very powerful reducing material when heated with reducible substances and hence its use as a flux It is extremely poisonous, either when taken internally or when introduced directly into the blood. It is extensively employed in electroplating as the solvent in the bath forming soluble double cyanides with gold, silver copper, and other metals It is also used as a flux in assaying and metallurgy Its greatest use at the present time is for the recovery of gold from low-grade ores and the tailings of other reduction processes. A weak solution is used to dissolve the gold, forming aurous potassium cyanide (AuCN KCN) It was formerly used in photography for 'fixing the image but for this purpose it has been largely replaced by sodium thiosulphate

Potassium ferrocyanide ($K_4Fe(CN)_6.3H_2O$) also called yellow prussiate of potash, is made by fusing together potassium carbonate, iron borings, and nitrogenous organic matter of any kind, such as horn hair, blood wool waste, and leather scraps The material in its pure form is produced in splendid large lemon yellow crystals. It is not poisonous. It is largely used for making Prussian blue, in calico printing and in dyeing, for case hardening iron, for making potassium cyanide and ferricyanide, and to a small extent in explosives, and as a chemical reagent.

Potassium ferricyanide or red prussiate of potash (K_3FeCN_6) is usually made by passing chlorine gas into a solution of the ferrocyanide until ferric chloride no longer forms a precipitate, but produces only a brown color in the liquid. It may also be made by exposing the dry powdered ferrocyanide to chlorine until a test portion dissolved in water gives nothing but a brown color, with ferric chloride. With ferrous

* Reprint of a bulletin issued by the U S Geological Survey

[1] Op cit pp 38 et seq

salts it gives the blue pigment, Turnbull's blue Its solution with caustic potash is a powerful oxidizing liquid, and as such is used in calico printing for a "discharge" on indigo and other dyes. It also forms part of the sensitive coating of blueprint papers. It has been recommended for use with potassium cyanide solution in gold extraction.

The following table shows the magnitude of the cyanide industry in the United States at the censuses of 1900 and 1905 The figures for the census of 1910 are not yet available

Potassium cyanide manufactured in the United States, 1900 and 1905

	1900	1905	Increase	Per Cent of Increase
Quantity pounds	8,460,989	11 196,318	2,735,329	32 3
Value	$1,595 505	$1 710,823	115,318	7 2
Value per pound	$0 189	$0 153		

Fertilizers

The class of fertilizers comprises numerous chemical compounds among them the so-called complete fertilizers which consist of superphosphate of lime potash salts, and ammoniacal compounds or nitrates The following table gives the quantity and value of complete fertilizers manufactured in the United States at the censuses of 1900 and 1905 together with the amount and percentage of increase The figures for the census of 1910 are not yet available

Complete fertilizers manufactured in the United States, 1900 and 1905

	1900	1905	Increase	Per Cent of Increase
Quantity tons[1]	1 478,898	1 608,847	125,081	8 5
Value	$56,818 995	$61 805 057	$4 986,062	18 9

[1] The ton used in this report is the short ton = 2 000 pounds except where otherwise stated

The following table gives the quantity and value of the principal potash materials used in fertilizers in the United States at the two censuses cited with the amount and percentage of increase the figures for the census of 1910 not being available This table includes only the materials used in the principal establishments in the United States

Principal potash materials used in fertilizers in the United States 1900 and 1905

Value		$2 050		

Bleaching Materials

The class of bleaching materials includes among a great many other chemicals potassium bisulphite The following table gives the quantity and value of bisulphites manufactured in the United States at the censuses of 1900 and 1905 with the amount and percentage of increase the figures for the census of 1910 not being available Potassium bisulphite forms a very small part of the total

Sodium potassium, calcium and other bisulphites manufactured in the United States 1900 and 1905

	1900	1905	Increase.	Per Cent of Increase.
Quantity tons	1 461	6 268	4,788	325 9
Value	$34,486	$110,155	$75,669	219 4

Chemicals Produced by the Aid of Electricity

Among the chemicals produced by the aid of electricity are potassium chlorate and potassium hydroxide. The following table gives the quantity and value of the potassium salts made electrolytically at the censuses of 1900 and 1905, with the amount and percentage of increase, the figures for 1910 not being available

Potash salts made electrolytically in the United States, 1900 and 1905.

	1900	1905	Increase.	Per Cent of Increase.
Quantity, tons.	1,900	3,908	2,008	105 7
Value	$90,097	$209,008	$119,911	140 7

Dyestuffs

Potash salts enter into the dyeing industry chiefly in the form of alum. The production of alum has already been given and will not be repeated here. Potassium sulphide is frequently used to improve the fire' in vermilion. Potassium bichromate is extensively used in the manufacture of chrome green.

Explosives

Potash salts in the form of nitrate enter into the manufacture of gunpowder The term gunpowder generally includes the nitrate-sulphur-charcoal combination used in blasting as well as that used in guns and for the last fifty years it has included the blasting powder made with nitrate of soda as well as that made with nitrate of potash Potassium nitrate is also a constituent of some of the higher grade explosives tested and listed by the Bureau of Mines as permissible explosives Potassium nitrate is made by the double decomposition of sodium nitrate with potassium chloride the former being largely imported from Chile The reaction ($NaNO_3 + KCl = NaCl + KNO_3$) is very simple The following table gives the quantity and cost of nitrate of potash used in the explosives industry in the United States in the years 1900 and 1905 the figures for 1910 not being available

Potassium nitrate used in the manufacture of explosives in the United States 1900 and 1905

	1900	1905
Quantity tons	8,315	4 114
Value	$270 186	$306,644

General Chemicals

Under the heading of general chemicals potash enters into the composition of a host of substances Some of these are arsenite of potassium used in the dyeing industry bromide of potassium used in photography and medicine chlorate of potassium used in fireworks matches and aniline colors chromate of potassium used in dyeing and electricity manganate and permanganate of potassium used in dyeing and bleaching in disinfectants and in medicine silicate of potassium used in making ordinary yellow soaps as a fixative for pigments in calico printing as a vehicle for pigments in fresco painting for rendering cloth and paper non inflammable etc cream of tartar and argols

THE DEPOSIT OF POTASH SALTS NEAR STASSFURT GERMANY[1]

Discovery

Although potash occurs in many forms and places in the United States as described in a subsequent part of this report up to the middle of the nineteenth century wood ashes constituted practically the sole source of supply In 1857 a shaft which the German government had been sinking for about five years near Stassfurt reached a depth of approximately 1 100 feet but in the meanwhile had passed through a deposit of so-called Abraumsalze or refuse salts consisting largely of compounds of potash and magnesia then considered worthless[2] This deposit is now and long has been the chief source of potash and the potassium salts of commerce It is estimated by C Ochsenius[3] that the German deposit of potash salts may last over 600 000 years

Theory of Occurrence

The theory developed by Ochsenius for the occurrence of salts at Stassfurt is briefly as follows A deep bay is imagined connected with the sea by a narrow and shallow channel but otherwise cut off from oceanic circulation by a bar If no large streams enter the bay the outflow from it will be small but sea water can enter freely to offset the losses due to evaporation Evaporation of course takes place only at the surface, and the upper layers thus becoming denser must sink, producing a saline concentration at the bottom In this manner being continually supplied with new material from without the salinity of the bay will gradually increase until saturation is reached and the deposition of salts begins So long as salt water can enter the bay this process will continue and the depths of the basin will in time become a solid mass of salt, covered with a sheet of bittern If meanwhile an elevation of the land takes place separating the bay completely from the ocean evaporation may proceed to its limit and the mother liquor containing the more soluble salts including the potash salts will deposit its contents in more or less well-defined layers above the salt at the bottom. In the Karaboghaz and other bays on the eastern shore of the Caspian Sea the process of saline concentration can now be observed in actual operation, but only part of the programme has yet been performed.

This theory of Ochsenius is not the only one possible to account for the concentration of salts It must be remembered that salt is not deposited from sea water until it has been concentrated to about one-tenth of its original volume. Suppose now a large sheet of water in whose bottom there is a deep depression be cut off from the ocean by any change in the level of the land The water in the depression will gradually become concentrated and its saline load will tend to accumulate there A layer of salt will thus form of much greater thickness than if evaporation took place over a comparatively level bottom and if the surface area of the depression is small in comparison with that of the original sheet of water the depth of the deposit may be very great Such a deposit might also be reinforced by leaching from other salt beds or from diffused salts in adjacent areas—a process which is now going on in the valley of the Dead Sea and in certain lakes of the arid region of the western part of the United States

Salts Deposited

In the Stassfurt or more properly the Magdeburg Halberstadt region the order of deposits from the surface downward is as follows

1 Drift about 8 meters (26 feet) thick

2 Shales sandstones and unconsolidated clays of varying thickness

3 Younger rock salt thickness very variable sometimes missing

4 Anhydrite rarely lacking 30 to 80 meters (98 to 262 feet) thick.

5 Salt clay average thickness 5 to 10 meters (16 to 33 feet) very rarely absent

6 The carnallite zone from 15 to 40 meters (49 to 131 feet) thick At Douglashall a layer of rock salt intervenes between the carnallite and the clay In parts of the field kainite overlies the carnallite is itself overlain by sylvinite or hartsalz and that in turn by schoenite These subzones are often missing

7 The kieserite zone

8 The polyhalite zone

9 Older rock salt and anhydrite Nos 7 8 and 9 have a total thickness ranging from 150 to perhaps 1 000 meters (492 to 3 280 feet) The anhydrite forms layers averaging 7 millimeters (0 27 inch) thick separating the salt into sheets of 8 or 9 millimeters (0 31 or 0 35 inch) These layers have been interpreted as annual deposits due possibly to seasonal variations in temperature or to alternating drought and rain If this supposition is correct a Stassfurt salt bed 900 meters (2 953 feet) thick would require 10 000 years to form

10 Anhydrite and gypsum

The above is a complete record of the saline deposition at Stassfurt ranging from the calcium sulphate at the bottom to the mother liquor or carnallite salts at the top Above the carnallite a protecting layer of clay was laid down and after that probably a new accession of sea water began the formation of a second series of beds which however are regarded by some as having resulted from the re-solution and redeposition of older beds

In the Stassfurt deposits more than 30 saline minerals have been found some of which are regarded as primary and others as derived from the primary minerals by secondary reactions A few are simple salts but the bulk are double compounds Chlorides sulphates and borates are most common but the mineral kainite contains both the chloride and sulphate radicles The sulphates found at Stassfurt are as *follows*

Anhydrite	$CaSO_4$
Gypsum	$CaSO_4\,2H_2O$
Glauberite	$CaSO_4\,Na_2SO_4$
Polyhalite	$2CaSO_4\,MgSO_4\,2H_2O$
Krugite	$4CaSO_4\,MgSO_4\,K_2SO_4\,K_2SO_4\,2H_2O$
Kieserite	$MgSO_4\,H_2O$
Epsomite	$MgSO_4\,7H_2O$ (reichardtite)
Vanthoffite	$MgSO_4\,3Na_2SO_4$
Bloedite	$MgSO_4\,Na_2SO_4\,4H_2O$ (astrakanite)
Loewite	$MgSO_4\,Na_2SO_4\,2\frac{1}{2}H_2O$
Langbeinite	$2MgSO_4\,K_2SO_4$
Leonite	$MgSO_4\,K_2SO_4\,4H_2O$
Picromerite	$MgSO_4\,K_2SO_4\,6H_2O$ (schoenite)
Aphthitalite	$K_3Na(SO_4)_2$ (glaserite)
Kainite	$MgSO_4\,KCl\,3H_2O$

Little is heard of these salts except of kainite and this is of great importance It is readily soluble in water and most of its potash being immediately available as plant food it is used extensively as a fertilizer

The chlorides found in the Stassfurt region are as follows

Halite or rock salt	$NaCl$
Sylvite[1]	KCl
Douglasite	$K_2FeCl_4.2H_2O$
Carnallite	$KMgCl_3\,6H_2O$
Tachhydrite	$2MgCl_2\,CaCl_2\,12H_2O = 3(RCl_2\,4H_2O)$
Bischofite	$MgCl_2.6H_2O$
Rinneite	$FeCl_2.3KCl\,NaCl$

As already stated these chlorides represent the con

[2] Potash in agriculture, The German Kali Works p 5

[3] Die Kunstdunger Industrie, vol. 11 No 9

[1] Sylvinite is a mixture of sylvite and rock salt Hartsalz contains these substances together with kieserite

centration of the mother liquors in the carnallite zone. They were the most soluble compounds existing potentially in the sea water and with the kainite $(MgSO_4 \cdot KCl \cdot 3H_2O)$ they were among the last substances to crystallize The chemistry of the deposition and the interreaction of these substances is most complex and the literature mostly in German is widely scattered

It must not be supposed that these zones of deposition are regularly and completely separated nor even that they represent in any close degree the products observed in the artificial evaporation of sea water or brine In the latter case a moderate quantity of water is concentrated by itself at Stassfurt more water was continually added from the ocean On the one hand calcium sulphate is deposited almost wholly at one time on the other, new quantities were precipitated so long as the evaporating bay retained its connection with the sea. In the salt pan gypsum $(CaSO_4 \cdot 2H_2O)$ forms a bottom layer before salt begins to separate out; at Stassfurt anhydrite $(CaSO_4)$ is found in greater or less amount through all the zones, and so also is salt (NaCl) When a shallow lake or isolated lagoon evaporates, the artificial process is closely paralleled but a concentration, with continuous replenishment, lasting for thousands of years, is a very different thing. The principles are unchanged, the broad outlines remain the same, but the details of the process are greatly modified.

(To be continued.)

The Crane Collection of the New York Zoological Park*

How Cranes are Kept in a Great Paddock

By Lee S Crandall, Acting Curator of Birds

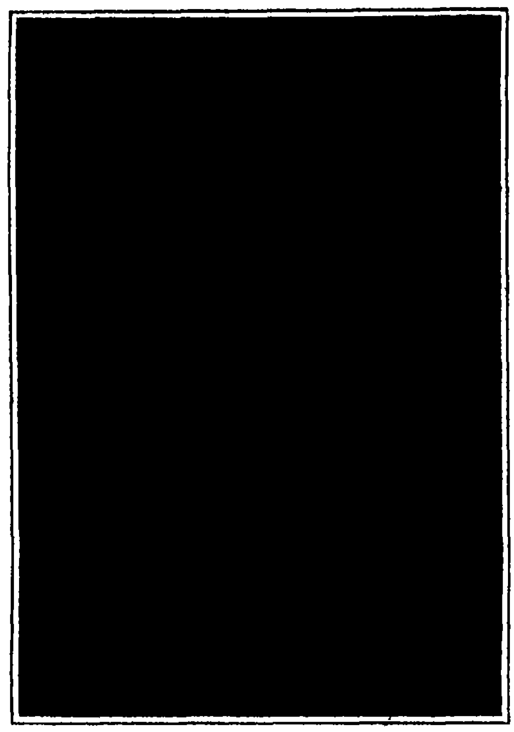
Among the many groups of birds possessing ornate qualities few are so hardy in captivity or thrive with such meager care as that formed by the cranes It is true that the ornamental value of these birds is not as yet fully recognized in America, although they are kept extensively on European estates still large numbers of cranes are brought to this country annually and there is no doubt that their popularity is steadily increasing

Captive cranes are perhaps of greatest interest when enjoying their liberty on an extensive range but the aviculturist who is truly interested in them will wish to confine his specimens where they can be kept under closer observation For this purpose a plot of two or three acres of ground should be selected and inclosed by a fence which need not exceed five feet in height The crane paddock in the New York Zoological Park is so nearly an ideal home for most of the members of the society's excellent collection that a description of it may be of interest

The paddock is about 150 feet square and is surrounded by an ornamental fence averaging four feet in height. While most of the inmates are pinioned they can leap this fence easily when alarmed although they never attempt to do so under ordinary circumstances The inclosure is well carpeted with grass which is kept closely cropped during the summer months A number of large shade trees is included within its limits besides several clumps of shrubs which afford seclusion to any birds which desire it One of the most valuable features however is a little stream that traverses the entire length of the paddock The birds derive an infinite amount of pleasure from wading and probing about in the little pools and the effect produced is certainly most pleasing to onlookers A small shed is provided for use during severe weather The Manchurian whooping white necked sarus and sandhill cranes are confined here while the others are divided between the wild fowl inclosure and the ostrich house

Few birds require so little attention as the cranes Their chief food is grain but occasional mice frogs fish or chopped meat are always appreciated and become a necessity during cold weather Many of the species are perfectly hardy provided healthy specimens are secured It acquired in the spring and given an opportunity for becoming acclimated they will live in the open through the winter happily and well requiring only that they receive their food and water regularly Some protection from wind should be provided of course and it is well to place within the inclosure a small shed although it is safe to say that the birds will use it rarely unless driven in

* Zoological Society Bulletin.



THE CROWNED CRANE (BALEARICA PAVONINA)

A surprising assiduity in the search for worms and tender roots is a failing which may become serious and result especially after rain in the uprooting of patches of turf Generally this can be checked effectively either by confining the birds for a short time following showers or by covering their favorite feeding grounds with small branches

The greatest difficulty in the maintenance of a large collection of cranes is found in the erratic disposition of the birds A number may live together for months in perfect harmony but just as the collector begins to congratulate himself on their good behavior one may be found with an eye missing or with its skull pierced' It really is not safe to associate the larger and smaller species in a permanent group unless the inclosure be very large or the number of birds very small Great care must be taken in introducing strange birds to a flock already well settled The new-comers are certain to be subjected to a more or less harrowing inspection by the original inmates who consider them as nothing more than intruders The strangers will be persistently driven from pillar to post for some days and will be fortunate indeed if they escape without some injury The safest way to establish a crane family is to place all of the intended members in the inclosure at the same time then none can use the prestige of previous occupancy as an excuse for tyranny Brought together in this abrupt manner the birds will soon learn to tolerate one another

The Order Gruiformes includes besides the true cranes six groups of remarkable birds such as the sun bitten the kagu and the seriema, which have been assigned to this order in lieu of a better place. Their structures are confusing and their relationships obscure The birds with which we are to deal here are divided into nineteen species which form the Suborder Grues and are cosmopolitan, with the exception that none are found in South America. Asia is particularly fortunate in being the home of seven species. Some of these birds are fairly easy to obtain alive but most of them are far from common in captivity and a few are seen rarely if ever

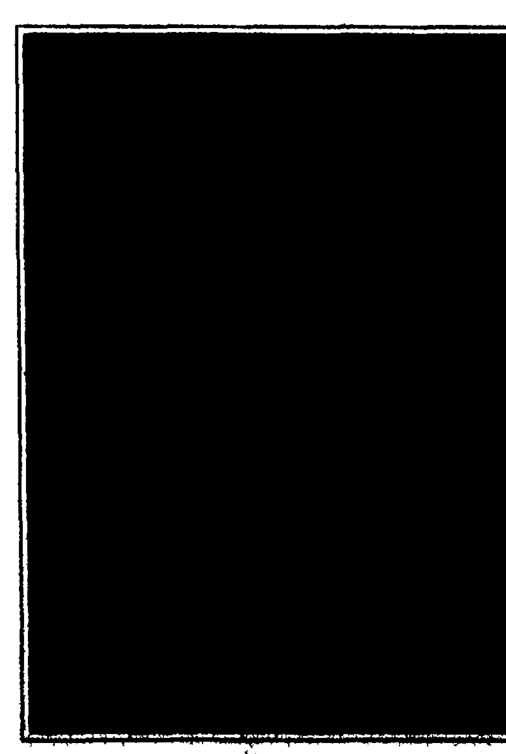
At present nine species all of which possess characters of interest are included in the Zoological Park collection Several of these are members of the genus *Grus* which includes the three species of North American cranes

The Sandhill crane (*G mexicana*) still is fairly common on the plains of western North America, where there is little cover to shelter skulking enemies, This is the most numerous of our cranes and therefore the best known It is rather small as compared with most of its relatives its length being about forty six inches its color is a uniform slaty gray with the bare skin of the crown reddish In captivity this crane becomes delightfully tame and is very hardy and long lived This species nested in the Zoological Park in 1904 and 1905 but the eggs proved infertile on both occasions

The little brown crane (*G canadensis*) is a very close relative of the sandhill and is distinguished by its smaller size and shorter tarsus It breeds through Arctic America and Siberia migrating to the western United States and Mexico for the winter The inaccessibility of its habitat explains its long confusion with the sandhill and also accounts for its scarcity in captivity The species is not represented in the collection at present.

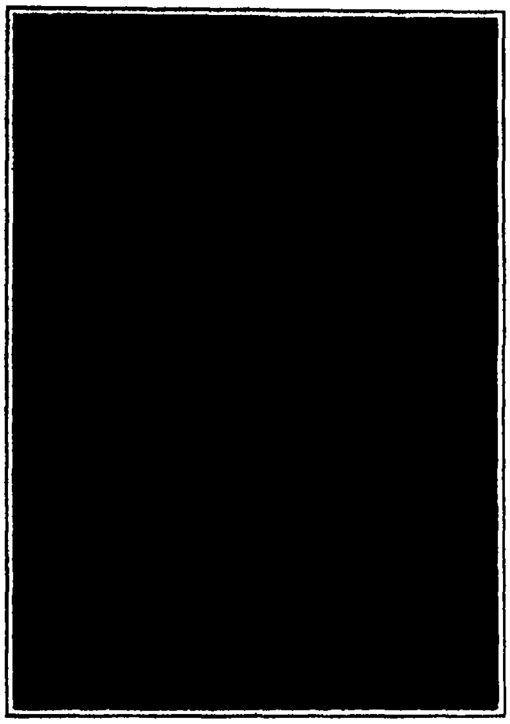
The third and rarest of the American Grues is the beautiful whooping crane (*G americana*) It is pure white in general color but the primaries are black and the bare portions of the head are reddish bordered posteriorly by a patch of blackish feathers The secondaries are curved downward and arch gracefully over the tail No doubt the great scarcity of this bird is due in part to reckless shooting but it seems probable that the invasion of settlers into its breeding grounds in the great middle territories of Canada, and the increasing cultivation along its migration route through the Mississippi Valley are hastening the inevitable extermination of this finest of American birds The numerical condition of a species in the wild state generally bears an exact ratio to the frequency with which it is met in confinement It is probable that the number of whoopers in captivity could be counted on the fingers of one hand It is unfortunate that this splendid crane cannot be induced to follow the example of the wood duck which is willing to save itself

THE BEAUTIFUL WHOOPING CRANE (G AMERICANA)



THE PARADISE CRANE (TETRAPTERYX PARADISEA)

from extermination by breeding freely in captivity Most of the wood ducks seen in American collections are birds bred in Europe! But cranes of most species are bred only on rare occasions, and then with great difficulty so there seems little to hope for from this source The Zoological Society is fortunate enough

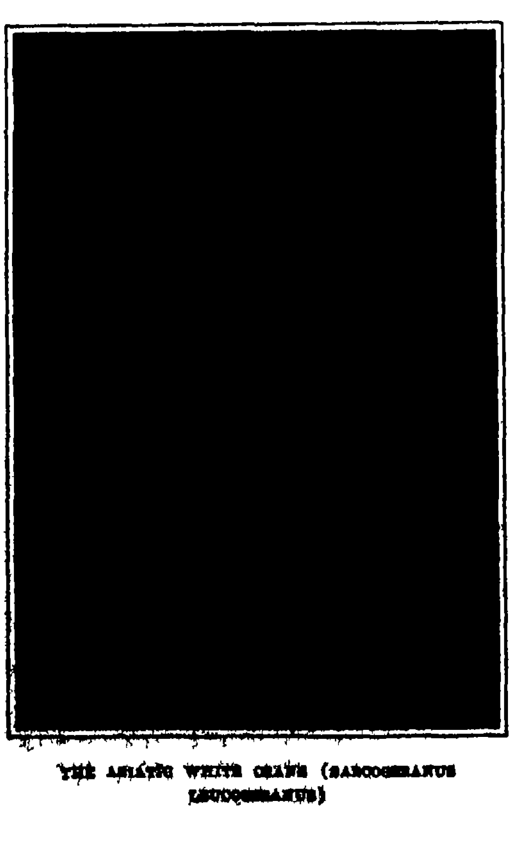


THE LITTLE BROWN CRANE (G CANADENSIS)

to possess a very fine whooper and it is hoped that he will be blessed with the usual longevity of his race

The Manchurian crane (*G japonensis*) is one of the most strikingly handsome of all the group It is very uncommon in captivity and now for the first time is represented in the collection Its general color is white as in the whooper but in this case the arched and pointed secondaries are black and the primaries white A slaty black band extends down each side of the neck the two joining on the nape The bird measures about fifty inches from tip to tip when fully extended It ranges from eastern Siberia to Corea and Japan in the last named island it was formerly held sacred and was allowed to be hawked by the nobles only The cranes depicted on Japanese screens are usually of this species

Next in systematic order comes the Asiatic white crane (*Sarcogeranus leucogeranus*) It is considerably smaller than the foregoing and is found from southeastern Europe to China and Japan It is white the primaries black and the head bare and reddish in color The immature birds of this species as well as those of the whooper have the white plumage infused with cinamon buff giving them a remarkable appearance This is one of those species most easily obtained alive and is brought to this country in some numbers It is quite hardy and easily tamable The specimen in the Zoological Park however has a temper so irascible that he cannot be approached with impunity and is no longer allowed the freedom of the large paddock.



THE ASIATIC WHITE CRANE (SARCOGERANUS LEUCOGERANUS)

Of the larger cranes the sarus (*Antigone antigone*) an Indian species, is most commonly seen in collections. It is the tallest of the order sometimes attaining a length of sixty inches Its color is a handsome French gray the overhanging secondaries closely approaching white the head and the upper part of the neck are bare and reddish the gray feathers of the lower neck being bordered above by a band of white The sarus is a most vigorous bird and inclined to be dangerous when associated with smaller and weaker species its height strength and an uncertain temper make it a companion to be feared

One of the rarities of the collection is the white-necked crane (*Pseudogeranus leucauch n*) This is a medium sized bird of a beautiful shade of gray with the throat and the posterior portions of the head and neck white the gray of the shoulders commencing at a sharp line The anterior part of the crown is bare and reddish The long and falcate secondaries which are very light in color are curved less abruptly and hence more gracefully than in some other species It is found in eastern Siberia, Corea and Japan and is very seldom imported alive In captivity it is quiet and docile showing a most pleasing absence of the pugnacity so frequent among its congeners

A crane of unusual and handsome appearance is the Stanley or Paradise (*Tetrapteryx paradisea*) It is a bird of fair size ranging throughout the southern portions of Africa where it is fairly common In color it is a uniform slate becoming practically white on the head the feathers of which are so lengthened as to give it a strangely swollen effect The drooping secondaries reach the height of their development and beauty in this species The Paradise is a very desirable bird for the aviculturist, for both its docility and beauty it is imported very infrequently

In captivity the crane most frequently seen is the dainty Demoiselle (*Anthropoides virgo*) It is the smallest of the family as well as the most widely distributed since it breeds in southern Europe and central Asia and spends the winters in southern Asia and northern Africa. Its general color is the conventional gray set off by the elongated black feathers of the breast, those over the eyes being drawn out into lateral tufts of silky white The demoiselle is brought to the United States each year in scores for the demand for it is great Its small size reduces its capacity for mischief even if its usually even temper should allow it to fall from grace its engaging ways excite the admiration of all who have opportunity to observe them This crane is willing to breed in confinement and has done so in this country on at least two occasions

The crowned crane (*Balearica pavonina*) of western Africa, differs from all the others in the possession of an occipital patch of straw like plumes from which it derives its name It is a handsome bird the blackish slate of its body plumage being contrasted by white wing-coverts and chestnut secondaries The sides of the head are bare and colored white above and pink below there are two small pinkish wattles on the throat. This crane is uncommon in America very few having been imported It is long lived and attractive and not so determined a root digger as most others but its temper among the society s specimens at least, is decidedly choleric

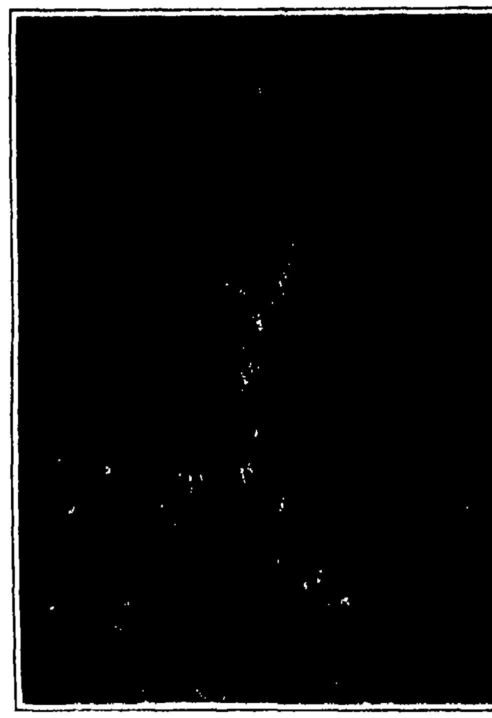
All of the cranes nest on the ground usually in marshes or on open plains forming their nests of grass and rushes The eggs are generally whitish or buff in color double-spotted with yellow or brown blotches and commonly two in number

Young cranes are most precocious being able to run about quite freely soon after hatching For a short time before the youngsters commence to forage for themselves their food consists mainly of insects brought to them by the old birds The parent birds are very devoted to their offspring caring for them with great solicitude and guarding them valiantly against intruders If an attempt to breed cranes in captivity is to be made a large grassy run should be provided for the exclusive use of the family as anxiety for the welfare and safety of the chicks is apt to make the parents over zealous in the treatment of the others in the same corral

An adult crane is a formidable antagonist not to be despised even by a man Frequently some members of the collection are so savage that they must be isolated, and the keeper must then continually guard himself against attack The crane stretches his long neck to the uttermost, and without hesitation makes frantic thrusts with his powerful beak so swift and certain that the eye can scarcely follow the movement.

An interesting characteristic of cranes is their habit of indulging at frequent intervals in grotesque dances which may be performed by an individual or by a group in graceful unison The leader starts off leaping and bowing with broad wings widely expanded, now seizing a leaf or bit of stick, now tossing it aside in capricious disdain The spirit of the dance is infectious and instantly the enclosure is a turmoil of leaping bobbing birds each striving to outdo the others in extravagance of gesture and motion

Most of the species are provided with lusty voices which they delight to use with great freedom However the tones which are clear and trumpet like are far from disagreeable and detract nothing from the performer s eligibility to a favored place in the list of captives



IL SANDHILL CRANE (G MEXICANA)

Animal Husbandry

EXPERIMENTS in breeding carriage horses has been continued in Colorado and Morgan horses in Vermont. The Colorado stud now has 71 animals the Vermont stud 30 Several additional zebra ass hybrids have been produced those now in their second year are larger than their dams though not as large as their sires That beef production may be a profitable business in the South when the cattle tick has been eradicated is shown by feeding experiments in Alabama now in progress for six years Feeding experiments with poultry indicate that fowls will not readily eat a ration containing more than 30 per cent of cotton seed meal and no harmful effects have resulted from such a feed Studies of the egg trade show that better methods of handling will greatly reduce the losses

The Secretary of Agriculture suggests that in order to secure the 2 000 or 2 500 horses now needed by the army every year 100 stallions should be owned by the Government and arrangements should be made for securing mares of proper type the War Department to have an option on the purchase of the foals

THE DEMOISELLE CRANE (ANTHROPOIDES VIRGO) THE SPECIES MOST FREQUENTLY SEEN IN CAPTIVITY

New Theories of the Evolution of Stellar Systems

Successors of Kant and Laplace

By F W Henkel, B A., F R A S

During the last f w years the researches of Chamberlin F R Moulton and See on the evolution of our system have greatly shaken the faith of astronomers in Laplace s well known Nebular Hypothesis More than a century ago Laplace who more completely than any other had worked out the consequences of Newton s theory of gravitation to the satisfactory explanation of almost every known feature of the motions of the planets developed a hypothesis previously proposed by Swedenborg Wright and the great philosopher Kant The solar system consists of a number of bodies arranged in an orderly manner all moving in nearly circular paths round the central body these paths being all nearly in the same plane and their motion in the same direction while there is a fairly regular progression of distances from the sun (Bode s Law) and the bodies are either spherical or spheroidal These features are by no means a necessary consequence of gravitation and seemed to imply an original connection or common origin Laplace supposed that at one time the matter now forming the sun earth and other planets was in the form of an intensely hot gas perhaps hotter than the sun is now This mass was of approximately spherical form and rotated slowly on its own axis the rotation becoming swifter as the mass grew colder and contracted In time rings of matter would be left behind the main mass (not thrown off as is sometimes stated) each of these rings would gradually collect into a single globe and thus the planets would be formed A planet thus formed continuing to revolve might itself abandon rings in contracting these rings would form into the satellites The rings of Saturn were at one time thought to be examples of this process but we now know that they are composed of swarms of meteorites rather than of continuous substance Plateau devised an experiment illustrating this formation of rings He prepared a mixture of alcohol and water of a specific gravity as nearly as possible equal to that of oil Some oil was then poured into the mixture As the bottom of the mixture was slightly more dense than the oil and the top slightly less dense the oil sank half way and floated in the middle as a round ball By means of a disk attached to a wire the ball of oil was set rotating The effect of the rotation caused the oil globe to expand into the form of a spheroid flattened at the poles and this flattening increased with the speed until at last a ring was formed which revolved round the globe After a time the ring broke up and gathered into a smaller globe which rotated besides revolving round the large globe

Laplace supposed that the rings would rotate as though solid their outer edges thus moving more swiftly than the inner and thus the planets formed therefrom would rotate in the same direction The exceptional cases of our system—the fact that the satellites of Uranus and Neptune move in the opposite direction to that in which most of the other members do and the swift revolution of the inner satellite of Mars—cannot be explained by this form of the hypothesis

M Faye however by modifying the original idea of Laplace and supposing that the planets were formed by local condensations (not by the detachment of rings) within the revolving nebula and that the outer planets Uranus and Neptune have been more recently formed than the rest has shown that these bodies would have retrograde rotation on their axes which he supposed to be the case from the motion of their satellites Since however Saturn s rotation is in the same direction as that of our own earth and eight of its satellites move in one direction but the last discovered (Phœbe) moves in the opposite direction we have still a difficulty unless we suppose this body to be a recent capture and not an original member of the Saturnian family The same thing is the case also with the eighth satellite of Jupiter whose motion is retrograde while the other seven have direct motion Prof Sir George Darwin by his theory of tidal evolution has attempted to explain the swift motion of the inner satellite of Mars the fact that the moon always turns the same face toward the earth and that the rotation period of Mercury (and probably that of some of the satellites of Jupiter and Saturn) is the same as that of its revolution He has given reasons for thinking that in former ages the period of rotation of Mars was much shorter than at present but that by tidal action of the sun this period has been gradually lengthened to its present value at the same time the satellite s period is supposed to be shortening and its distance from the planet slowly diminishing In the case of the moon he considers that millions of years ago our earth was rotating much more quickly than at present In contracting a portion separated from the rest and gradually receded becoming the moon The earth s tidal action upon the latter has resulted in the periods of rotation and revolution becoming equal to one another The ancient Arcadians are said to have boasted that their race came into existence before the moon but they were probably unaware of the period they claimed for their ancestry (fifty-seven millions of years!) The observations of Schiaparelli having led him to the conclusion that the planet Mercury (which is the nearest known planet to the sun) rotates on its axis in a period equal to that of its revolution round the sun (88 days), Sir George Darwin considers this is due in a similar manner to the tidal action of the central body having lengthened the planet s period of rotation until the latter always presents the same hemisphere toward the sun just as the moon does toward the earth The same thing has been asserted of the planet Venus also but it still seems probable that the shorter period of 23½ hours determined by the early Italian observers is the true length of the day on the earth s twin sister

Further modifications in consequence of increased knowledge of actual existing nebulæ and the applications of the principles of energy and thermodynamics have been proposed from time to time and most supporters of the nebular hypothesis no longer believe that in its original condition the nebula was even at so high a temperature as that of the sun at present It is considered probable that the original nebula was largely composed of meteorites which by collisions during their gradual drawing together would grow hotter and hotter After a time the central mass would become an intensely hot white star Later on the loss of heat from radiation exceeding the gain from contraction and condensation the star would cool down and perhaps finally become a dark body like the companion to Algol The planets being smaller than the star or sun round which they revolved would cool down at a much quicker rate losing more heat from their surfaces and becoming non luminous bodies while their interiors would be still very hot Our earth and the inner planets seem to have reached this stage while Jupiter and Saturn appear to be still to a small extent self luminous Estimates of the past and future duration of our system have been formed by Lord Kelvin Helmholtz and others but the very various lengths of time given ranging from twenty to four hundred millions of years alone show that these periods are little more than rough guesses needing further knowledge to be of value The discovery of the properties of radium has enormously extended the probable future duration of the sun s heat "We have every reason to think says Arrhenius that the sun s chemical energy will suffice to maintain its heat during thousands of millions perhaps billions of years

In 1861 Babinet proposed the application of a criterion based on the mechanical principle of the conservation of areas He showed that if ω be the sun s angular velocity of rotation with radius r and ω_1 represent these quantities when the globe is expanded so as to have the radius r_1 then

$\omega r^2 = \omega_1 r_1^2$ [Moment of momentum a constant quantity for a system rotating freely and subject to no external forces]

or

$$C = \Sigma m r^2 \omega = \omega \Sigma m r^2 = \omega_1 \Sigma m r_1^2$$

Suppose now the solar nebula extending to the earth s orbit let us find its time of rotation We get for this

$$25.3 \text{ days} \left(\frac{23\,445}{109.5}\right)^2 = 3\,192 \text{ years}$$

For the case of Neptune whose mean distance is thirty times that of the earth from the sun the solar nebula when reaching to that distance will rotate in

$$25.3 \text{ days} \left(\frac{30 \times 23\,446}{109.5}\right)^2 = 2\,888\,533 \text{ years}$$

(These figures are taken from a paper by Dr See)

Applying this criterion to the case of the various planets and satellites of our system we find periods in every case much greater than the known periods of revolution of these bodies The earth revolves in one year about the sun Neptune in about a hundred and sixty five years Thus it follows that the 'hypothetical solar nebula could not have rotated with sufficient speed to detach the masses" when it extended to the orbits of the several planets, as Laplace supposed. The evolution of the planets by separation of rings of matter from the central condensation through rotational instability must therefore be abandoned It is, however possible that secondary condensation nuclei might be formed by gravitational instability within the gaseous nebula and this has been pointed out by Mr Jeans in papers which he has contributed to the Philosophical Transactions of the Royal Society

We turn now to the alternative hypothesis developed by the work of Prof T J J See He has recently pointed out that some remarkable anticipations of his views as to the action of a resisting medium were made by Euler in 1749 The essential features of this hypothesis are that the Solar System has been formed from a spiral nebula and that the planets have not been detached from the central mass through its rotation but have been captured or added on from the outer parts of the nebula The roundness of the orbits of the planets and satellites in general use is due to the action of a resisting medium which has reduced the size of their paths and well nigh obliterated the deviations from circularity Just as the planets have been captured by the sun s action so in like manner the satellites have been captured by their several primaries not detached by rotation of these latter The moon too was originally a planet which neared the earth and was finally captured and made a satellite The asteroids or minor planets between the orbits of Mars and Jupiter are the surviving remains of millions of small planets most of which have been swallowed up by colliding with larger ones though many are still moving in independent paths round the sun Our own earth frequently encounters some of these objects and we have then a more or less brilliant meteor shower" The satellites having been captured in this way it is not surprising that a few of them should revolve in the opposite direction to the rest It is also remarkable that the paths of Phœbe (Saturn s 9th satellite) and of the 8th satellite of Jupiter are much more oval than those of any other known satellites from which it would appear that the density of the resisting medium must have been very slight at the great distances from the planets at which they revolve The planetary rotations have also been produced by the capture and absorption of small bodies and thus the larger planets Jupiter and Saturn should rotate most rapidly as is known to be the case

It has long been known that the effect of a resisting medium on the paths of bodies moving in it in a manner analogous to the planets moving round the sun is (1) to reduce their distances from the central body (2) to diminish the eccentricity of their orbits i e to make these more nearly circular

The proof of this is given in works on analytical dynamics (Cheyne s *Planetary Theory* and other books) and was of course well known to Laplace who says At the same time the planet approaches the sun by the effect of the resisting medium the orbit also becomes rounder The well known comet of Encké is thought to be gradually drawing nearer to the sun by such an action

Thus the present shape of the planetary paths is accounted for the action of the resisting medium having changed their orbits Around each planet circulates a vortex of cosmical dust and the descent of this material upon the surfaces of sun and planets is considered to give rise to the accelerations of their equatorial regions—i e the fact that the parts of the sun Jupiter and Saturn near their respective equators have a shorter period of rotation than those farther north or south However there is no perceptible difference of rotation in different regions of our own earth or of Mars so far as known and the amount of matter required to produce such an effect (at present) seems greater than can reasonably be supposed to fall upon the surfaces of the planetary bodies

A similar difficulty occurs in the meteoric theory of the sun's heat, attributing the latter to the impact produced by the fall of countless meteorites upon its surface. No doubt such bodies do fall upon the surface of the sun in considerable quantities, but the amount required to maintain the sun's output of heat is so enormous that there should be an enormously greater quantity in regions near the sun so that our own earth ought to receive nearly half as much heat as she gets from the sun by impact with meteors. This is certainly not the case

The descent of matter upon the sun increasing its mass may also account for the small secular acceleration of the earth indicated by the observations of eclipses, and the outstanding motion of the perihelion

of Mercury, which Leverrier attributed to a planet or ring of small planets lying between Mercury and the sun, may be also explained in this manner

The moon having suffered numerous collisions with smaller satellites has had its surface marked with the round sunken craters which are so distinctive a feature

So different a theory from the ordinary volcanic one however will not be easily accepted by selen ologists Prof See considers that the almost perfect circularity of Neptune s orbit shows that it cannot be the outermost planet of our system the roundness indicating that the nebulous medium was quite dense at that distance and consequently the limits of the system are much farther out Others planets lying beyond Neptune have been suspected and may yet be discovered by the telescope It is remarkable that Prof Forbes considers that one of these bodies whose distance he supposes is about a hundred times that of the earth from the sun and consequently would have a period of a thousand years (by Kepler s third law squares of periodic times as cubes of distances from sun $1\,000^2 = 1\,000\,000 = 100^3$) moves in a very eccen tric orbit whose plane makes a large angle to that of the ecliptic the resisting medium at that distance apparently having had little effect on its motion

The solar system in the opinion of Prof See was formed from a spiral nebula the latter arising from the meeting of two or more streams of cosmical dust The system began to whirl about a central point and thus gave rise to a vortex Great numbers of spiral nebulæ are now known to exist scattered out over the heavens millions of these objects being visible in the most powerful telescopes On the other hand it has been pointed out that there are very few nebulæ of the oblate spheroidal form such as the hypothesis of Laplace assumed to be met with in the sky Such nebulæ as we see have it seems a greater analogy with the solar corona than with the fiery condensing mists conceived of by Laplace (Proctor Old and New Astronomy § 1447)

The rotation period of Mars being about 24 hours 37 minutes and that of our own earth 23 hours 56 minutes Prof See considers that the period 23 hours 21 minutes for Venus obtained by the early Italian observers, is probably about its true value and thus the planet is habitable and probably inhabited by intelligent beings

It is well known that periodic comets probably owe their present position as permanent members of our system to the action of the planets When a comet coming from outer space in a parabolic orbit ap proaches a planet its motion is either accelerated or retarded In the latter case the parabola becomes an ellipse and the comet henceforth moves in a closed path around the sun always coming at each revolu tion to (or near to) the point where this retarda tion commences Thus arise the planets families of comets

A very large number of members of Jupiter s family of comets are known Halley s famous comet is a member of Neptune s family In a similar man ner it is supposed that the asteroids and satellites have attained their present positions The whirling of the gaseous matter of a spiral nebula is considered to be due to the unsymmetrical meeting of two streams or to the settling down of a nebula of unsymmetrical figure From this ultimately results a star surrounded by a system of planets and satellites The two oppo site branches of spiral nebulæ often seen on photo graphs represent the original streams of cosmical dust which are coiling up and forming spiral sys tems If the streams so converge that the nebulous mass becomes very concentrated the nebula may di vide at its center and give rise to a double star

This theory of the capture of the planets and the rounding of their orbits by the action of the resisting medium gives results in some cases the exact oppo site to those which are given by the theory of tidal evolution as investigated by Sir George Darwin

While tidal friction usually increases the major axis and eccentricity of an orbit the resisting medium as regularly decreases both elements In the actual physical universe both causes are at work together sometimes one influence preponderating and then the other With a large central sun and small planets as in our system the action of the resisting medium is most effective for systems made up of two large masses tidal friction is the predominating agency

There can be little doubt that these researches form a most important advance in our knowledge of the genesis of our system and though answers more or less satisfactory may be found to parts of the criti cism of Laplace s famous hypothesis yet we may fairly say that if not completely disproved it has been very seriously undermined

It is not to be supposed however that the alterna tive hypothesis is free from difficulties some of which have been slightly outlined but we may still say that it gives a reasonable explanation of many remarkable peculiarities Further evidence in its favor is no doubt wanted as well as spectroscopic proofs of mo tions derived from the study of actual existing spiral nebulæ Some recent work by Dr Nolke on the effect of a resisting medium in the evolution of the solar system from a primitive nebulous condition has been published by him at Berlin Sir George Darwin in his article on The Genesis of Double Stars gives an interesting historical account of work on the theory of the equilibrium of revolving liquid bodies by Poin caré Jeans and others together with an application of their results to stars of the Algol type Probably there is no subject more fascinating than the question as to the past and future of our system and though from our limited experience both in time and space there is the greatest necessity for caution in drawing conclusions yet the mind of man seems so consti tuted that it cannot help doing so It remains for the future to show whether the vast masses of ob servational data accumulated by the persevering in dustry of self denying men of science can be put together in the manner indicated above to yield the laws of stellar evolution —*Science Progress*

Cheese as an Article of Diet

A Food That is Much Neglected

WHILE experiments have established the facts as to some debatable questions concerning the comparative digestibility of green and cur d cheese perhaps the most valuable result has been in showing clearly the great value as food of all the more common varieties of cheese

The Swiss who are a very healthy people eat largely of cheese in fact bread and cheese form the greater part of the diet of many of them Many other European races eat largely of cheese The miners of England consume very much of the poor cheese made in the United States especially the high acid cheese using it extensively for seasoning and the Germans eat large quantities of the cheap but highly flavored skim milk cheese such as the hand käse which has perhaps the most pungent ordor of all the varieties of cheese made

In the matter of comparative food values it was thought that the results of the experiments given in this report made it safe to assume that cheese was as fully digested as most of the ordinary food materials which have been studied in earlier experiments car ried on in connection with the nutrition work of the Department of Agriculture It would in fact be un desirable for a larger per cent of any food material to be absorbed than was the case with the cheese

Heretofore cheese has seldom been regarded seri ously by consumers of any class in the United States as a possible cheap staple food All consumers of cheese with very few exceptions use it as a luxury in small quantities at comparatively rare intervals While in the aggregate a large quantity of cheese is eaten in the United States the quantity is neverthe less almost negligible when compared with some other products of less food value and inferior palat ability

The greater part of the cheese consumed in this country is eaten without any preparation while in many European countries the cheese is either sprinkled on other foods—vegetables usually—or is cooked with the food Americans evidently have much to learn from Europeans of some of the possibilities of preparing such dishes A number of European vari eties of cheese are made extensively and exclusively for use in connection with other foods or in cooking Among these is the well known Parmesan a hard cheese made from skimmed milk and also the sap sago cheese a small conical-shaped cheese made from skimmed milk and highly seasoned with herbs The Italians use cheese for flavoring as Americans use salt and pepper having it grated and constantly at hand in a small shaker With them macaroni with cheese is a common dish, as are other cheese preparations An excellent dish is the cheese omelet while warmed up potatoes can be mad very appetizing when cook d with cheese

It may be perhaps that the American people have gone so far in the consumption of only partly ripened and mild flavored cheese that the probability of learn ing to use cheese as a flavoring are very remote as it is only the well ripened or highly flavored cheeses that are satisfactory for flavoring purposes It is per haps a matter for some regret that so much mild flavored cheese has come to be us d as it is probable that much more satisfaction would be felt by con sumers in general with this great food product if they had learned to like the well ripened product with a well developed flavor It is generally conceded that people who like a highly flavored cheese never become tired of it

A comparison of the food value of cheese with that of other highly nitrogenous food materials may be of interesting value No kind of meat excepting dried beef carries such a large percentage of protein as cheese and as dried beef contains a much greater percentage of water the other food constituents aside from the protein are much less than is found in cheese Fresh beef as purchased has weight for weight little more than half the food value of cheese in either protein or fat and the same is true of prac tically all other fresh meats which have in many cases such a large percentage of refuse and in all cases such a large percentage of water that they are noticeably inferior to cheese in food value Bacon or fat pork are exceptions but their food value is mostly in the fat which can be and is replaced to a great extent by the carbohydrates of vegetables at a much less cost and sometimes perhaps at a benefit to the health of the consumer Fish and pork each have a notably large percentage of refuse while eggs have a high percentage of water To sum the matter up a pound of cheese has nearly the same food value as two pounds of fresh beef or any other fresh meat as food It is worth as much as or more than a pound of ham and is more digestible and it is equal to two pounds of eggs or three pounds of fish In price good cheese made from unskimmed milk costs about a third more than round steak and twice as much as the cheaper boiling beef while it costs practically the same per pound as smoked ham and bacon It costs usually a third more than fresh fish

Cottage cheese or cheese made from partially skimmed milk is cheaper even than the American or Cheddar cheese The first costs about one third as much and the partly skimmed product about two thirds as much as the so-called full cream cheese Practically the only food product that rivals cheese in food value and cheapness is dried beans

In view of the foregoing comparison of food values it is a matt r of som wonder why there is not more of a demand for cheese especially by people of lim ited means Estimates made by the Departm nt of Agriculture in the twenty second and twenty sixth annual reports of this bureau and in Bulletin 55 of the Bureau of Statistics show that the people of the United States consume between 169 and 185 pounds of meat annually per capita besides fish and poultry while the annual consumption of cheese is only about four pounds per capita Even granted that fresh meats are more palatable to most people some other explanation must be found for this wide difference in the quantity of the two products eaten A great pro portion of the laboring class in this country are able to eat plenty of wholesome food but they cannot af ford to discriminate against a cheap palatable and wholesome food in favor of a higher priced food The only way to account for the comparatively limited de mand for cheese is on the basis of custom and lack of knowledge People usually eat what they have been accustomed to making variations within narrow limits only and never changing the general character of their food New foods are not sought

In this connection particular interest attaches to the quantity of salt or cured pork products eaten in comparison with cheese Cured pork ham and ba con to about seven times the value of cheese are eaten annually No one can say that the pork prod ucts with the exception of good ham are more palat able than cheese and they are not known to be more healthful These pork products are usually eaten by the poorer classes who cannot afford to buy fresh meat but who could afford to buy cheese and cheese makes a better food in the dietary because of its high protein content

Cheese can no longer be discriminated against be cause of a suspicion that it is not a healthful food The absolute lack of any disturbance of the general health of the subjects used in th experiments re ported in this bulletin is proof that cheese can be eaten in large quantities without danger to health The Swiss cheesemakers also many of the Swiss farmers of southern Wisconsin eat unusually large quantities of cheese and they are noted for athletic attainments and physical endurance They brought the custom of eating cheese from their native coun try where cheese is a very important item in th diet The consuming public especially that part of it which needs to practice economy in buying food would do well to turn its attention a little more toward cheese since greater quantities can be used at a saving to the consumer —Abstract from Circular 166 Bureau of Animal Industry

The Use of Electricity in the Metallurgy of Iron

A Turning Point in the History of Iron

A turning point in the history of iron occurred in the sixteenth century when the increasing demand for iron led to the employment of water power to work the bellows of the blast furnace and consequently led to the location of iron works beside water falls The steadily increasing capacity of the bellows which was made first of leather afterward of wood and was not superseded by the iron cylinder pump until 1760 enabled the height of the furnace to be correspondingly increased the fuel (wood charcoal) to be better utilized and the temperature to be raised sufficiently to produce large quantities of fused pig iron containing much dissolved carbon instead of the small lumps of half fused malleable iron produced by the old low furnace with its bellows laboriously worked with the hand or foot

The invention of the steam engine made it possible to dispense with water power so that in the eighteenth century the iron industry began to leave the waterfalls and to seek sites convenient to the coal mines for the depletion of the forests made it necessary to employ coal or coke instead of wood charcoal Now barely 150 years after this second revolution the iron industry appears to be returning to the streams at least in regions abounding in water power and thus preparing for the day some 200 years hence when it will be necessary to economize the rapidly diminishing store of coal by obtaining from electrical energy produced by water power most of the heat required for the manufacture of iron

This is the opinion of Dr Prettner who gives in

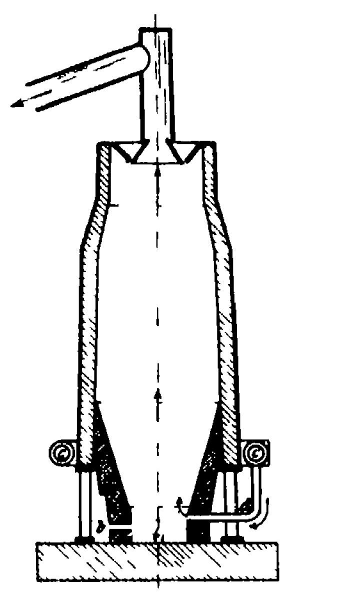


Fig 1 COMMON BLAST FURNACE

Ir mathcus the following comparison between electric and other iron and steel furnaces

Iron furnaces heated by coal or gas are of two classes blast furnaces in which pig iron is produced from the ore and the various furnaces employed in the transformation of pig iron into malleable iron and steel of different qualities For the present the same distinction must be observed in electric iron furnaces although it appears possible to produce steel directly from iron ore in the electric blast furnace Hence we will first compare the ordinary blast furnace with its electric rival and then make a similar comparison of refining and steel furnaces

The world's annual output of 50 million tons of pig iron is practically all produced in blast furnaces of the general type shown in Fig 1 The ordinary furnace of this type is 60 or 70 feet high and produces about 100 tons of pig iron per day but 300 tons are produced daily by each of the two largest German furnaces operated by the Krupps and the Rhenish Steel Works

The furnace is filled with alternate layers of coke (sometimes charcoal especially in Sweden) and of iron ore mixed with a certain proportion of limestone or other slag forming material As the mass settles down in consequence of combustion and fusion the furnace is replenished at the top and the operation continues without interruption for months or years The very high temperature estimated at 2 000 deg C (3 632 deg F) required at the bottom or hearth is obtained by a blast of air heated to 500 or 600 deg C (about 1 000 deg F) which is forced in through pipes called tuyères (*d* Fig 1) The carbon dioxide (CO_2) formed by the combination of the entering air with the glowing coke which it first meets takes up more carbon from the other layers and is thus reduced to carbon monoxide (CO) At the bottom of the furnace some of this carbon monoxide meets small grains of very hot but unmelted and very pure iron and is partially reduced to very fine particles of carbon, which unite with the iron to form a fusible com-

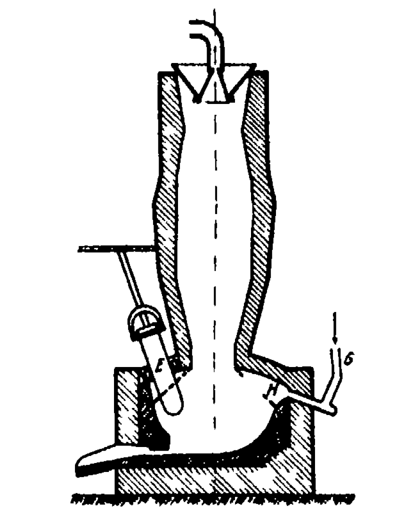

Fig 2—SWEDISH ELECTRIC BLAST FURNACE

pound containing from 3 to 5 per cent of carbon This compound known as pig iron, collects in liquid form at the bottom of the furnace, whence it is drawn off at intervals by tapping the furnace at the point *a*, and is run into sand molds, forming "pigs" The lighter fused slag is drawn off through an orifice at *b* Pig iron contains in addition to carbon varying quantities of manganese silicon phosphorus and sulphur which affect the quality of the iron and determine the methods by which it is converted into steel In the upper part of the furnace another portion of the carbon monoxide reacts with the heated ore (usually an impure oxide of iron) producing carbon dioxide and the pure granular iron already described The gas which escapes from the top of the furnace contains 60 per cent of nitrogen 12 per cent of carbon dioxide 24 per cent of carbon monoxide and 4 per cent of hydrogen and hydrocarbons Hence the mixture is combustible The combustion of one cubic meter of blast furnace gas produces 900 calories, or units of heat (Standard illuminating gas yields 5 000 calories per cubic meter) The gas is burned intermittently in towers or chimneys about 50 feet high containing numerous masonry barriers which store up the heat of combustion and subsequently communicate it to the hot air blast which is passed through the same towers Steam boilers are also heated with blast furnace gas

In its present stage of development the electric blast furnace appears puny and insignificant in comparison with its veteran adversary Canada, rich in ore and water power but poor in coal presents ideal conditions for the production of iron by electricity A Canadian commission experimented with Keller's electric furnace in 1904 and with Héroult's furnace in 1906 The experiments proved that all varieties of iron ore could be reduced by electricity that either gray or white pig iron containing only 1/100 per cent of sulphur could be produced at will by regulating the quantity of coke and that charcoal of inferior

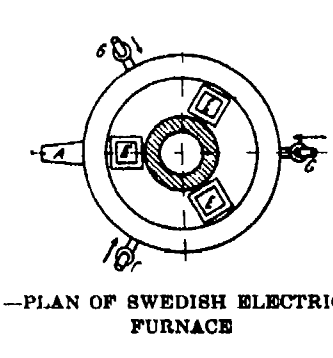

Fig 3—PLAN OF SWEDISH ELECTRIC BLAST FURNACE

quality could be employed (Gray pig iron presents a gray surface of fracture with distinct crystals of carbon in the form of graphite and contains a large proportion of silicon White pig iron presents a white fracture without visible particles of carbon, and contains a large proportion of manganese.)

The electric furnaces used in these experiments were of small height, open at the top and built of fire-resisting stone. The electrodes were blocks of solid or compressed carbon, one of which formed the bottom of the furnace while the other was suspended in the upper part.

Three Swedish engineers, Grönwall, Lindblat and Stalhane, independently of their French predecessors subsequently developed the first practical electric blast furnace in Sweden where the conditions are similar to those found in Canada This furnace was in continuous operation during three months in 1909, until it was stopped by a general strike The results were so encouraging that a 2 500 horse-power furnace capable of producing 7 500 tons of pig iron per year has recently been built and the erection of others is contemplated An ordinary blast furnace produces nearly five times this quantity but the electrometallurgy of iron is still in its infancy

The Swedish electric blast furnace (Fig 2) bears a general resemblance to the ordinary blast furnace It consists of a wide hearth 8 feet high surmounted by a narrower shaft 16½ feet high The various chemical processes which are distributed throughout the height of the common blast furnace here take place almost entirely in the hearth which is lined with fire-resisting magnesite and is arched above so that an annular space (*H* Fig 2) is left vacant above the cone of ore and coke which has descended from the shaft This space is essential to the durability of the furnace and its effect is increased by blowing in cooled furnace gas through the pipe *G* In the preliminary experiments the wall of the furnace was soon punctured at this point by its contact with the electrode and the hot contents of the furnace There are three electrodes of carbon about 5 feet long (*E* Figs 2 and 3) which penetrate the hot mass to a depth that can be regulated and are connected with a three-phase system of 25 periods and about 40 volts The currents traverse the poorly conducting mixture of

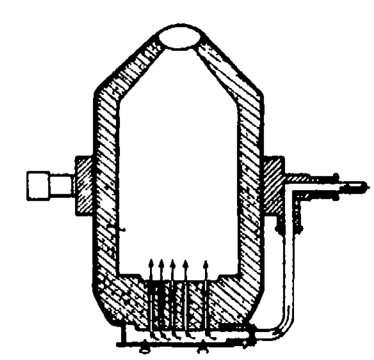

Fig 4—BESSEMER CONVERTER

ore coke etc and heat it so strong that the quantity of coke used need be only enough to deoxidize the ore and furnish the carbon of the fusible pig iron. Thus the large quantity of fuel required to maintain the high temperature of the reaction and to melt the iron and slag in the common blast furnace is here replaced by electric energy As no air is admitted, the furnace gas contains no nitrogen It consists of 40 per cent of carbon dioxide 48 per cent of carbon monoxide and 12 per cent of hydrogen and it produces, in combustion 1 750 calories per cubic meter nearly twice the heat produced by ordinary blast furnace gas This gas is cooled and blown into the furnace to cool the electrodes thus accomplishing a closed cycle It appears probable that by still further diminishing the quantity of coke and by other modifications a sort of crude steel can be produced in the electric blast furnace

The heat produced by 1 kilogramme (2 2 pounds) of good fuel can be furnished according to Stassano by 3 and according to Lowthian Bell by 4 horse-power hours of electric energy Hence in districts where 1 kilogramme of good coal costs more than 3 or 4 electric horse-power hours the electric blast furnace can be used with advantage This is the case in Sweden. In the German iron producing districts in Silesia, Westphalia and along the Rhine iron ore and coal are found so near each other and coal is still so abundant and cheap that electricity is not yet needed for the reduction of iron ore but even here the electric steel furnace has begun to claim attention

In order to describe intelligibly the considerable progress that has been made in the development of the electric steel furnace, we must first review briefly the current methods of producing steel and malleable iron The pig iron produced in the blast furnace is available for a few uses, as cast iron, but its impurities make it too brittle for most purposes It contains, according to the character of the ore and that of the ultimate product of which it is designed to serve as the raw material, the following percentages of impurities carbon 3 to 5, silicon 1/5 to 3, man-

ganese 1/10 to 6 or more sulphur to 1/2 and phosphorus to 3. Wrought iron contains from 1/20 to 1/2 per cent, steel from 1/2 to 1 8 per cent of carbon and neither should contain more than 1 per cent of silicon or manganese or more than 3/100 per cent of phosphorus or sulphur The function of refining and steel furnaces is to reduce the impurities of pig iron to these permissible limits

The classical types of modern steel furnace are the Bessemer and the Siemens Martin

The Bessemer converter invented in 1855 (Fig 4) differs from all other refining furnaces by being hung on trunnions so that it can be emptied by tipping and also by employing no fuel except the superfluous carbon of the pig iron which is poured into it in the fused state at a temperature of about 1 300 deg C (about 2 400 deg F) The converter is made of iron and is lined with quartzite The charge having been introduced compressed air is forced through a pipe which passes through the outer part of one trunnion and terminates in a chamber at the bottom of the converter whence the compressed air flows through a number of passages in the bottom lining and bubbles upward through the molten pig iron burning out most of the impurities particularly carbon silicon and manganese The heat produced by this internal combustion is sufficient to raise the temperature of the mass above 1 800 deg C (about 3 300 deg F) and to cause violent ebullition or spitting if the process is not carefully regulated By this operation the pig iron is converted into very pure malleable iron containing a small proportion of carbon In order to produce steel a quantity of carbon usually in the form of spiegel eisen a variety of cast iron which contains a large proportion of carbon is added toward the end of the process The entire operation including this recarbonizing' phase is accomplished i 20 or 2 minutes and yields from 10 to 15 tons of steel according to the size of the converter

In the Bessemer process the phosphorus of the pig iron is oxidized to phosphoric acid which cannot combine with the quartzite or silica, with which the converter is lined Thomas substituted a lining of lime and magnesia which absorbs the phosphoric acid and permits the employment of pig iron containing a large percentage of phosphorus The used linings form a by product known as Thomas slag which contains a large proportion of phosphoric acid and is sold as an agricultural fertilizer for a sum which covers a large part of the cost of the operation The introduction of the Thomas-Bessemer process in 1878 has given great value to extensive German deposits of iron ore containing so much phosphorus that it was formerly almost worthless and has saved millions of dollars which otherwise would have been expended for imported phosphates

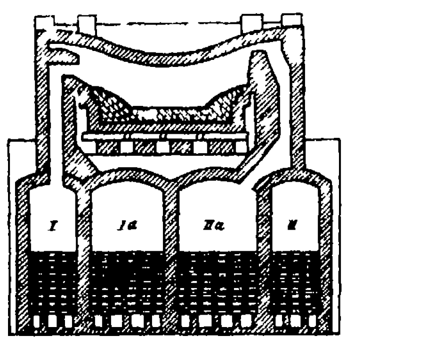

Fig 5—SIEMENS-MARTIN FURNACE

At present the Bessemer converter is employed less extensively than the Siemens-Martin furnace which saves the great cost of compressed air and also affords a means of utilizing the constantly increasing accumulations of scrap steel and wrought iron This scrap melted with varying proportions of pig iron in the Siemens Martin furnace yields Siemens Martin steel or malleable iron The furnace is of the open hearth type the iron being melted by a gas flame applied to its upper surface The gas is produced by the imperfect combustion of coal in special generators and is rich in carbon monoxide and hydrocarbons. The Siemens-Martin furnace (Fig 5) consists of the Martin furnace proper and four Siemens regenerators placed beneath it These regenerators are partly filled with masses of fire brick The coal gas and the air required for its combustion are first admitted to the furnace through the left hand chambers *I* and *Ia* (Fig 5) the larger chamber *Ia* forming the air channel while the hot product of combustion or furnace gas escapes through the right-hand chambers *II* and *IIa* After a time the flow is reversed so that the coal gas and air enter through the right hand chambers which have been heated by the hot furnace gas while the freshly formed furnace gas escapes through the left hand chambers By thus reversing the flow at intervals determined by experience the

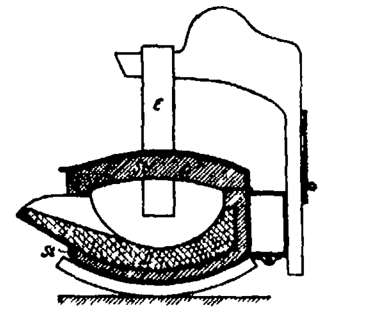

Fig 6—HÉROULT'S ELECTRIC ARC FURNACE

hot furnace gas is caused to give up indirectly to the coal gas and air a quantity of heat which added to the heat of combustion produces the very high temperature of 3 300 deg F which is required to melt wrought iron Recarbonizing is practised in the Siemens Martin process and various additions are made at different stages while the process is carefully watched and controlled by testing samples of the product. The ordinary Siemens Martin furnace produces 10 to 15 tons in 5 to 8 hours

The finest grades of steel used for instruments of precision etc have hitherto been produced in crucibles of 50 to 150 pounds capacity combined in large numbers in elaborate and costly furnaces which are also better adapted than the Siemens Martin furnace to the production of the nickel steel chrome steel and tungsten steel of which screw propellers and armor plates are made

Now all of these crucible steels and still finer grades can be produced with advantage in the electric steel furnace, the first cost of which is less than that of the crucible furnace and which can usually be operated cheaply by gas engines fed with blast furnace gas The electric process also is more flexible than any other A portion of the product can be drawn off at any stage and the remainder can be converted into steel containing less or more carbon or into nickel steel etc The electric furnace may also be allowed to freeze or become cold as the metal is not exposed to the air but is protected by a layer of slag so that it can be remelted at any time by turning on the current. If a filled Bessemer converter freezes it must be taken apart In the Siemens Martin furnace a frozen charge can be remelted but not without losing much iron in the form of slag Electro steel is superior to crucible steel in its absolute freedom from bubbles and sulphur and phosphorus streaks as well as in its forging qualities It also can be made from inferior raw material

In the direct electric process the material is both fused and refined in the electric furnace In the indirect process which consumes less current the crude fused product of a Siemens Martin furnace for example is run into the electric furnace and the substances required to effect the desired change in composition are added The choice between the two methods is governed mainly by the relative cost of coal and of electric energy

Electric steel furnaces are of three types Arc (Héroult Stassano etc) resistance (Girod) and induction (Kjellin) Héroult's arc furnace (Fig 6) appears to be the best of its class It is a vessel of heavy sheet iron thickly lined with fire brick (*St*) provided with a movable cover and so mounted that it can be emptied by tipping The bottom has an inner lining of calcined magnesian limestone *D* the function of which is to absorb the oxides of sulphur phosphorus and silicon Two carbon electrodes (one of which is shown at *E* in Fig 6) extend downward through the cover to within two inches of the surface of the fused metal The electrodes are moved as required by electric motors and are supplied with alternating current at 100 volts The heat required for fusion and refining is produced by the electric arc formed between these electrodes In the indirect process from two to five tons of crude fused steel according to the size of the furnace are run in from a tipping Siemens Martin furnace of the Wellmann type and are covered with iron ore The combined oxygen of the ore supplies the place of the free and too active atmospheric oxygen employed in ordinary steel making processes which oxidizes some of the iron and thus causes both loss and impurity The combined oxygen of the ore oxidizes only the sulphur phosphorus and silicon to their respective acids which are partly absorbed by the lime and magnesia below After 30 minutes the fused slag derived from the ore is drawn off and the surface of the fused metal is immediately covered with a calculated quantity of carbon This is covered in turn with lime which absorbs the remainder of the oxides of sulphur phosphorus and silicon A little manganese ore is mixed with the lime and the other required ingredients are added subsequently

Kjellin's induction furnace (Fig 7) is employed by the Krupps and several other German steel makers The fused metal occupies an annular trough surrounding a vertical bar electro magnet or transformer The primary coil of the transformer is fed with alternating current at 220 volts and the secondary coil delivers alternating current at 8 volts The secondary current is conducted through the metal in the annular trough where it produces sufficient heat to maintain the temperature of fusion In the direct process the trough is filled with solid pieces of crude steel cast iron etc which make such imperfect contact with each other that it is difficult to establish the current The difficulty is overcome by laying a steel ring in the trough or by leaving in it a small part of the preceding charge The subsequent operations are similar to those of the Héroult furnace

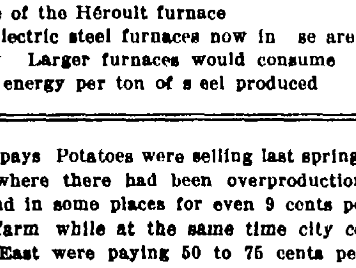

Fig 7—KJELLIN'S INDUCTION FURNACE

The electric steel furnaces now in use are of small capacity Larger furnaces would consume much less electric energy per ton of steel produced

No Well grounded Complaint Against the Farmer

After presenting many details with regard to the increase of prices on farm products between farmer and consumer the Secretary of Agriculture declares that the conclusion is inevitable that the consumer has no well grounded complaint against the farmer for the prices that he pays. The farmer supplies the capital for production and takes the risk of his losses his crops are at the mercy of drought, and flood and heat and frost, to say nothing of noxious insects and blight ing diseases. He supplies hard exacting unremitting labor A degree and range of information and intelligence are demanded by agriculture which are hardly equaled in any other occupation. Then there is the risk of overproduction and disastrously low prices. From beginning to end the farmer must steer dexterously to escape perils to his profits, and indeed to his capital, on every hand. At last the products are started on their way to the consumer The railroad, generally speaking, adds a percentage of increase to the farmer's price that is not large. After delivery by the railroad the products are stored a short time are measured into the various retail quantities more or less small and the dealers are rid of them as soon as possible The dealers have risks that are practically small except credit sales, and such risks as grow out of their trying to do an amount of business which is small as compared with their number

In continuation of this subject, the Secretary of Agriculture suggests that the problem of high prices is one for treatment by the consumer Why do not consumers buy directly from the farmers? he asks A distribution of farm products in this simple way has already begun in England where co-operative organizations of farmers are selling by direct consignment to co-operative organizations of consumers in cities. Farmers co-operative selling associations are numerous in this country but co-operative buying associations among the people of cities and towns are few Aside from buying associations maintained by farmers, hardly any exist in this country It is apparent, therefore, that the consumer has much to do to work out his own salvation with regard to the prices that he pays Potatoes were selling last spring in some places where there had been overproduction for 20 cents and in some places for even 9 cents per bushel at the farm while at the same time city consumers in the East were paying 50 to 75 cents per bushel although there was nothing to prevent them from combining to buy a carload or more of potatoes directly from the grower and for direct delivery

Many new forage crops from all parts of the world are being tested every year Only a few of these possess sufficient value to compete with the crops now grown Four such plants however recently introduced have given such admirable results that there can be little question that they will prove of great value Experience of the last three years has shown that Rhodes grass is especially adapted to the Gulf coast region In southern Florida three cuttings have been made during the winter months and as many as six during the entire season This grass has fine upright stems and good seed habits and should be extensively cultivated in this region

Airship and Aeroplane in War*

The Relative Merits of the Dirigible Balloon and the Aeroplane

By Lieut Frank P Lahm, U S A.

With both the dirigible balloon and aeroplane now in actual use in European armies it is not too early to compare the two types of air craft and draw conclusions as to which should be given the preference in equipping our own forces for equip them we surely must and will and that before long

First let us look into the different rôles to which air machines may be adapted in war In general, I would limit them to three: First and by far the most important, is reconnaissance, both strategical and tactical; second communication particularly on the field of battle third and last combat I will first take up the third rôle as it need occupy but little of our attention

The idea of dealing death and destruction in the form of fire and explosives dropped from the air of annihilating battleships, armies and cities has from the first appealed to the popular mind But let not the imagination run riot for experiments show that to produce its full effect the explosive must be confined A bomb dropped on the deck of a battleship would do little or no harm except to those of the personnel who chanced to be exposing themselves, and no projectile can be given sufficient impetus from an aircraft to penetrate steel and iron Furthermore experiments have shown that the chances of hitting the mark from an airship in flight are quite remote unless the craft approaches within a distance at which it would itself be exposed to extreme danger from the enemy's fire

The effect of dropping explosives on an army would be more moral than physical, for here again arises the difficulty of hitting the mark and moreover even if it were struck the effect would be limited to a small area and a few men

Dropped on a city explosives and inflammables would have an appreciable effect but stop and estimate the number of bombs and the number of aircraft required to carry them in destroying a city the size of one or our large seaports such as New York Boston or San Francisco

Communication on the field of battle these days of large armies and extended areas of combat has opened a large field of usefulness to aircraft Wireless and wire lines can now be utilized in connecting the different headquarters and subdivisions of an army on the field of battle but there must always be an element of unreliability and uncertainty in this method of communication It takes time to run wire lines, the headquarters to be connected are constantly changing their positions are often many miles apart and only a limited amount of wire can be carried Interference limits the number of wireless stations so but one station can send messages at a time. Then there comes times when telegraphic communication is not sufficient A map or sketch must be transmitted an insurpassable obstacle intervenes between two parts of the line, the commanding general wishes to visit in person some point of the line or to call a conference of his division commanders What better means than air machines which know no obstacle and travel in an air line, that is by the shortest and quickest route?

Reconnaissance is where aircraft will find their real sphere of usefulness For this they are pre eminently fitted and here we may expect to see those changes in strategy and tactics due to the appearance on the horizon of a new and powerful arm

Let us now look into the special qualifications and limitations of the different types of aircraft Then we can better draw a comparison between the dirigible and aeroplane and assign each to its proper sphere

The practical dirigible preceded the practical aeroplane by seven or eight years and gained a lead the latter has had to contend against ever since The first military dirigible the French Lebaudy No 1 which appeared in 1902 was a comparatively small machine with a capacity of 90 000 cubic feet one forty horse power motor and a speed of a little over twenty miles an hour in still air It was found that this was not sufficient to contend with the ordinary wind so the dirigible has gone on increasing in size horse power and speed until we now see monsters of the Lebaudy type such as the new 'Morning Post' owned by the British government It has a capacity of over 350 000 cubic feet and is capable of making a speed of over thirty five miles an hour Other examples of aerial Dreadnoughts are the 'Clément Bayard II' with a capacity of 250 000 cubic feet engines of 260 horse-power and a speed of thirty five miles; the Wellman transatlantic type which required 345 000 cubic feet of hydrogen to fill it; the Zeppelin rigid type of 150 000 cubic feet capacity

Among the advantages to be attributed to the dirigible are its weight carrying capacity and its adaptability for long cross country flights Hydrogen gives the lifting power and 1 000 cubic of this very light gas will lift 70 pounds The Zeppelin airships lift as much as 16 tons, and Wellman's dirigible with which he tried to cross the Atlantic Ocean had an ascensional force of over 12 tons The former has carried as many as forty passengers at a time and the latter besides its crew of six men was loaded with fuel and provisions sufficient to last ten days, the maximum length of time they expected to be in the air

On the other hand the dirigible has serious limitations which must be taken into account It cannot operate in a high wind for like a ship at sea, it must have headway to steer and maintain its course Winds as a rule are not steady especially those nearest the earth's surface A balloon capable of making thirty five miles an hour in still air would be helpless in a thirty mile wind for gusts exceeding thirty miles would be frequent, and five miles an hour is not sufficient headway to maintain a course into or perpendicular to a thirty mile wind Here however arises an advantage peculiar to the dirigible It is not dependent on its motors for its buoyancy and even were the speed of the wind greater than its own speed, it would simply have to ride out the storm then proceed to its port, and if the wind were blowing in the direction it desired to go, it would proceed under the double power of the wind and its motors, or should the latter break down it would be carried by the wind like a free balloon

The most serious disadvantage of the dirigible lies in its large size entailing great cost and numerous personnel, a large gas supply and above all, difficulty in maneuvering on the ground at the start and in landing The dirigible must operate from a fixed port where it can have a house to protect it at night or during a heavy blow and equally important, a supply of hydrogen gas which must be constantly added to maintain the form of the balloon and preserve its buoyancy Nearly all the serious accidents to dirigible balloons have occurred owing to difficulty in maneuvering on the ground A dirigible may be compared to a large sail, in some cases over 500 feet long When the wind strikes it, human power is not sufficient, so when the airship lands it must be promptly sheltered in a suitable house Various expedients have been resorted to for the purpose of anchoring a dirigible in the open and keeping its head into the wind but at best it will always be a decidedly hazardous undertaking In November, 1907 the French dirigible 'La Patrie' was caught away from its house broke loose in a storm and in spite of the two hundred soldiers holding it and after drifting across France England Ireland and Scotland floated out over the North Sea and disappeared In August, 1908, the 'Zeppelin IV while flying from Cologne to Lake Constance, was forced to make a landing near Stuttgart Germany A storm struck it shortly after tore it loose from its moorings, carried it into the air; an explosion followed, the airship fell to the ground and was reduced to a mass of tangled wreckage When the 'Morning Post' made its memorable trip, November 26th from Paris across the English Channel to the military headquarters at Aldershot, a distance of about 210 miles, in five and one-half hours the aeronautical soldiers were not able to hold it on landing and it drifted away A second attempt was successful but on towing it into the balloon house the envelope was torn and the gas escaped

The life of the dirigible is its gas supply Every day this must be replenished as an unavoidable leakage is constantly going on and air is constantly filtering into the gas, reducing its buoyancy and eventually necessitating a complete new supply Gas is generally provided in steel tubes loaded with hydrogen under high pressure at the gas factory and shipped into the field A 100-pound tube will carry 200 cubic feet of gas from which we can estimate for a 350 000 cubic foot balloon; 1 750 of these tubes weighing 175 000 pounds This would be sufficient to fill it once For each day it is inflated, an additional three or four thousand cubic feet will be required to replace the gas lost

Experiments have been made in firing at captive balloons anchored to the ground at fixed points, and it was found that shrapnel fired at mid or even long ranges, could bring them down No firing has been conducted at dirigible balloons in flight We know that it offers a large target and that a hole in the envelope allowing the gas to escape will bring it down but what are the chances of hitting this target? In reconnaissance it is necessary to operate at as low an elevation as three quarters of a mile which would be easy range for a high angled balloon gun, but when we remember the target is moving at a speed of at least twenty miles an hour and can constantly vary its altitude the difficulty of hitting it is very apparent

The aeroplane small compact, of comparatively light weight speedy easily handled both on the ground and in the air has all these advantages to adapt it to military purposes It is hardly safe to quote figures or records so rapidly are they surpassed—the wonder of yesterday becomes the commonplace of to-day and the marvels of to-day will be commonplace to-morrow Already the aeroplane has far exceeded a speed of mile a minute has risen to a height of more than 11,000 feet, has flown continuously without landing for over eight hours, has carried six persons and has demonstrated its ability as a cross-country craft. These are the performances of to-day; by to-morrow they may appear insignificant No other product of man's inventive genius has made such rapid strides in its early development. It is now just five years (December, 1905), since Wilbur and Orville Wright made the first human flight in a heavier-than air machine Now there are three hundred licensed aeroplane pilots in France alone and successful machines of different types too numerous to mention.

Perhaps the aeroplane's greatest advantage lies in its speed, for speed is the weapon with which aircraft combat their greatest enemy—the wind. With its great speed, it gains in manageability and invulnerability On October 27th, at Belmont Park, Long Island, we had the remarkable spectacle of aeroplanes 'flying backwards' On that day Johnstone and Hoxey while operating in a sixty mile wind, were carried away—one of them more than fifty miles. Both landed safely and returned the next day when the wind had subsided A year ago few pilots were willing to risk their machines in a twenty-mile wind—now no first-class pilot with a good machine hesitates to fly in a wind of twenty, thirty, forty or more miles an hour One of the next improvements we may look for in the aeroplane, is automatic control, which will largely eliminate the personal equation and skill of the pilot, and make it manageable, even under the most unfavorable conditions.

The vulnerability of the aeroplane need hardly be considered Though no experiments have been made, and we have no data, a consideration of the premises is sufficient to convince us that a small target like the aeroplane, flying at a height of three-quarters of a mile or more at an unknown speed of ten to one hundred miles an hour depending on whether it is traveling with or against the wind, constantly changing its elevation and direction, is a most difficult target to hit

The high speed of the aeroplanes has been cited as one of its disadvantages Some critics maintain it is impossible to observe accurately from an aeroplane moving at forty miles an hour They lose sight of the fact that at such altitudes a particular position is in sight long before it is reached and long after it is passed The aeroplane already has a slow record of less than twenty-three miles an hour By throttling down the engine and passing over a given point headed into the wind, the aeroplane can carry a skilled observer at such a rate of speed that he will have no difficulty whatever in carrying out his observations

The aeroplane has carried as many as six persons and can be built to carry more, but we shall never see it used as a means of transportation for large numbers or large weights, for in aeroplane construction, increasing the area by the square, increases the weight by the cube, that is, to double the size of the machine, it is necessary to triple the weight.

Now to compare the dirigible and aeroplane and draw conclusions as to their relative merits in warfare

From the point of view of manageability, both on the ground and in the air, the advantage is entirely with the aeroplane The day that Hoxey and Johnstone controlled their machines in a wind of more than sixty miles an hour, brought them safely to earth and later returned to Belmont Park under their own power, no dirigible balloon would have dared to leave its cover or had it been caught unawares in such a wind, it would have had to choose between an attempt to cross the Atlantic Ocean or landing with a certainty of being seriously damaged and probably wrecked.

A military dirigible carries a crew of about six men and on the ground requires *an entire company* to handle it The personnel for an aeroplane is one officer and ten men, which is sufficient to render it entirely independent The crew comprises an observer and two operators taken from the above personnel.

The cost, while a question of minor importance in time of war is not to be compared in the two types of machines The current price for a military aeroplane is \$5,000 to \$8,000 The price for a dirigible is more than a hundred thousand dollars The amount paid for a 'Clément Bayard II or a 'Morning Post,' or a Zeppelin would pay for fifty aeroplanes The upkeep of an aeroplane consists largely in oil and gasoline for the engine wood and cloth for repairs and the expense of maintaining one officer and ten men For the dirigible in addition to the same items for fuel, we must take into account the expense of maintaining an entire company and most important of all the gas supply Hydrogen gas as manufactured at present, costs from \$7 00 to \$10 00 a thousand cubic feet, simply for materials and power alone, without taking into account the expense of the plant and its operation, nor shipping the gas to the point where it is to be used

In manageability, both in the air and on the ground, in cost, in vulnerability in speed, we must accord the aeroplane the advantage In weight carrying, in long distance communication and in adaptability for wireless communication, the advantage goes to the dirigible From these relative advantages we can now assign each to its proper sphere

In the first place the dirigible must have permanent points of attachment, or bases from which it must operate, and to which it must return at short intervals for its gas supply, and especially for protection from the elements This condition leads us to eliminate it from field armies Permanent stations along the coast at various points along the main lines of communication inland should be established and equipped with dirigible balloons. Here they can operate from mixed sources of supply and, during invasion, would fulfill their rôles of strategical reconnaissance and long distance communication

But more important, let us first equip our field armies with aeroplanes, for it is on them we must depend for the last strategical reconnaissance, then for reconnaissance and communication on the field of battle and afterward for keeping in touch with the pursuing, or we hope, the retreating foe.

A group of aeroplanes should be attached to the headquarters of the army in the field. Each will re-

* Abstract of an article in the *Journal of the Military Service Institution*.

quire a personnel of one officer as observer, two skilled pilots, who will be non-commissioned officers, and eight other enlisted men capable of assembling, repairing and dismounting the machine. A housing of canvas is all that will be required, something that can be readily erected and taken down and can be carried on an escort wagon

On the field of battle, the commanding general will use aeroplanes to personally inspect any part of his command, to reconnoiter any position on his front or flanks, or through a combined reconnaissance of his en tire group of aeroplanes, can receive frequent detailed and accurate reports from all the subdivisions of his command, can know the enemy s dispositions and movements both at the front and on the flanks. No longer need his movements be timid or hesitating He knows where the enemy is concentrated. He knows where he is weakest—a rapidly transmitted order to each of his subdivisions enables him to concentrate at the most favor able point and to take full advantage of his adversary s weakness.

Each subdivision commander will depend on his aeroplane scouts to protect himself from surprise and to report to army headquarters the latest developments in his front.

Other first-class powers are not neglecting this new factor in warfare We do not know who our next opponent will be, but if it is a first-class power we shall surely find it with a trained and equipped aeronautical auxiliary Let us have a sufficient number of aeroplanes, of skilled operators, of trained observers, so that we can take the field on an equal or better footing for aircraft must be opposed by aircraft and the ad vantage to be gained by the use of these machines will go to the side which has the largest number and the speediest, and which makes the boldest and most skillful use of them

A Convenient and Inexpensive Furnace for Very High Temperatures

By D F Calhane Ph D

In an article by Pip in the August 15th, 1910, num ber of the *Zeitschrift fur Elektrochemie* is described a small furnace for high temperature work

It occurred to me that a description of a furnace that I have used for the past two years in my laboratory might be of interest.

Some two years ago, in connection with work on nickel alloys, I had occasion to employ high temperatures, over 1,500 deg C (2 732 deg F) It was especially desired to obtain the melts without carbon contamination In the furtherance of this work the following simple and efficient furnace was devised:

Referring to the figure

A shows the end of two fire-bricks Four of these were employed to form the outside of the furnace The two end bricks were cut down to give the proper width to the body of the furnace

C represents the cross section of a small fire-clay muffle, such as is sold by the Buffalo Dental Company in connection with its No 40 Fletcher's crucible furnace This sits inside the inclosure formed by the fire brick and the extra space is filled with a heat insulating composition composed of Portland cement, magnesium oxide and powdered asbestos This is shown by *B* in the figure.

At the bottom of the muffle is placed an alundum block *D* On this rests a No. O graphite crucible, shown by *G* in the figure

In this graphite crucible is cast an alundum lining, which keeps the melts from carbon contamination

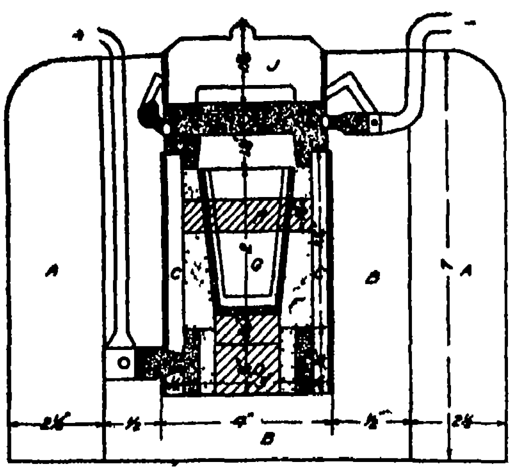

DIAGRAM OF VERY HIGH TEMPERATURE FURNACE

- *A* Fire Brick
- *B* Portland Cement, Magnesia Oxide and Asbestos
- *C* Fire Clay Muffle Iron Band
- *D* Two Alundum Blocks.
- *E* Carbon Ring
- *F* Powdered Carbon
- *G* Alundum Lined Graphite Crucible
- *H* Alundum Insulating Ring
- *I* Graphite Ring
- *J* Fire Clay Cover

The current enters by the lead at the bottom of the furnace, and is evenly distributed by a graphite ring *E*, that fits flush at the bottom of the muffle This ring was cut from an odd end of a graphite electrode The graphite electrodes lend themselves to this kind of work, as they are easily machined, whereas carbon is not.

The carbon resistor is denoted by *F* This is com posed of carbon powder obtained from the National Carbon Company *H* is an alundum ring that is dough nut-shaped. The inner hole is filled to within about one-quarter inch around by the crucible.

This design gives a simple method of insulating the main portion of the resistor, and directs the current flow along the walls of the crucible up through the ring between the walls of crucible and inner edge of the ring Herein lies the high efficiency of the furnace Intense heat is concentrated where it is wanted namely on the walls of the crucible By varying the area of the space between the crucible and the inner side of the ring, and the height of the block *D* the voltage and wattage of the furnace can be varied widely

On the top of the muffle sets a graphite ring *I* also made from an electrode end This ring has contacts screwed in as shown, connected with the leads for the exit of the current

On the upper edge of the ring sits the cover of the muffle *J* The top from the upper surface of the fire bricks over to the edge of the cover *J* is built up with the same insulating mixture used at *B* and is fash ioned to give a symmetrical outline to the furnace The whole outside may be painted with a water white to give a neat appearance The whole body of the fur nace rests on a cement base that is contained in a shallow, oblong box The furnace can be thus carried about as the whole thing weighs only about 25 pounds

A couple of examples showing the efficiency of the device may be of interest

In one case the heat resistivity of the device was pushed to the limit For this size of furnace 1,330 watts were found to produce a temperature that fused alundum and must have been over 2,500 deg C (4,532 deg F) In this experiment the furnace absorbed 70 amperes at 19 volts

In another instance the furnace was calibrated with a platinum iridium thermocouple and galvanometer up to the limits of this apparatus namely 1 660 deg C (2 912 deg F)

The results showed that at 700 watts a temperature of 1 660 deg C (2 912 deg F) was recorded by the pyrometer A rough extrapolation on this basis to 1,330 watts would indicate a temperature in the neighborhood of 2,800 deg C (5 072 deg F)

It might be asked how such a temperature could be attained without melting down the alundum com pletely The answer is that the intense heat zone is only along the walls of the crucible where no alundum is directly in contact.

A furnace on the above lines of 6 kilowatts capacity will soon be in use

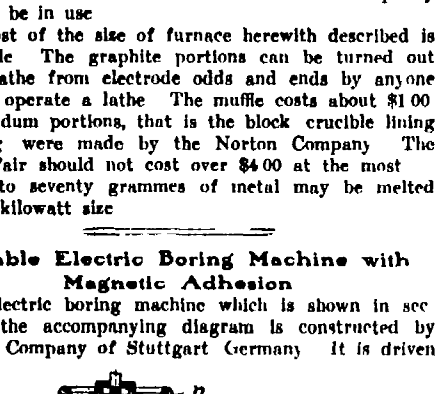
The cost of the size of furnace herewith described is very little The graphite portions can be turned out on the lathe from electrode odds and ends by anyone who can operate a lathe The muffle costs about $1 00 The alundum portions, that is the block crucible lining and ring were made by the Norton Company The whole affair should not cost over $4 00 at the most

Sixty to seventy grammes of metal may be melted in the 1 kilowatt size

* *Metallurgical and Chemical Engineering*

Portable Electric Boring Machine with Magnetic Adhesion

The electric boring machine which is shown in sec tion in the accompanying diagram is constructed by the Fein Company of Stuttgart Germany It is driven

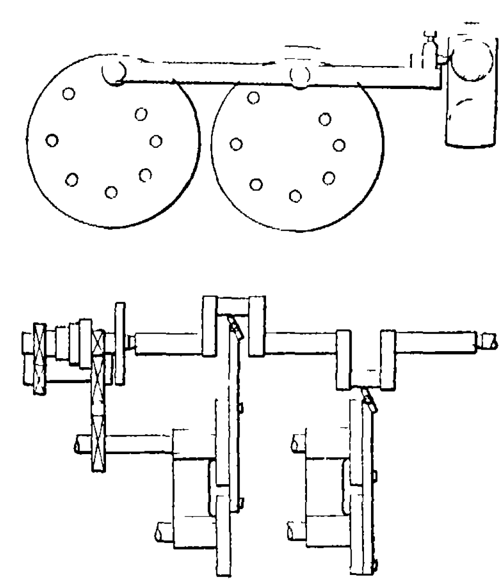


PORTABLE ELECTRIC BORING MACHINE WITH MAGNETIC ADHESION

by a small electric motor *m* by means of the bevel gear *e* The boring tool is advanced as the work progresses, by the pressure of the spiral spring *r* the ten sion of which can be regulated by the wheel *v* At the same time the machine is pressed forcibly against the plate by the attraction between the latter and the poles of the electromagnet e_1 e_2, which closely embrace the boring tool (This action occurs only with plates of iron or steel, for which the machine is designed) The machine is easily operated in any position. It is only necessary to suspend it from a convenient support to apply the tool to the place to be bored and to close first the circuit of the electromagnet, and then that of the motor The work of attendant is confined to watching the operation and turning the tension wheel *v* from time to time as the work ad vances – *Le Génie Civil*

Crank Turning Device

Patents have been applied for in Great Britain for the device working on the principle shown in the line engraving herewith intended for turning crank pins, and pieces rotating around a central shaft in a similar manner In the upper part of the figure, the general principle of the device is indicated, the lower part being a plan view showing diagrammatically its con nection with the lathe to which it is applied The principle of the device is easily seen from the illus tration The crank shaft is mounted on its own cen ters in the lathe and the working tools are given a reciprocating motion vertically and horizontally so as to coincide with or follow the motion of the work being turned The motion of the tool is positive and interdependent of the motion of the crank or shaft In the lower part of the engraving the device is



CRANK TURNING DEVICE OF NOVEL DESIGN

shown in two positions first when operating on one and then when operating on the other crank pin of a crank shaft having two pins While not shown in the engraving, the two disks to which the tool holder arm is connected must be positively geared together, as otherwise difficulties are sure to be encountered. To what extent a device of this kind will prove practical for the purpose for which it is intended it is difficult to say –*Machinery*

TABLE OF CONTENTS

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending March 21, 1911.

AND EACH BEARING THAT DATE

The Preparation of Gas for Balloons*

What Chemistry Has Done for Ballooning

By A. Sander

Technical chemistry has contributed a very important share to the successful development of aerial navigation within the past few years, for a number of products of chemical industry function as important auxiliaries in the construction and operation both of dirigible balloons and of aeroplanes. It is only necessary to call to mind the several special steels and the light aluminium magnesium alloys which are of the highest importance as materials of construction for aeronautical purposes, or the India rubber used for impregnating the light and yet highly resistant and tough gas proof balloon fabric; there is also the *very important item of gasoline and oil* on the proper chemical purification of which the safe operation of the motor depends in a large measure; lastly there is the important problem of the production of the balloon gas, which places before the technical chemist a number of difficult problems for solution. Just as in a flying machine the motor is the vital point, so in ballooning the preparation of the buoyant gas is of fundamental importance.

Before turning to the consideration of the technical production of the balloon gas, it will be well first of all to briefly call to mind its purpose and the requirements which it is called upon to fulfill. The purpose of balloon gas is of course to lift a car, which together with its passengers, ballast and apparatus has a considerable weight. The dimensions of the balloon and car must be so chosen that the weight of the entire system is less than that of the air displaced thereby. Hence the first demand laid upon balloon gas is that it shall be very light as compared with air. This however is not by any means the only condition which has to be satisfied. The ideal balloon gas, which unfortunately is as yet but an ideal, should in addition to low density possess the following properties. It must not attack the balloon envelope and should be incombustible, in other words it should be chemically inert. Furthermore it should be as little as possible affected by changes in temperature, it should be readily liquefiable, non poisonous, and last but not least it must be cheap. While a large number of gases might be cited which fulfill more or less satisfactorily the first condition, that of low density, when we strike from such a list all those gases which fail to satisfy one or other of the remaining conditions we are left with practically only three substances as having hither to been used for a balloon filling, and they are heated air, illuminating gas and hydrogen. We will briefly consider each of these in turn.

I. *Heated Air.*—The art of aerial navigation may be said to date from the year 1783, in which the Montgolfier Brothers made a public ascent in their home in Brittany by the aid of a paper balloon covered with linen and inflated with hot air. It is on record that these same inventors had in the first instance experimented with steam as a filling for the balloon, the idea being suggested to their mind by the sight of the clouds drifting in the sky. In point of fact steam would make a very fair gas for ballooning were it not for the impossibility of preventing its condensation. The Montgolfier hot air balloon had a number of obvious limitations. The fact that fire had to be carried on board placed the occupants in considerable jeopardy owing to the risk of the balloon itself being set in flames. Furthermore, the extreme height to which it could ascend was only about 8 000 feet, for in order to rise higher than this it would be necessary to heat the air above 100 deg. C., which could not be done without injuring the balloon cover.

II. *Illuminating Gas.* Of much greater importance than hot air for ballooning purposes is the use of illuminating gas. Its introduction into the art is usually ascribed to an Englishman, Greene, in 1818. It has however been demonstrated from old documents by Dutch chemists that illuminating gas was used as early as 1783 in their country, that is to say in the very same year in which the brothers Montgolfier made their first ascent.

At the present day gas works are the principal centers from which most balloon ascents take place, and the quantity of gas consumed for this purpose is rapidly increasing. A very brief resumé of the preparation of illuminating gas may here suffice, inasmuch as its mode of manufacture is more or less a matter of common knowledge owing to its extended use in everyday life. As is well known, illuminating gas is prepared by the dry distillation of coal. This process is usually carried on in fire clay retorts arranged in batteries of six to twelve in one furnace. The gas issuing from the retorts is passed through an elaborate and extended series of apparatus in which it is cooled and freed from certain impurities. The purified gas is collected in so-called gasometers, whence it is forced into the mains for general distribution. Illuminating gas is colorless, but readily recognized by its odor. It is not a chemical individual but a mixture of gases, its principal constituent, amounting to about fifty per cent, being hydrogen. The composition of the gas is somewhat variable, and in consequence its density also fluctuates between about 0.36 and 0.52 (expressed in the scale which gives to air the density 1). This corresponds to a *lifting power of 0.052 to 0.39 pound per cubic foot.* As regards density the requirements of balloonists and of the general consumer of illuminating gas are at variance, for as a balloon filling a light gas rich in hydrogen is the desideratum, while for illuminating purposes a gas rich in the heavier illuminants is more advantageous. Nevertheless there are few gas works in Germany whose product has density greater than 0.45. Heavier gas occurs only where exclusively silesian coal is distilled or where much water gas is added.

In the course of the distillation of coal the composition of the gas issuing from the retorts varies considerably, and especially toward the end of the distillation a very light gas rich in hydrogen is obtained. It has therefore been suggested to collect the last portions, which are of comparatively low illuminating value, separately, and to utilize them for ballooning purposes. This mode of procedure would however introduce considerable complication into the manufacture of coal gas, and has therefore found no application in practice. On the other hand a method which of recent years has been applied with much success consists in converting the purified gas into a lighter product by heating it at a high temperature. This process is not altogether a new invention. In the year 1894 Bunte and others had observed that by this treatment ordinary illuminating gas can be made to yield a product containing about 80 per cent hydrogen and having a density of about 0.2. The process was however not put into practice until very recently, when Dr. von Oechelhäuser gave publicity to the fact that a gas company in Dessau had succeeded in producing a special balloon gas by simply heating illuminating gas to 1 200 deg. C. The apparatus used is very simple. The gas is passed through highly heated retorts charged with small coke. At the temperature indicated the hydro-carbons are split up into their constituents, as for example

$$CH_4 = C + 2H_2$$

This change is accompanied by an increase in volume of 20 per cent, while the carbon is deposited upon the retort walls in the form of soot or graphite. The gas produced is passed through a small purifying plant and into a gas holder. The additional cost of converting the ordinary illuminating gas into balloon gas is just about the same as the cost of distributing the ordinary gas to consumers, so that the price of balloon gas at the works should be about the same as the price of illuminating gas at the point of consumption. The specific gravity of the balloon gas fluctuates between 0.225 and 0.3, with an average of about 0.27 and a *lifting power of about 59 pounds per cubic foot.* This corresponds to $26 to $34 per ton of lifting power (German conditions). The gas contains about 80 per cent hydrogen and only 5 per cent of methane. It is free from benzine and other hydrocarbon which would attack the balloon envelope. It has a very much weaker odor than ordinary coal gas and is much less sensitive to temperature changes.

While this process of making balloon gas represents a very considerable advance for the purposes of ordinary balloons, it is hardly likely that it will ever have any value for dirigible balloons. For on account of the great weight of such crafts it is necessary to employ the highest buoyancy available, so that the only gas which enters into consideration is hydrogen.

III. *Hydrogen.*—The lightest of all known gases is hydrogen, whose density compared with air is 0.07. It has the further advantage for ballooning purpose of being comparatively non-sensitive toward temperature changes. It is very hard to liquefy, hardly soluble in water and diffuses with great ease even through the smallest openings. This last is the reason why the attempts of the brothers Montgolfier to fill paper balloon envelopes with hydrogen were entirely unsuccessful. The physicist Charles of Paris, was the first to succeed in sending up a balloon filled with hydrogen. He prepared the gas by the action of dilute acid upon iron. The balloon envelope was made of silk taffeta. Although its volume was less than 1 400 cubic feet, it took three days and three nights to fill, and required no less than 1 100 pounds of iron filings and 550 pounds of acid. The method which Charles used for generating the gas was extremely wasteful of material. Coutelle's attempt to prepare hydrogen on a large scale by passing steam over red hot iron did not prove well adapted for large scale working. A great step forward was made by Renard and Giffard, who used the same reaction as Charles, but modified the process by feeding continually fresh quantities of acid to the iron while drawing off the iron sulphate liquor. In this way a much more complete utilization of the iron was secured. Nevertheless this process also represented an extremely costly method of preparing hydrogen. It was only toward the end of the nineties that a new source of hydrogen became available and almost completely drove out the old process. This new source is the electrolytic hydrogen produced by the Fabrik Griesheim Elektron, who produced large quantities of hydrogen as a by product in their electrolytic process of manufacturing caustic alkali. This industry has at the present day reached such a scale that the firm named above produces in its three works daily no less than 700 000 cubic feet of hydrogen. Although of late years the consumption of this gas has increased very greatly, as a matter of fact only a small portion of the gas is at present collected and compressed into steel cylinders at 120 to 150 atmospheres, while the bulk of it is discharged into the atmosphere. The placing upon the market of hydrogen from this source has done much to further the interests and development of aerial navigation in Germany. The electrolytic hydrogen possesses some very remarkable advantages owing to its purity and more especially its freedom from arsenic. This has led to the establishment of plants built especially for the electrolytic production of hydrogen on its own account, that is to say quite apart from the manufacture of alkali. For this purpose the electrolyte is simply water rendered conducting by the addition of a small percentage of acid or preferably alkali. The advantage of alkali is that its use permits the employment of iron vessels and diminishes the wear and tear of the electrodes.

While electrolytic hydrogen possess the advantages which have been referred to, it unfortunately presents at the same time rather severe drawbacks. Thus the number of costly steel cylinders required for a large production is quite excessive. Furthermore there is added to the cost of production, which it is true is moderate, the cost of compressing the gas, and there is obtained as a by product with every two volumes of hydrogen one volume of oxygen, an outlet for which must be found. Lastly the item of freight is very considerable, especially in view of the fact that the return of the empty cylinders represents practically the same expenditure as the first shipment of the charged cylinders. In view of the immense gas consumption of the modern air ship, such as for instance the Zeppelin type of fifteen thousand cubic meters (528 000 cubic feet) capacity, it has become imperative to look for a process of manufacture of hydrogen which would render it possible to produce large quantities of gas at moderate cost, and which would obviate the use of compressed gas and of steel cylinders. A process of this kind has been installed at Friedrichshafen by the Carbonium Company, based upon the splitting up of acetylene and other hydrocarbons into their components. The gases are decomposed by electric sparks into carbon and hydrogen in cylinders provided with stirring gear. The carbon which is deposited in the form of soot is the principal product, and it is claimed that the material so obtained is superior to that from other sources for the production of printers ink, paint, and other uses. No data are available at the present time as to the practical operation of this process, owing to the fact that a part of the works was destroyed by an explosion last July. Indications, however, seem to be that the process will represent a very economical source of hydrogen.

Another process, which has been worked out by the International Hydrogen Company of Frankfurt-on-the-Main, is based upon the reaction between steam and red hot iron discovered by Lavoisier. As has been mentioned above, an attempt to turn this to technical account had been made years ago by Coutelle, without success. The difficulty was to reduce the oxide of iron formed in the process back into iron, so as to restore

* Adapted from *Zeitschrift für angewandte Chemie*.

the raw material and render it available for further use It has been discovered that pyrites cinders are very well adapted for the process They are very porous and for this reason readily reducible to metallic iron by passing generator gas over them On leading steam over the reduced iron so obtained a very pure 98 per cent hydrogen is readily prepared

Another very promising process has been introduced by Siemens and Halske and starts from calcium carbide as raw material As is well known to every layman at the present day this substance when treated with water under ordinary conditions yields acetylene The inventors have discovered that the reaction proceeds along an entirely different course if the calcium carbide is treated with steam at red heat The formation of acetylene and other hydrocarbons is almost completely avoided and the reaction proceeds essentially according to the following equation

$$CaC_2 + 5H_2O = CaO + 2CO_2 + 5H_2.$$

From the mixtures so obtained the carbon dioxide can be readily extracted by passing the gases over some of the lime produced in a previous run The apparatus required is extremely simple and the raw material is cheap so that this process ought to find wide application

We now come to a group of processes all starting from the same raw material namely water gas This gas as is well known consists of a mixture of about 50 per cent hydrogen and 50 per cent carbon monoxide (C O) In practice the gas is contaminated with a certain proportion of carbon dioxide and nitrogen The density of water gas is 0 52 to 0 54 so that it might be directly utilized for balloon filling owing to its highly poisonous character however this would be very undesirable and dangerous

The first efforts to use water gas as a source of pure hydrogen date many years back At first the endeavor was to simply carry out the water gas process in such manner that only a small proportion of carbon monoxide was formed Tillard found that if an excess of steam was used the carbon monoxide was oxidized to carbon dioxide which latter can readily be eliminated from the mixture The reaction is simply

$$C + 2H_2O = CO_2 + 2H_2$$

It is however very difficult to carry this out in practice on a large scale and to-day the efforts in this direction have been practically abandoned It is now the general practice to start out from the finished product water gas and either to eliminate the carbon monoxide by absorbing agents or to introduce in its place an equal volume of hydrogen As absorbing agent cuprous chloride has been used but the product obtained by its means contains only 80 per cent hydrogen A considerably better result is obtained according to Frank and Caro by passing water gas through retorts containing moderately heated calcium carbide This reagent absorbs not only the carbon monoxide but also the carbon dioxide and the nitrogen There is thus obtained a very pure gas and in addition to this two valuable by-products namely graphite and calcium cyanamide A still simpler method of eliminating the carbon monoxide is by liquefaction This process also has been introduced into practice by Frank and Caro in collaboration with Linde The liquid carbon monoxide obtained as a by-product is utilized in a gas motor which furnishes the power for compressing the water gas Still another process has been worked up by the Chemische Fabrik Griesheim Elektron in which the carbon monoxide is replaced by an equal volume of hydrogen The principle on which this process is based is as follows When moist water gas is passed over lime heated to 500 deg C calcium carbonate is formed and hydrogen is liberated

$$CO + H_2O + CaO = CaCO_3 + H_2$$

In order that the product may contain as high a percentage of hydrogen as possible it is essential that the water gas be nearly free from nitrogen a condition which can be fulfilled by the use of specially designed generators Considering that this process makes use of only water gas and lime for its raw materials it ought to prove extremely cheap

Very similar to the preparation of producer gas is the oil gas process It consists in blowing oil instead of steam into a generator charged with red hot coke In this way it is possible to obtain directly a gas containing as much as 90 to 96 per cent of hydrogen A special advantage of this process is that the installation can readily be designed in transportable form being mounted upon two railroad trucks The importance of this for aerial navigation in military operations is very obvious although it may be necessary to carry the portability even farther than is possible with this arrangement As a matter of fact in the Boer War the English Army carried hydrogen in steel cylinders using camels as beasts of burden Each camel transported two bottles of 140 cubic feet capacity For the service of the English balloons having a capacity of 1 400 cubic feet a train of fifty camels was therefore required In the Russo-Japanese War the method employed by the Russian Army consisted in the generation of hydrogen from aluminium and caustic soda This reaction proceeds very rapidly rendering special cooling precautions necessary The method is of course very expensive Another process which is specially adapted for military purposes is based on the reaction

$$H_2O + Si + 2NaOH = Na_2SiO_3 + 2H_2$$

The special advantage of this is that only two kilograms of silicon are required for the production of one cubic meter of hydrogen This process was used by Spain in the Morocco campaign Lastly may be mentioned the production of hydrogen from calcium hydride a gray substance prepared by passing hydrogen over molten calcium This substance reacts with water liberating hydrogen according to the equation

$$CaH_2 + 2H_2O = Ca(OH)_2 + 2H_2$$

The production of one cubic meter of hydrogen requires the use of only one kilogram of calcium hydride The process has hitherto been used only for filling small pilot balloons but it would seem to be well calculated to fulfill the requirements of military practice

This concludes a review of the most important processes which have been proposed and carried out with some measure of success for the production of balloon gas It is impossible at the present time to judge which of the numerous methods proposed will ultimately prove the best But this can be said that the problem as a whole is well on the way towards solution and that the keen competition which is at work among the several processes now recognized as practically feasible will bring results in the near future so that we shall soon have at our command one or more thoroughly practical processes satisfying the various conditions imposed by the conditions of consumption

The Effect of Radium on the Higher Animals

Prof London's Researches

In 1903 Danysz observed that tubes containing radium introduced under the skin in the region of the brain or spinal cord produced symptoms of paralysis in three hours and tetanic convulsions in six hours The effect was greatest in the youngest animals Similar results were obtained by a different method by Prof London the celebrated Russian physiologist from advance sheets of whose forthcoming work on Radium in Biology and Medicine as reprinted in *Die Umschau* the following account is derived Prof London exposed mice to the radiation of 30 milligrams of radium placed above their cage within an inch or less of the animals On the third day of the exposure the mice became dull and sleepy and their ears became red On the fourth day these symptoms were more serious the hind legs became paralyzed and the animals died on the fourth or fifth day

In 1904 London exposed three rabbits to the action of radium in a similar manner During two weeks no morbid symptoms appeared On the sixteenth day the ears reddened and red spots appeared on other parts of the body These spots developed into ulcers which gradually healed Six or eight weeks after the beginning of the experiment the ears were almost entirely bald and the hair began to fall from the back The bald places then became inflamed and ulcerated After sixteen months the ears were greatly thickened and deformed and covered with crusts and the entire back was destitute of hair In the eighth month motor disturbances appeared The animals gradually lost control of their hind legs until finally they moved forward by means of their fore legs alone dragging themselves on their bellies with their hind legs trailing helplessly

The eyes were frequently examined and in all cases were found more or less affected The greatest changes were produced in the retina As death approached the eyes were generally quite closed and covered with a thick secretion The retina was not equally affected in all cases probably because the radium rays fell upon it only when the eye was directed toward the tube

For several months no effect on the sexual functions was observed and the female gave birth to three litters, in July September and November After wards the sexual impulse progressively weakened and finally vanished.

Despite the fact that the injurious influence of the radiation soon appeared the rabbits steadily increased in weight at first but they afterward lost weight very rapidly

London also investigated the influence of radium emanation on frogs and white mice Two frogs were placed in two 2-quart glass bottles containing a little water One of these bottles was connected for two days with a vessel in which emanation was being evolved and was then disconnected and corked After three days it was uncorked and allowed to remain open 48 hours and was then again connected with the radium vessel for 48 hours after which it was again disconnected and corked When the experiment was arranged in this manner the frog died three or four days after the second dose of emanation while the control frog in the other bottle remained in perfect health

The same result can be obtained by permanently connecting one of the bottles with the source of emanation In this method the successive phases of the effect can be followed more satisfactorily The morbid symptoms which begin to appear on the sixth or seventh day include sluggishness of movement sleepiness slimy appearance of the skin and difficulty in respiration which causes death on the thirteenth to fifteenth day The attitude of the frog and the appearance of the water are characteristic In the control vessel the frog stands in a normal manner on all fours and the water remains clear but in the vessel exposed to emanation the frog's head and chest are extended forward and the water is turbid

The frog exposed to the emanation exhibits a radioactivity which can be detected on the first day Very interesting experiments can be made in the dark with frogs killed in this way Thus it can be shown that the frog emits Alpha Beta and Gamma rays and photographs itself on a sensitive plate covered with black paper The imprint is most distinct when the exposure is continued three hours The most strongly radio-active portion is the skin If part of the skin is removed and the experiment is repeated the outline of the section removed appears distinctly in the photograph The blood was found very dark and the skin abnormally soft. The microscope showed extensive changes in the skin and spinal cord

In another experiment three or four suckling mice were placed in a bottle into which radium emanation had been admitted during 48 hours The bottle was then corked and the mice were left exposed to the action of the emanation for four hours after which the bottle was uncorked the mice remaining in it two hours longer The same number of mice of the same litter were placed in another bottle not containing emanation for comparison During the entire experiment and the two following days the mice showed no abnormal symptoms On the third day the mice which had been exposed to the emanations lay on their sides breathed with difficulty and died with symptoms of dyspnoea Death came most quickly in proportion to the length of exposure to emanation The cause of death is probably to be sought in a disturbance of respiration

Electricity from Falling Drops of Water

Some time ago A Schmauss showed that drops of water falling through ionized air take up a negative charge Seeliger experimenting with ordinary water in Munich found that in ordinary air no negative charge was gained and when ionized by Rontgen rays only a quite feeble negative charge was assumed To explain this Seeliger supposes a charge effect due to Volta p d The author in the present paper seeks to show that Seeliger's explanation is not tenable and further goes on to explain the cause of the want of agreement between his own results and those of Seeliger It appears that the taking up of an ionic charge from the air depends on the kind of water used and while Schmauss's result is obtained with distilled water Munich tap water behaves in the way described by Seeliger Experiments with NaCl solution show that this assumes a positive charge when it falls in drops through ionized air and in general Seeliger's results may be explained by the following experimental facts (1) Distilled water which exhibits a positive charge as Lenard effect takes up a negative charge in the drop experiments (2) NaCl solutions (and perhaps also Munich tap water) which shows a negative charge as Lenard effect takes a positive charge The opposite behavior of distilled water and NaCl solution shows that a charge action caused through Volta p d of the metallic parts of the apparatus is not the explanation of the effects but that there must rather be assumed specific forces acting between the liquid drops and the surrounding positive and negative ions The drops may draw to themselves those ions whose charge is opposite to their own on account of the charge arising from the Lenard double layer —*Annalen der Physik*

The Air-brake as Related to Progress in Locomotion—I*

The History of a Great Invention

By Walter V Turner, Chief Engineer, Westinghouse Air Brake Co, Pittsburg, Pa

GENERAL AND HISTORICAL

Every moving body is capable by virtue of its motion of doing an amount of work before its motion can be diminished or stopped which is directly proportional to the weight of the body and to the square of the speed at which it is moving In the case of a vehicle means must be provided which will permit this work to be done harmlessly and in a proper and predetermined manner Otherwise the element of danger involved increases so rapidly with the weight and speed of the vehicle that locomotion except in its most primitive stages is prohibitive The development of locomotion and consequently of transportation is therefore dependent in no small degree upon a like or even superior progress in the art of controlling vehicles in motion

The laws according to which this art progresses can be determined only by following the successive developments which have been made in train control apparatus This will be treated briefly in what follows dealing primarily with the principles upon which such apparatus must operate the methods both theoretical and practical by which these principles have been and are being applied to the problem in hand and the fundamental conditions of service which fix the requirements that must be satisfied by a reliable and practical device of this character

Primitive Vehicle Brakes Knowing that the ancients traveled extensively and that the great empires of history moved large armies over the then known world accompanied by trains of baggage wagons and war machines it is natural to suppose that the necessity for retarding those vehicles must have been plainly manifested But as a matter of fact the first suggestion of this necessity by the use of a practical mechanism designed for the purpose does not appear to have been more than 250 to 300 years ago The primitive carts and wagons which were used in agricultural work and in connection with the transportation of baggage and supplies for armies were of such construction that the natural resistance to rotation of their wheels was quite sufficient to bring them to a stop upon ordinary roads and in cases of steep grades it was always easy to chain a log or stone (Fig 1) to the back of the wagon so that by dragging it over the ground the speed of the vehicle was checked

Indeed to find the time when the question of braking first came into prominence it is necessary to go no further back than the period when highways became sufficiently well made and maintained as to admit of a heavy vehicle being drawn over them at comparatively high speed

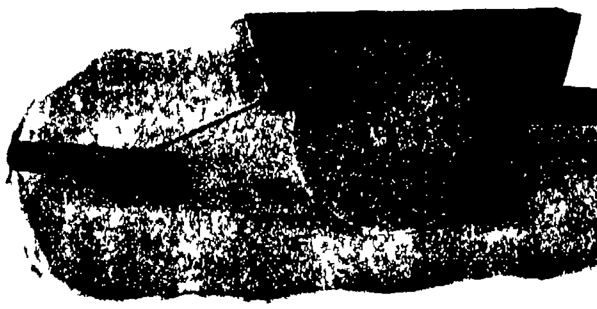

Fig 1—THE DRAG

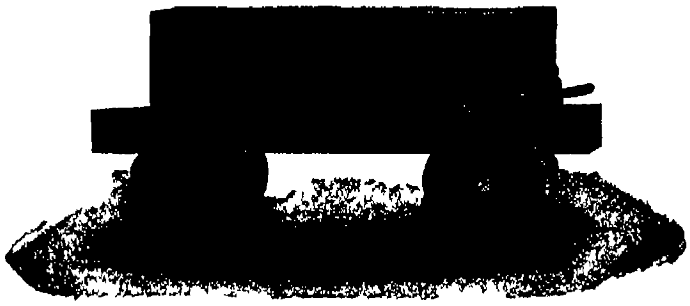

Fig 2—PRIMITIVE RAILWAY WAGON BRAKE

A remarkable adherence to one basic combination of elemental parts of the same general character and function is to be observed in even the earliest types of brake apparatus This extends from the simplest primitive forms through the entire progress of the art until they are found to-day associated it is true with great specialization and complexity of detail but still having essentially the same fundamental components

This is natural because as the moving vehicle must be controlled by self contained apparatus it was first necessary to devise means whereby a source of energy or pressure, located on the vehicle, might be made to generate retarding force, opposed to the motion of the vehicle

It is easy to see that the revolving wheels and axles offer the convenient and practicable opportunity required and consequently it is not surprising to find that practically all brake devices no matter how widely diversified in details have one feature in common This consists of a block or brake shoe as it is called so located that it may be pressed against the wheel tread with more or less force as may be necessary This develops a frictional force or pull between the relatively stationary shoe and the revolving wheel which so long as it does not exceed the adhesion of the wheel to the rail or roadway on which it rolls tends to retard and finally stop the motion of the wheel and thereby of the vehicle itself

Fig 4—STEVENSON'S STEAM LOCOMOTIVE BRAKE

It can be proved by experiment that the adhesion of a wheel to a rail while rolling (static or, more properly rolling friction) is greater than the frictional force at this point when the wheel is sliding (kinetic friction) Therefore the maximum retardation on the vehicle as a whole is obtained when the brake shoe pressure is such as to produce a frictional force at the shoe nearly but not quite sufficient to cause the wheel to slide This explains why wheel sliding must be avoided for theoretical as well as practical reasons

Early Railway Brakes—One of the earliest and simplest means of retarding the wheels of a vehicle in this way was forced by a change in existing conditions just as the many subsequent changes in methods of locomotion have been responsible for the perfection of the brake as we know it to-day About the year 1630 an enterprising mine owner at Newcastle-on-Tyne finding the roads between his mine and the river so bad as to seriously interfere with the hauling of coal, conceived the idea of laying wooden rails in the road and running his cars thereon The tractive effort of these cars was thereby so much increased that the necessity of some contrivance to check their speed was at once apparent and brought out simple forms of brakes One of these forms consisted of a metal tipped beam which was fastened to the frame of the car in such a way as to scrape along in the ground at the side of the track. Another form was a simple lever pivoted to the side, near the center of the car, and ordinarily held up by a chain, which, when desired for use, could be liber-

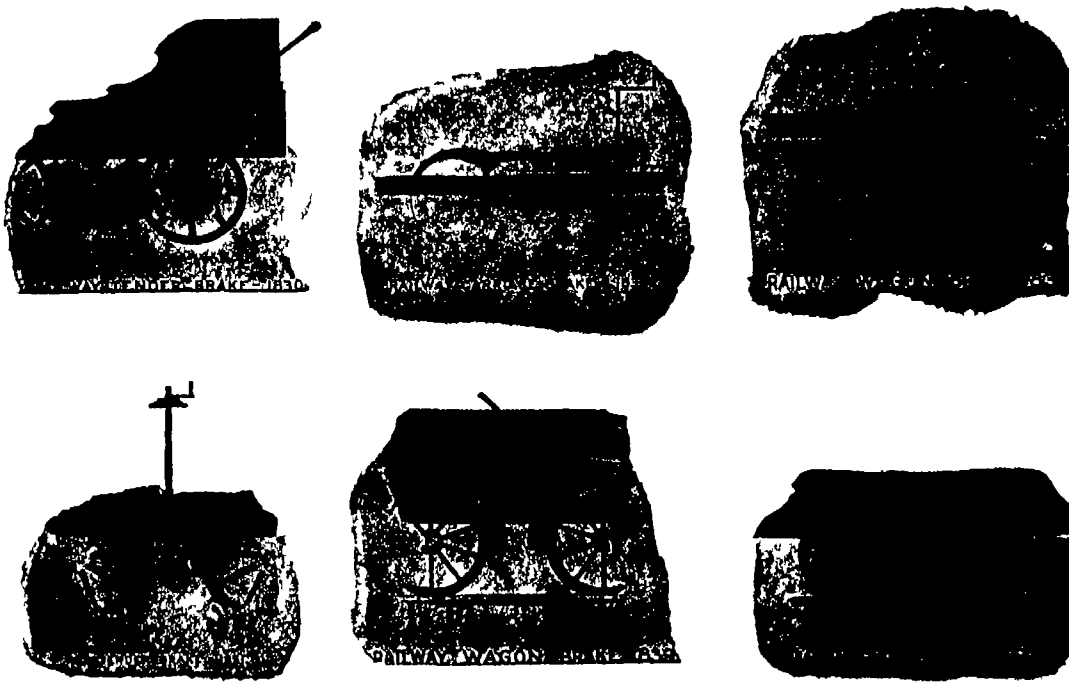

Fig 3 SIMPLE AND EARLY TYPES OF HAND BRAKES

* Presented at the meeting of the Mechanical and Engineering Section

ated and pressed by hand or foot against the top of the wheel as shown in Fig. 2

Many other simple devices of like nature were adopted by such rail or tram roads as then existed which require mention only to point out that all made use of a block or shoe forced against the tread of the wheel either directly or through the medium of some simple combination of rods and levers whereby the strength of the man applying the brake might be augmented or multiplied (Fig 3)

The Steam Brake—As the speeds on these roads were generally quite low and the cars small enough to be drawn by draught animals such devices served all practical purposes until the inauguration of a new order of things by the advent of the steam locomotive With the speeds and weights of cars which then had to be reckoned with it soon became evident that something better than a manually operated brake was needed In 1833 Stevenson patented his steam brake (Fig 4) in which steam pressure acting on a movable piston was made to take the place of the hand-operated mechanism by which the force was applied through a system of rods multiplying levers (and cams in this case) to the brake shoe In this first form of power brake we have all the elements of a complete power brake viz

1 Source of power—steam

2 Means whereby this power may be made to act

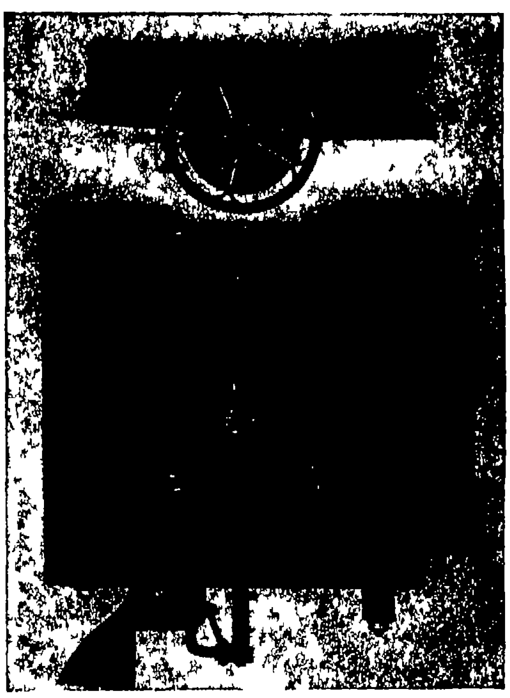

Fig 5—CREAMER BRAKE 1853

upon the rods and levers of the brake rigging proper—a brake cylinder with movable piston and rod

3 Connecting rods and multiplying levers to transmit and increase the pressure exerted on the brake piston—called the foundation brake gear

4 Means for transmitting the force exerted through the foundation brake gear to the wheels as retarding force or 'pull'—this being the function of the brake shoes as already explained

In the case of the cars the hand operated brake with various forms of foundation brake gear met all practical requirements for some time though a general realization of the necessity for some form of power brakes is attested by the fact that during the first seventy years of the nineteenth century about 650 patents were granted in England for various kinds of brakes for railroad service

PNEUMATIC BRAKE

The first pneumatic brake was a vacuum brake patented by James Nasmyth and Charles May in 1844 In 1848 Samuel C Lister patented an air brake having an axle driven pump and suitable reservoir to be placed on the Guard's Carriage and suitable cylinder pipe and connections on the various cars to constitute a straight air equipment much the same as that which followed many years after except that it was designed to be operated by the guard and not by the engineer

Continuous Train Brake—Of course the earlier types of hand brakes underwent considerable improvement, but while the majority of passenger as well as freight cars, were braked by hand as more and heavier cars came to be handled in the same train the necessity for a continuous brake or one capable of being put in action on the various cars comprising the train at the will of the engineer himself became more and more evident Some of the various systems originating in this country were extensively tried and seemed to meet the conditions for which they were designed with various degrees of success The Creamer brake (Fig 5) which was brought into use in 1853 consisted of a large spiral spring attached to the brake staff at the end of the car and which was wound up by the brakeman immediately after leaving a station Attached to the mechanism was a cord which ran through the train to the engineer's cab and the brake was so designed that when the engineer pulled the cord the coil springs on each vehicle were released and these at once wound up chains leading to the foundation brake gear thereby bringing the brake shoes against the wheels

The Loughridge Chain Brake (Fig 6) which came into use in 1855 consisted of a system of rods and chains continuously connected throughout the train as follows On each vehicle were two pairs of small pulleys each pair sliding toward the other upon an iron framework but held apart by a spring to each pair was connected a chain leading to the foundation brake gear Upon the engine was placed a drum connected by a worm and gear to a small friction wheel which in the engineer's cab was pulled this friction wheel was brought into contact with the periphery of one of the driving wheels thereby causing the drum to wind up the chain and shorten its length throughout the train in so doing the pulleys upon each vehicle were brought closer together thereby applying the brakes

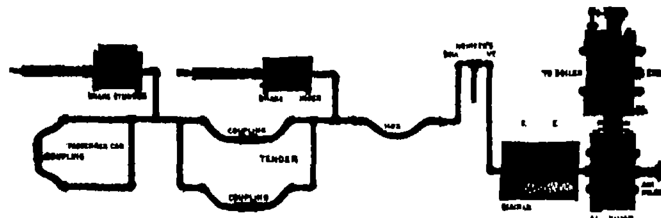

Fig 7—STRAIGHT AIR BRAKE

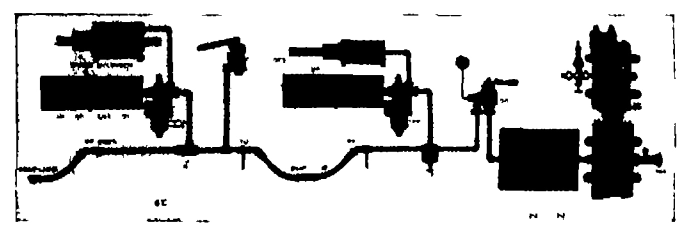

Fig 8—THE WESTINGHOUSE PLAIN AUTOMATIC AIR BRAKE 1872

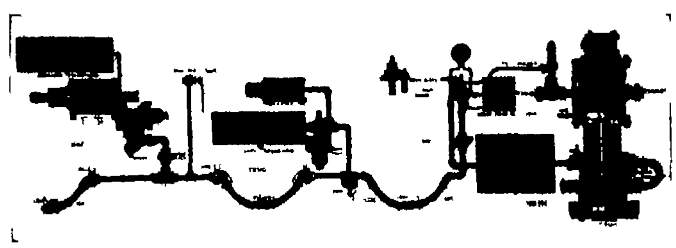

Fig 9—THE WESTINGHOUSE SYSTEM QUICK ACTION AUTOMATIC BRAKE 1887

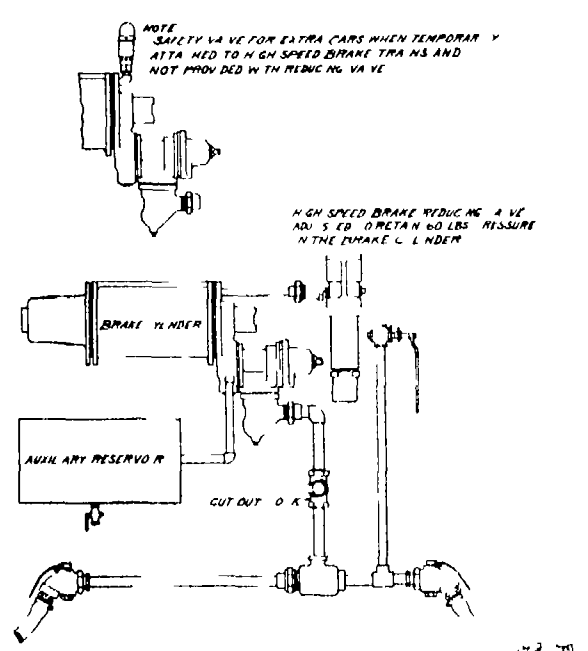

Fig 10—HIGH SPEED PASSENGER BRAKE

In addition to the above various forms of continuous brakes other than air brakes were tried to a greater or less extent from time to time Among those may be mentioned the Smith Vacuum Brake the Westinghouse Vacuum Brake the Eames Vacuum Brake the Hay Mechanical Brake the Clark & Webb Chain Brake the Barker Hydraulic Brake the American Buffer Brake the Widdifield & Button Friction Buffer Brake the Rote Buffer Brake the Carpenter Electric Air Brake and the Card Electric Brake From the length of this list it will be seen that to give an adequate description of these various systems would be to occupy with matter of purely historical or curious interest valuable space and the time of the reader which promises already to be overtaxed by the demands of modern practice and recent development

While these types of brakes were the result of much ingenuity and skill and attained to a degree of success sufficient to prove the necessity for and advantage of a reliable and efficient continuous brake

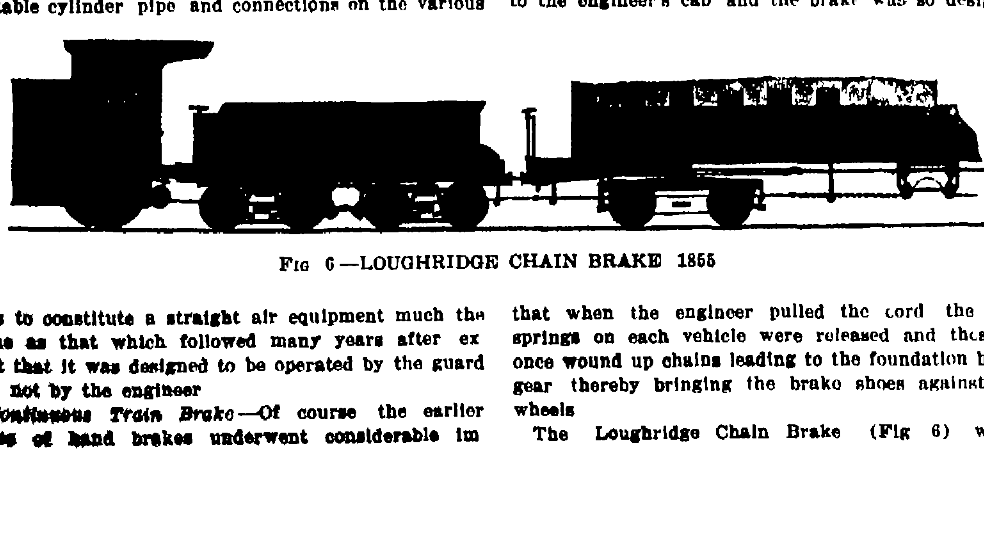

Fig 6—LOUGHRIDGE CHAIN BRAKE 1855

none of them satisfied enough of the fundamental requirements of a practicable continuous brake to result in their universal acceptance as a standard in this country

The Air Brake—Straight Air Type The first steps of the complete solution of the problem were taken and a new line of development opened up by the genius of Mr George Westinghouse who in 1869 took out his first patents for the Westinghouse Non Automatic Air Brake since generally designated as the Straight Air Brake

The source of power adopted for this system was the expansive force or pressure of compressed air obtained from a steam actuated air pump placed upon the side of the engine and a reservoir in which the compressed air could be stored A pipe line from the reservoir was carried throughout the length of the train connections between vehicles being made by means of flexible hose and couplings Each vehicle was provided with a cast iron cylinder the piston rod of which was connected to the brake rigging in such a way that when the air was admitted to the cylinder the piston was forced out and the brakes thereby applied A three way cock or valve located in the engineer's cab by means of which compressed air could be admitted to the train pipe and thus to the cylinders on each car to apply the brakes or the air already in the cylinders and train brake pipe could be discharged to the atmosphere thus releasing the brakes

An early form of the Straight Air Brake is shown in Fig 7 The air pump is one of the first forms to come into general use the so-called trigger or jigger valve motion and octagonal piston rod being features of particular interest

This type of apparatus has many good qualities and a very large degree of flexibility that is the increase or decrease of the pressure or braking power so called was under the control of the operator to a very marked degree but had shortcomings which made it unsuitable for use on trains of any considerable length on account of the time required to apply and release the brake and the unequal braking effort throughout the train More important still the factor of safety was low as no warning was given in the event of the hose coming uncoupled and a parted train meant no brakes Thus it is seen that it lacked the first essentials of an efficient brake which is that it must be its own telltale That is if an accident occurs to the system it must result in a brake application instead of a loss of the brake

PLAIN AUTOMATIC AIR BRAKE

In the natural process and development of railroads the requirements became more exacting and it was evident that the straight air brake was not only unsuitable for the reasons just mentioned but that it lacked essential features It became more than ever important that the brake must apply automatically in case of the train parting This was so fundamentally necessary that even if the flexibility of the straight air brake had not already been lost to a large extent by the lengthening of the trains it would have had to be abandoned because of the infinitely greater safety inherent in a brake of the automatic type Therefore the straight air brake having served its purpose as an advance agent of something better gave way to the automatic brake which afterwards came to be called the plain automatic brake to distinguish it from a later type that locally reduced the brake pipe pressure thus producing what is called quick action

The first form of this brake probably the greatest advance ever made in the art was invented and introduced by Mr George Westinghouse in 1872 (Fig 8)

The automatic feature resulted from the obtaining of an indirect application of the brakes through the medium of a valve device called a triple valve and an auxiliary storage reservoir which were added to the brake cylinder on each car All of the triple valves were connected together by a continuous pipe called the brake pipe with flexible connections between the cars this pipe being charged with air whenever the brakes were in operative condition By this means the auxiliary reservoir was charged with compressed air for braking purposes on the vehicle to which it was attached therefore it was no longer necessary to transmit the air *from* the locomotive to the vehicle when an application of the brakes was desired The triple valve is the essential mechanical element in such a system possessing the three functions of charging the auxiliary reservoir and of applying and releasing the brakes in accordance with variations in the air pressure carried in the brake pipe the medium for producing such operations as desired being for all general operations a manually operated brake valve on the locomotive

By means of this valve the engineer could apply the brakes *either* to a part of their capacity by steps or graduations or fully by a continuous decrease of the brake pipe pressure but he had no control of the release of the brakes (as with the straight air) The automatic brake releasing locally on each car while the release of the straight air brake was controlled on the engine Therefore one of the elements of flexibility possessed by the straight air brake was lost, but as has been said this feature had already been very much reduced in value by the lengthening of the train

Thus through the instrumentality of the triple valve the air brake became automatic which term applies to that *application* of the brakes which occurs through any material depletion from any cause of brake pipe pressure either at the will of the engineer by hose parting burst hose leakage or at the instance of the train crew so that this system very materially increased the factor of safety and permitted the use of air brake on longer passenger trains and on the already existing freight trains in a way that was not possible with the straight air brake equipment

Quick Action and Automatic Air Brake—This plain automatic brake was a great improvement in many respects over the straight air brake but chiefly from an emergency or safety standpoint for much of the flexibility (that is the ability of the operator to increase or decrease the cylinder pressure at will and for any desired number of times in rapid succession) for ordinary service brake operations had to be sacrificed This brake served the purpose fairly well while trains were short and speeds weight and frequency low but as these factors changed *its* limitations became more and more apparent particularly with reference to emergency operation The application was too slow with long trains *and for* reasons differing only in degree from those which had affected the straight air brake Thus when a quick application was attempted the shocks were great nor was the stop as short as required The reason for this slowness of operation was because the air in the brake pipe could not be quickly and uniformly reduced throughout its whole length this because of increased volume frictional resistance and the necessity of its traveling to the one outlet which was through the brake valve at one end of the train This limitation was overcome by the invention (in 1887) *of the* quick action triple valve and the equipment with which it was used came to be known therefore as the Quick Action Automatic Brake (Fig 9) The quick action triple valve was identical with the plain triple valve as far as service operations were concerned but differed from it in emergency in that it automatically vented air from the brake pipe locally on each car The rapid brake pipe reduction thus resulting is transmitted to the next triple valve and from it serially in the same manner to all the valves in the train thereby reducing the time of full application to about one sixth of what is inherent with plain triple valves on a fifty-car train and shocks were therefore correspondingly lessened and stops shortened The reason for this is that the brake pipe reduction with the plain triple valve took place at only one point in the train instead of fifty as with the quick action valve

The feature of serial venting of the brake pipe was so important that a second feature of this brake system which the first mentioned made possible was and is to-day overlooked by many and perhaps is often not rated at its true value This feature was the then possible attainment of a different and higher braking power for emergency than for service applications Up to this time the cylinder pressure or retarding force attainable had been the same for both service and emergency application but now since the brake pipe pressure vented could be and as a matter of fact was vented into the brake cylinder with one form of the device the pressure therein was materially increased whenever quick action took place

From this it will be seen that to the automatic and graduating features of the brake two others were added namely serial quick action and difference or increase in braking power between service and emergency applications All four of these are now generally recognized (though often not appreciated as they should be) as being fundamentally essential in a brake worthy the name Moreover these four features have had and still have great possibilities of extension and development Attention should be called again to the wonderful adaptability of the original combination of brake cylinder triple valve and auxiliary reservoir to the ever increasing need of more powerful and what naturally follows a more flexible brake It is truly remarkable that through all subsequent improvements not one of the original functions of the triple valve has been discarded but that they have been extended and expanded and many new functions added

So far the apparatus employed was the same for both passenger and freight cars but the still greater frequency of trains heavier vehicles and higher speeds made it necessary to provide means whereby a still greater stopping power for passenger service might be available when needed, particularly for emergency applications This was possible only by increasing the air pressure, since any other method would have made the brake too severe for low speeds In other words, the percentage of braking power per pound of cylinder pressure was already as great as practical operation would permit.

THE HIGH SPEED BRAKE.

It was thought, however that to increase the brake pipe pressure sufficiently to give the desired braking power would result in unpleasant or dangerous shocks slid and flattened wheels and other damage from the high brake cylinder pressure obtainable therefore this was not done until the valve known as the high speed reducing valve was perfected in 1894 The principles utilized by this type of apparatus had been thoroughly demonstrated by the classic Westinghouse Galton tests in England in 1878 These tests showed that, while the adhesion between the wheel and the rail—which causes the wheels to persist in their rotation—is practically uniform at different speeds the friction between the brake shoe and the wheel—which acts as a resistance to the rotation of the wheel and thereby stops the train—is considerably less when the wheels are revolving rapidly than when they revolve slowly It was thus demonstrated that a greater pressure not only could be safely applied to the wheels by the brake shoes at high speeds but also that such considerably greater brake shoe pressure *must* be applied to the wheels at high speeds in order to then resist the motion of the train as effectively as it is resisted with a more moderate brake shoe pressure at low speeds This was accomplished by the use of a higher brake pipe air pressure with the standard quick action apparatus with only the addition of a high speed reducing valve attached directly to the brake cyclinders This device was designed to limit the brake cylinder pressure obtainable during a service application of the brakes to what was considered safe and necessary but when an emergency application of the brakes was made to permit the brake cylinder pressure to rise to a considerably higher value than the maximum permitted in a service application and then to cause a gradual reduction of brake cylinder pressure quite slow at first but becoming more rapid so as to proportion as far as possible with such a device working on a fixed range the blowdown of brake cylinder pressure to the reduction in speed as the stopping point is approached Superior stopping capacity was obtained as already stated by increasing the brake pipe air pressure from the generally adopted 70 pounds as used with a quick action brake equipment to 110 pounds which in emergency applications and with the sizes to brake cylinder then in use would give about 85 pounds cylinder pressure in stead of about 60 pounds or in other words raise the nominal percentage of braking power from 90 to 125 per cent of the weight of the vehicle

With this improved equipment when an emergency application was made full cylinder pressure (85 pounds) was quickly obtained but was automatically reduced to 60 pounds and held at this point by means of the automatic reducing valve Thus if the stop was long enough the initial nominal percentage of braking power was 125 per cent while the final was 90 per cent but the actual retardation of the train kept fairly constant due to the difference in the retarding power of the shoes at high and low speeds already mentioned Though the co-efficient of brake shoe friction was known to be less at high speeds than at low speeds it was predicted by many that much wheel sliding would result from raising the nominal power above 100 per cent of the light weight of the car but on the contrary wheel sliding was lessened and naturally so when the situation is analyzed

In service applications the opening from the reducing valve was larger than in emergency application so that if such a reduction or brake pipe pressure was made as would cause the brake cylinder pressure to rise above 60 pounds the reducing valve would open and vent the air which otherwise would cause an undesirably high brake cylinder pressure to the atmosphere

This combination with the quick action triple valve is known as the high speed brake and is illustrated in Fig 10

(To be continued)

Grain Standardization and Wheat

THE study of grain standardization has been progressing satisfactorily Three hundred samples of various varieties classes and grades of wheat were experimented with in connection with the improvement of the handling and marketing of this crop The important study of seed testing for the purpose of improving the quality of the different seeds and for ascertaining the particular seeds for different climates is being rapidly developed The Department of Agriculture has been directing special effort to extend the area of possible cultivation of hard winter wheat by the introduction of varieties harder than those now grown. The Kharkov variety has proved to be the best.

Correspondence

The Bergen-Christiania Railway Contrasted with Two American Railroads

To the Editor of SCIENTIFIC AMERICAN SUPPLEMENT

The description of the grades of the Bergen-Christiania Railway given in the SCIENTIFIC AMERICAN of February 11th last gives a basis for a profile which I have constructed and present herewith For purpose of comparison I have prepared outline profiles of two American railroads on the same scale and covering nearly the same distance

The Bergen-Christiania Railway was recently opened across the Scandinavian peninsula and the profile shows how it climbs the mountains in order to save forty out of fifty four hours of travel Owing to the necessary difference between the horizontal and vertical scales the grades are of course greatly exaggerated.

Fig 2 shows the Delaware Lackawanna and Western Railroad for nearly three fourths of its distance between New York and Buffalo At its highest point in crossing the Pocono Mountains in Pennsylvania it is nearer the clouds than any of the four other trunk lines between the two cities yet considerably less than half as high as the Scandinavian Railway The steady climb westward to Bath at 1 102 feet is continued beyond the bounds of this drawing till a second summit is reached at Wayland at 1 361 feet then it is a rapid descent into the Genesee Valley at Groveland 448 feet and another moderate climb to East Bethany 1 006 feet to surmount the watershed which all the other lines also must conquer in getting into Buffalo

Fig 3 is the profile of the New York Central Railroad for two of its three main divisions between New York and Buffalo The contrast between this grade and those of the Scandinavian and Lackawanna railroads is very marked It is rightly called the water level route There is no ascent all the way to Albany

From there a sharp ascent followed by a swift descent brings the trains into the Mohawk Valley which gives an easy grade to Utica and Rome from which the long level of the Erie Canal is duplicated by the long level of the railroad to Syracuse where the altitude is barely above 400 feet The highest station on the line is Batavia 895 feet The Scandinavian Railway ascends more than four times the greatest altitude reached by the New York Central and nearly ten times anything reached between New York and Syracuse—for there is a little summit of 477 feet west of Utica—and 80 times the highest point between New York and Albany

THE GRADES OF THE BERGEN-CHRISTIANIA RAILWAY

Alloys for Permanent Magnets

IN the investigations of electrolytic iron and its alloys which have been carried out by C F Burgess and J Aston and which are described in the *Metallurgical and Chemical Engineer* it seems that tests were made of the magnetic quality of all the samples Among these were many which showed low permeabilities and high coercive force suggesting their utility for permanent magnets rather than as electromagnetic material Upward of 100 samples were tested for this feature all of the bars contained Cr Mn Mo Ni and W as binary alloys or in various combinations together or with other elements The tests recorded in the paper are for the most part on carbon free alloys The results are mainly of value therefore as indicating the influence of the various elements in inducing the conditions necessary for a good permanent magnet They were carried out on an Esterline permeameter The bars were tested as forged and after water quenching at 1 000 deg C To prevent oxidation of the samples while heating them for quenching a barium chloride bath was used The quenching at 1 000 deg C will probably not have brought out the best qualities of some of the bars but it was deemed the best general treatment since with so many bars under test it was impossible to subject each sample to tests for its critical points and special conditions of heating In addition to these general tests all bars which showed a fair retentivity and a coercive force above 30 were subjected to a test of their ability to hold residual magnetism after shock For this test the bar was subjected to the maximum magnetising force of 200 C G S units and the retentivity noted when this magnetising force was reduced to zero The bar was then removed from the machine, subjected to the disturbing factor and the retentivity again recorded after reinserting the specimen in the permeameter The two means commonly employed in practice for seasoning permanent magnets were used viz jarring or rapping the bar and boiling For the latter treatment each bar was inserted in a piece of wrought iron pipe which served as a shield to prevent the mutual influence of the magnetic fields and boiled in water for three hours A large number of trials of the rapping and boiling treatments showed them to be practically equal in their effect An extensive series of tables is given in the paper which set forth the main results of the investigations From the figures it is deduced that Cr Mn Mo and W are the most important elements for use in the manufacture of permanent magnets The presence of a third element is necessary While carbon is beneficial it is possible to obtain highly satisfactory materials either by various combinations of the four above-mentioned elements or by suitable additions of Si or V the latter in particular being very suitable When the material for the permanent magnet is to be hardened by quenching the presence of a considerable amount of carbon is desirable

Effect of Paris Flood on Electrical Machinery

THE effects of the Paris floods on electrical machinery are described by Guery in the Societe Int Elect. Bull It seems that a great deal of damage was done by the floods to machinery both on railways and in central stations but of these 16 000 different units have been rendered serviceable without any rewinding Everything was first carefully washed to remove mud etc sometimes a bath of dilute sulphuric acid was used in cases where injury had been caused by the overflow of acid from accumulators Some sort of drying process was then adopted after the windings had been sufficiently loosened to expose them to the air Some sorts of insulation such as fiber press-spahn and cardboard were found to be so much deformed as to be useless Some of the fixed machinery was dried by passing current but suitable pressures were not always available Some of the machines were driven at slow speeds and dried in various ways electrically and some of the railways treated all their fixed machinery by this method In some cases the apparatus was dried by stoving the temperature being kept between 110 and 120 deg C never exceeding 130 deg C In other cases much lower temperatures were employed requiring a much greater length of time In one case [illegible] that of the State railways stoving under a vacuum was tried this seems to have given no result at 65 degrees a satisfactory result at 75 degrees but probably a better result at 100 degrees Some motors were more or less burnt so far as their insulation was concerned by passing overheated air through them It seems to have been found that both heating in air at 106 degrees and in a vacuum at 65 degrees were ineffective There were many failures with transformers but in most other cases success was attained provided no time was lost in beginning work Underground conductors supported on glass or porcelain were of course hardly affected and this was also the case with supports of paraffined wood used as a third rail support though here were a few failures Some of the older types of rubber cables were found to be useless for high pressures though serviceable for 110 volts even after being submerged for twenty days Paper cables generally speaking were little injured even after their immersion for a month under heavy pressures of water some damage was done and the junction boxes were a weak spot Batteries were found to be very little injured The paper concludes with some notes as to precautions that may reasonably be taken in future together with a brief notice of the various incidents of the flood of last year

Breakwaters on the West Coast of Jutland

The Vornpör and Hanstholm Walls

By C Van Langendonck

Two breakwaters have recently been completed on the west coast of Jutland one at Vornpör and the other at Hanstholm The object of the construction is to produce for the fishermen additional safety during their work in beaching their boats in stormy weather and to prolong the fishing season by enabling the men to go to sea under circumstances which would otherwise make it impossible for them to do so Both breakwaters form approximately a right angle with the coast but that at Vornpör has a direction northwest to north while that at Hanstholm runs due north There will consequently always be shelter at one side of one of the piers

The breakwaters which constitute an interesting piece of engineering work are each 1 000 feet long and their construction has involved an expenditure of about $500 000 The basis for the contract was the plan worked out by the Danish Water Construction Department according to which both breakwaters were to consist of concrete blocks of up to twenty tons weight which were to be placed within a framework of iron on a foundation layer of shingle laid to level the irregularities in the lime stone underneath The grooves between the iron frame and the concrete blocks and between the concrete blocks themselves were afterwards to be filled with neat cement The size of the iron boxes was 16 feet in the direction of the length of the breakwaters while the breadth at the top varied from 20 to 22 feet the batter on the side was 1 6 An iron box filled with concrete blocks was estimated to weight from 300 to 7 0 tons The surface of the iron boxes was to be of the same height as the ordinary water level

A modified construction was however proposed by the contractors Messrs F V Blom og Saabye and O Lerche viz the adoption of reinforced concrete boxes instead of iron boxes which were to form the section of the pier and yet at the same time like the iron boxes form the outer casing for the filling which consisted of concrete blocks The reason for these alterations was a desire to employ larger concrete blocks and to avoid the use of the temporary iron framework This suggestion was accepted by the authorities and the contractors received the option of either entirely or partly building the piers in this manner These concrete boxes have the same length and breadth as the iron boxes and a weight of 80 to 90 tons being divided vertically into three pieces They are filled with solid concrete blocks of about the same weight The proportions of the mixture forming the concrete boxes are 1 2 4 and in the solid blocks 1 3 6

Each of the two breakwaters consists of sixty two sections of which the one farthest out stands in about 20 feet of water on a firm limestone bottom Supposing a section of one of the outer boxes then cement through a pipe for which provision was made in the corners of the block In order to prevent the cement from running out into the sea the bottom was covered with sackcloth nailed to a timber frame, which was molded in the lower side of the bottom box This sackcloth was fixed by divers as soon as the lowest box section was placed in position and crane passed lie at 11 feet above the datum line, and all the rails on shore where the blocks were made, are of course at the same level It was the original plan to build the bridge of wooden piles, but in the whole of the outer section heavy iron piles had to be adopted as it was found impossible to drive effectively to the limestone bottom

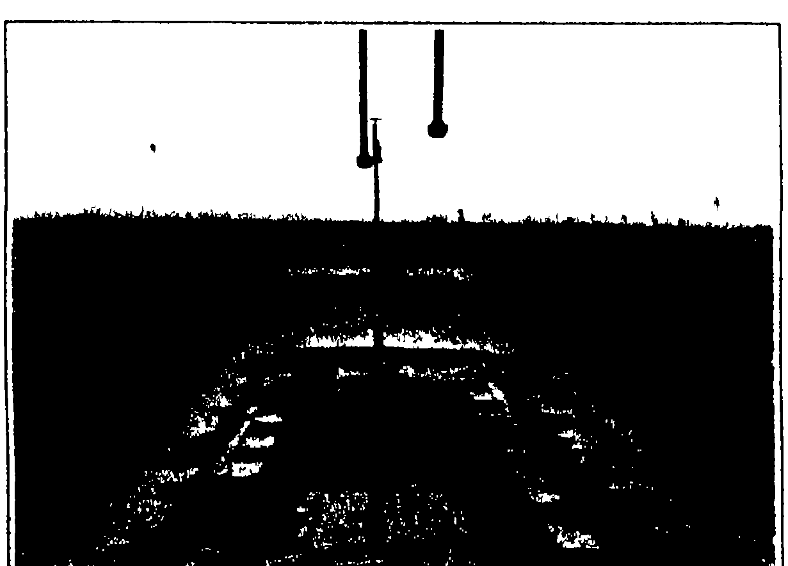
TESTING THE GREAT CRANE WITH A LOAD OF 12? TONS OF RAILS THIS CRANE IS USED FOR HAULING THE GREAT BLOCKS

weighed down by stone An upper monolithic portion of the pier was formed on the top of the boxes the topmost of which reached to from 1 foot to 2 feet above ordinary water level Into the upper portion was placed a number of old rails in the longitudinal direction of the pier Both the outer sides of the boxes and the upper structure are covered all over with granite facing bedded into the concrete Outside the breakwater on both sides and in front of it is placed a protecting apron in the shape of concrete blocks 3 feet to 5 feet high also covered with granite pavement This is quite necessary owing to the wear and tear from sand and pebbles through the incessant motion of the waves These protecting blocks have a weight of 8 to 15 tons each and lie in pairs in the outer portion there is a triple row A space as already mentioned was left between the shore and the nearest end of the breakwater so

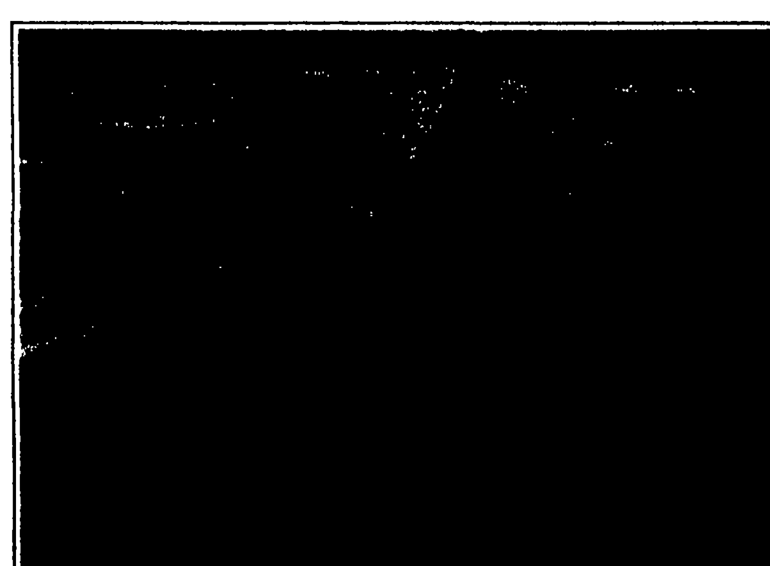
The upper structure of the breakwaters was built in the following manner Concrete blocks made on shore were placed on both sides in final position and the space between these was filled in on the spot with concrete

The arrangements on shore comprised three casting pits which formed a right angle with the direction of the pier The blocks were transported from the casting pits to the rails by means of a Goliath crane This last placed the block on a truck which then conveyed it to the crane at the end of the pier

The work at Vornpor was commenced in the summer of 1904 by constructing the molding pits for the concrete blocks and the building of the pile bridge to the breakwater when the placing of the boxes was commenced In the autumn of 1905 six boxes were laid in 1906 nineteen the following year fourteen in 1908 nineteen while the two remaining



THE OUTER PORTION OF THE BREAKWATER IN THE COURSE OF CONSTRUCTION



THE BREAKWATER NEARING COMPLETION

BREAKWATERS ON THE WEST COAST OF JUTLAND

the former would consist vertically of three boxes The interior space is filled with solid blocks and the large intervals between the blocks with small stones averaging about an inch in size similar stones forming the layer upon which the blocks rest As soon as the inside blocks were brought into position these intermediate spaces with the stones were filled with that a current could pass between the breakwater and the land This gap had of course to be bridged On account of the heavy traffic which had to pass over it, this connecting piece had to be constructed of substantial materials The transverse beams consist of eight timbers of dimensions varying from 14 by 14 inches to 16 by 16 inches The rails along which the ones were placed in the spring of 1909, when the work upon the upper structure was taken in hand, proceeding from the outer end in the direction of the shore The Vornpör breakwater was completed in the course of last year (1910) The work has proceeded in a satisfactory manner, and there have been no mishaps Stormy weather has proved a

hindrance now and again, and in order to be more independent of turbulent seas, concrete screens, so arranged that they could be used at different depths were made and occasionally used. They, in a way, answered their purpose, but their practical value was not very great, still they were serviceable in cases of emergency. The building of the Vornpör breakwater has had the unexpected effect that the sea north of the breakwater has made considerable inroads on the shore both on the foreshore and the

THE VORNPÖR BREAKWATER NEARLY COMPLETED

more elevated coast some houses having been washed down.

At Hanstholm the work was commenced in the spring of 1904. The original scheme with iron boxes was adhered to at this breakwater as far as the work hitherto done is concerned. The first box was placed in position in April 1905 and in the course of the same summer eight additional boxes were placed. The work was then discontinued pending the completion of the Vornpör breakwater. Now the heavy plant has been conveyed from there to Hanstholm and the work will be continued in accordance with the modified system used at Vornpör.

Our photographs represent the different phases of the building of the Vornpör breakwater.

Production Per Acre Overtaking Population Increase

Production per acre is beginning to overtake increase of people declares the Secretary of Agriculture in discussing one of the features of his report. The evidence is very plain that the yields per acre of our crops are now increasing and if the facts were assembled in detail for the States it would be found that the percentage of increase in yield of many of them is greater than the percentage of normal increase of population—that is the increase of births over deaths in the old native element.

That this is a fact, in greater or less degree is stated comprehensively in the report. During the ten years, 1896-1905, the production of wheat per acre on the average increased over the average of the preceding ten years in a greater degree than the normal increase of population (that is, apart from immigration and the temporarily high birth rate of the foreign born) in twenty-six States, and two more States are all but ready to join them. In fourteen States corn production per acre has increased faster than the normal increase of population and this is almost true of five more States. The number of States in this list in the case of barley is 21, rye 30, buckwheat, 19, cotton 3, potatoes, 24, hay 35, and more or less States are almost ready to enter this list in the case of all crops.

A demand that is more difficult to fulfill in production per acre is for an increase that equals or exceeds the actual increase of population including the immigrants and the temporarily high birth rate of the foreign born. But notwithstanding the fact that this difficulty is greater in the United States than it is in all other countries that have practically ceased to take much new land into cultivation many of the States of this nation are each maintaining an increase of production in the case of one or more prominent crops that is greater than the actual increase of population. Ten States are doing this in the case of corn for wheat the number is 22, for oats 16, for cotton and tobacco 1 each, for rye 21, for potatoes 15, and for hay 20.

We cannot look for any other result than that the yields per acre of all crops shall increase at an even faster rate in the future in view of the intense interest with which our people are turning their attention toward agricultural improvement. If there are certain forces at work which if unchecked and made more prevalent will in the future compel us to bid against the world for food, the counteracting forces have nevertheless been already set in motion with the promise of increasing effect.

Eradication of Animal Diseases

The work in cattle-tick eradication resulted in the release from quarantine of 57 518 square miles, the largest area released since the beginning of the work in 1906. The total area so far released is 129 611 square miles in 11 southern states.

Areas aggregating 390 000 square miles including all of Washington and parts of Oregon, Nevada, Utah, Arizona and Colorado were released from the sheep scab quarantine. A quarantine for this disease was placed on Kentucky. Areas released from quarantine for scabies of cattle amounted to 53,021 square miles. The Department inspected 52 749 920 sheep and 18 190 456 cattle while 12 153 356 sheep and 1 336 829 cattle were dipped under supervision.

In August 1909 a quarantine was established because of malignant lip-and-leg ulceration of sheep which appeared in Wyoming. The Department has kept a force of veterinarians in the field to assist sheepmen and state officers in treating the disease and to enforce the quarantine. About one-fourth the quarantined area has been released, the number of cases has been reduced and the spread of the disease prevented.

For the eradication of tuberculosis among cattle in the District of Columbia the Department arranged to test all cattle in the District with tuberculin, to supervise the slaughter of those that reacted to the test and to reimburse the owners. Over 18 per cent of the cattle in the District reacted to the test and of these 98½ per cent showed tuberculosis on post-mortem examination. All cattle brought into the District are now tested. It is also intended to retest the herds at intervals. Continued for a reasonable time this course will completely eradicate tuberculosis from the cattle of the District.

The efficiency of the serum treatment for the prevention of hog cholera devised by the Bureau of Animal Industry was strikingly demonstrated in a test at Kansas City. Thirty-five pigs were placed in a pen together, of which 4 had been inoculated with virulent hog-cholera blood, 22 injected with the preventive serum and 9 not treated. The 4 and the 9 died of hog cholera while the 22 remained well.

Coal-Dust Experiments at the Pittsburg Experimental Gallery

A preliminary account of the experiments which are being made by the United States Geological Survey is given by G. S. Rice in the bulletin of the United States Geological Survey Paper No. 425.

The gallery in which the tests are carried out was built in 1908. It consists of fifteen sections of riveted steel plates 6 1/3 feet in diameter, total length 100 feet; each section is 6 2/3 feet long and provided with a lateral window and a relief valve on the top. The gallery is closed at one end by a block of concrete 8 feet in depth, the gun used for igniting the dust is sunk flush into this block. Dust is spread on lateral shelves or blown into the gallery and kept in suspension by the ventilating current (Koerting exhauster and blower connected to every third section) but it does not appear that the stated dust densities per cubic foot of air space were really maintained. Ignition of the various dusts was obtained in all cases, propagation in most cases. Like Taffanel the experimenters believe that the inflammability of the dust is proportional to the percentage of volatile matter present. Experiments in which charges of 2½ pounds of black powder were tamped with dry or with wet coal dust were not decisive; the wet dust sometimes actually yielded longer flames (up to 64 feet long) than the dry dust. When moist preheated air was circulated through the gallery for many hours (up to 70) the explosibility of the dust was not decreased before moisture actually settled on the dust. Coal dust mixed and kneaded with water still remained explosive when the moisture content was raised to about 30 per cent (2 per cent being the natural moisture in the dust); the flame died away after 30 feet. The laboratory experiments on the absorption of oxygen by dust and on the explosive pressures were conducted by J. C. W. Frazer. The chief work in the gallery so far concerns the relative safety of different explosives.

Potash Salts: Light on an International Controversy—II*

Their Uses and Occurrence in the United States

By W C Phalen

Concluded from Supplement No 1839, page 198

GERMAN POTASH SALTS IN THE UNITED STATES

According to Consul General A M Thackara of Berlin the American consumption of German potash in various forms embraces more than half of the export trade material and nearly 18 per cent of the entire production But while the great bulk of the potash salts consumed in the United States comes from Germany that country on the other hand is dependent on the United States for a large part of the mineral phosphates it uses

According to the latest report of the German potash syndicate the following are the quantities of several potash salts which were handled by its members and exported to the United States in 1908

Muriat of potash (chloride of potassium or Chlorkalium) at 80 per cent 288 524 metric tons[2] of which 10[illegible] 281 tons were consumed in Germany 104 048 tons were exported to the United States and the remainder to other countries The amount exported to the United States therefore was 36 per cent of the total

Fertilizer at 80 per cent (muriate of potash) 21 268 metric tons all of which was exported to Scandinavia and Denmark

Sulphate of potash (Schwefelsaurekali) at 70 per cent [illegible]4 751 metric tons of which Germany used 2 821 tons the United States 2[illegible] 000 tons (47 per cent) England 4 986 tons and France [illegible] 110 tons the remainder being sent to other foreign countries

Calcined sulphate of potassium and magnesium (double manure salts) at 48 per cent 3[illegible]7[illegible]6 metric tons of which 16 928 tons or [illegible]0 per cent were sold to the United States and 1[illegible] 124 tons to Holland the remainder being consumed in Germany and other countries

Crystallized sulphate of potassium at 40 per cent 16[illegible] metric tons all of which was used in Germany

Manure salts with 20 per cent 30 per cent and 40 per cent K O 284 989 metric tons of which Germany consumed 171 01[illegible] tons the United States [illegible]2 731 tons (18 per cent) Scandinavia and Denmark 24 005 tons and other countries the remainder

Calcined kieserite 668 metric tons of which [illegible]42 tons were used in Germany and the remainder in various other countries

Kieserite in blocks 2[illegible] [illegible]32 metric tons of which 20 [illegible]0 tons were consumed in Germany 2 794 tons (11 per cent) in the United States and 1 788 tons in all other countries

Kainite and sylvinite 2 388 381 tons of which Germany consumed 1 613 [illegible] tons the United States 3[illegible]1 322 tons (1[illegible] per cent) other countries 413 503 tons

Carnallite and Bergkieserite 74 38[illegible] metric tons of which 71 403 tons were used in Germany and the remainder exported

In the following tabulated statement compiled from official statistics are shown the production of potash salts in Germany during 1907 and 1908 the value of the products and the average value per ton

Production and value of potash salts in Germany 1907 and 1908

	1907		
	Quantity (Metric Tons)	Value	Average Value per Ton
Kainit	2 624 412	$8 505 840	$3 2[illegible]
Other potash salts	3 194 956	965 126	3 33

[illegible]	52 [illegible]	[illegible]9 462	84 11[illegible]	66 644	[illegible] 0
[illegible]	1 4[illegible] [illegible]	8 381	71 581		
Total	$2[illegible] 502 625	$2 2[illegible] 150	$8 4 [illegible] 0	$3 1 5 599	

The above statement shows that the 21 mines earned in 190[illegible] an average profit of 1 9 per cent on the invested capital and declared an average dividend of 13[illegible] per cent It can be safely assumed that the works not included in this statement also reached this average as among them were a number of the most profitable mines and but few of the minor companies

In discussing the position of the potash industry as developed by the late potash syndicate Thackara's report already cited gives some interesting information as to the cost of production of the different grades of potash salts based on expert opinion it being impracticable for several reasons to give the official figures The following statement shows the cost of production and the foreign and domestic prices of the several grades per metric ton

Cost of production and prices of potash salts

	Per Cent K	Cost of Production per Metric Ton	Price per Metric Ton: Foreign	Price per Metric Ton: Domestic
Kainit	12 4	$1 [illegible]4 to $1 9[illegible] 4	$1 [illegible] to $1	$3 [illegible]
Muriate of potash	[illegible]	11 [illegible] to 1[illegible] 85	33 [illegible]	3[illegible] [illegible]
Sulphate of potash	[illegible]	18 08 to 2[illegible] 18	3[illegible] [illegible]	39 [illegible]
Manure salt	[illegible]	8 [illegible] to 11 9[illegible]	13 [illegible]	15 [illegible]

Except for the 40 per cent manure salts the costs of producing which are higher in consequence of the small output the costs of production of the salts listed above vary between 40 and 60 per cent of the receipts from sales These figures are based on the normal running time of the works in 190[illegible] In the two years 1907 and 1908 the costs of production somewhat increased They may at some plants even have passed the maximum of 60 per cent The costs are still low however when compared to those of other mining industries In coal mining for example the costs of production amount to 70 or 80 per cent of the total receipts and are often even greater These facts explain how the selling policy of the potash syndicate and the comparatively low costs of production have stimulated the establishment of new plants

OCCURRENCE OF POTASH SALTS IN THE UNITED STATES

Igneous Rocks

Potash is abundant as a constituent of the rocks which form the crust of the earth According to F W Clarke the percentage of potash (K O) in the earth's crust is 3 00 this result being an average of 1 434 determinations made in the laboratories of the United States Geological Survey up to January 1st 1908 In some varieties of igneous rocks particularly those rich in the potash feldspars there is a large amount of potentially valuable potash The feldspars are widely distributed minerals and comprise about 60 per cent of the earth's crust Among the igneous rocks containing large amounts of potash are the glasses of which the chief are obsidian pumice perlite and pitchstone In these rocks the potash may run as high as 5 or 6 per cent The rhyolites are also rich in potash Examples of this rock containing more than 5 per cent of potash are common and a certain rhyolite from Silver Cliff Colo has been shown to contain 8 38 per cent[2]

[1] Bull U S Geol Survey No 419 1901 p 27

[2] Cross Whitman Proc Colorado Sci Soc December 5th, 1887 p 229

The trachytes and phonolites are also rich in potash consisting chiefly of that variety of potash feldspar (orthoclase) known as sanidine Some of these rocks are known to contain nearly 8 per cent of potash Among the granitoid rocks should be mentioned granite monzonite and syenite which contain considerable amounts of the potash feldspars The leucite rocks of the Leucite Hills, Wyoming contain so far as known the largest amount of potash among the igneous rocks These rocks have been described by Whitman Cross of the United States Geological Survey Certain of them wyomingite and orendite contain from 9 81 to 11 91 per cent of potash (K_2O) In many localities there occur large dikes or deposits of more or less pure feldspar commonly orthoclase which run much higher in potash than the ordinary granite rocks and may approach the theoretical potash content of pure orthoclase feldspar—16 8 per cent of potash Such deposits have been developed in the New England States Pennsylvania New York and Maryland where they have been mined extensively and the feldspar ground to fine powder principally for use in pottery manufacture These deposits may constitute in themselves a comparatively high grade fertilizer were the potash all available for plant food As the feldspar for use in pottery making must be almost entirely free from mica or iron bearing minerals large quantities of such potash rich material are rejected at every quarry But the potash of these rocks even when thus finely ground has been generally supposed to be tightly locked up being practically insoluble by any known cheap commercial process Ten eight or even five per cent potash rock of which there are millions of tons well distributed over the globe would be highly valuable as a fertilizer were there any known cheap method of making the potash available for immediate use to the growing plant

Experiments have been made by the United States Department of Agriculture[2] for the utilization of this potash supply through fine grinding or pulverizing the feldspathic rocks in a manner similar to the grinding for pottery So far as known these experiments have not been completed and the results thus far attained have not proved conclusive This source of potash has also been investigated by individuals among whom may be mentioned Dr A S Cushman formerly assistant director of the Office of Public Roads who on April 30th 1907 took out patent No 851 822 for a process for the extraction of potash soda and other soluble bases from ground rocks This patent is described as follows[3]

Feldspathic or other potash bearing rock is ground to fine powder slimed with water and placed inside of a suitable wooden container which is then set inside of another larger vessel Water is now placed in the outer vessel and electrodes inserted so that the inner or slime chamber becomes connected with the positive pole and the outer chamber with the negative pole A current of electricity from a dynamo is then turned on When this is done the potash soda, and other soluble bases are partially set free from the combinations with alumina and silica in which they exist in the feldspathic rocks

Under the influence of electrolysis the soluble bases pass through the wooden partition and the water in the outer vessel becomes alkaline owing to the accumulation of potassium and sodium hydroxide The electrical resistance of the cells arranged in this way is so high that only a small fraction of an ampere passes through under a potential of 110 volts After a certain percentage of the alkali has been extracted in this manner the action slows down and it has been found necessary to devise methods to accelerate it

Dr Cushman has discovered two methods of accelerating the decomposition of the rock slime and hastening the extraction of the potash (*a*) By a suitable grinding or churning arrangement the slime in the inner chamber can be kept in a continual agitation which causes the necessary reactions to go on more rapidly (*b*) If a small quantity of hydrofluoric acid is added to the slime a very great acceleration in the rate of decomposition and extraction is obtained and it is possible in a reasonably short time

[1] Am Jour Sci 4th ser vol 4, 1897 p 130

[2] U S Dept Agr Bur Plant Industry Bull. 104 1907

[3] Chem Engineer vol 5 1907 p 21, Bur Census, Bull. 92 1908 p. 39

to make a complete extraction of all the potash con tained

If instead of caustic potash it is desired to make various salts of potash such as are in ordinary use for fertilizers and other purposes—that is nitrate sul phate chloride and phosphate—the corresponding acids (nitric sulphuric hydrochloric and phosphoric) are fed in a dilute form into the outer or so-called cathode chamber fast enough to neutralize the caustic alkali as it forms By varying the amount of acid added the resistance of the cell can be controlled and the decomposition of the rock carried on under the best and most economic conditions

Greensand Marls of New Jersey

Potash is found in river waters but in smaller quan tities than soda (Na_2O) The difference is still greater in ocean water owing to the fact that the potash for some unknown reason is largely taken up by the sedi ments forming glauconite while the soda is largely held back in solution This glauconite is an important constituent of the greensand marls of New Jersey

About 30 years ago the greensand marls of the south ern portion of New Jersey were in great demand On the first geologic map of that State the location of the marl beds was shown and in some of the earlier re ports the deposits were described and numerous analyses given as well as instructions in the use of the marl In recent years however marl has been supplanted to a large extent by the more highly concentrated artificial fertilizers and is no longer dug extensively

The following analyses show the composition of the different grades of marl as dug and applied to the soil The glauconite or greensand in them is of nearly uniform composition but mixed with it are carbonate sulphate and phosphate of lime quartz sand sulphide and phosphate of iron shells etc The differences in the kind and quantity of these substances cause wide differences in the appearance of the marl containing them as well as in its com position and properties

The following table gives the potash and phosphoric acid content in percentages of typical specimens of New Jersey marl

Potash and phosphoric acid in typical greensand marl of New Jersey

	1	2	3	4	5
Phosphoric acid	1 14	1 33	1 16	2 34	2 69
Potash	5 05	6	6 22	5 18	6 31

	6	7	8	9	10
Phosphoric acid	2 56	3 58	3 8	3 58	30
Potash	4 62	3 5	4 11	4 2	8 53

New Jersey marl[1] has been of incalculable value to the region in which it is found It has raised this region from the lowest stage of agricultural exhaus tion to a high state of improvement Found in places where no capital and but little labor were needed to get it the poorest people have been able to avail themselves of its benefits Lands which in the old style of cultivation had to lie fallow by the use of marl produce heavy crops of clover and grow rich while resting Land which had been worn out and left in common are now by the use of this fertilizer yielding large crops of the finest quality Every where in the marl district may be seen farms which in former years would not support a family but which are now making their owners rich through their productiveness Bare sands by the application of marl are made to grow clover and then crops of corn potatoes and wheat Pine barrens by the use of marl are made into fruitful land The price of land in the greensand marl belt of New Jersey was considerably below that in the northern part of the State 40 years ago now that the lands are improved their price is higher than that of lands in the north ern part of the State

A recent invention[2] proposes to use glauconite or greensand (such as is found in New Jersey) as a principal ingredient in the manufacture of hydraulic cement In making the cement the potash of the greensand would be volatilized at the temperatures employed and its recovery as a by product would be possible

Salines

The known occurrences of potash salts in the United States are few in number Those which are known and which promise results are confined to certain arid portions of the Western States Here the structural conditions are favorable for the reten tion of any salines that may have been deposited and the presence of alkaline lakes suggests the possibility that others may once have existed and are now cov ered by later deposits, their saline content being concealed. Though potash salts occur in this region

[1] From Ann Rept. State Geologist of New Jersey 1886

[2] Patent 912988, dated February 9th, 1909

in the waters of the alkaline lakes it has yet to be proved that these waters contain a commercially valu able quantity of potash salts An idea of the quan tity of potash salts in the waters of some of these lakes may be obtained from the figures given in the following tables[1] Though the waters of these lakes have never been utilized for their content in potash it appears as if they would prove of some commer cial value It must be admitted however that the German deposits are unique not so much in the quality of the salts contained in them as in the quan tity and in the fact that the overlying geologic forma tions are such that they have been kept intact so far as known a condition which is as important as the deposition of the original material itself

Potash salts occur in the water of Owens Lake Inyo County Cal This lake at the present time has no outlet and on the completion of the Los Angeles aqueduct will be deprived of the greater part of the drainage hitherto tributary to it Its ancient shore line nearly 200 feet above its present level indicates that at one time it had an outlet to the south and was there joined to a chain of lakes Its waters are strongly alkaline and the principal salts contained in them are the chloride and carbonate of sodium A number of analyses more or less complete have been made of its water These vary according to the con ditions under which the samples were collected and the analyses made The dilution of the water of this lake after storms in the surrounding mountains and its concentration at the end of summer explain in part differences in the analyses One of the first anal yses of water from this lake is as follows

Analyses of water of Owens Lake

	Grains per imperial gallon
Sodium chlorid	14_ 1o
Sodium sulphat	9 6 80
Sodium carbonat	_914 4
Potassium sulphat	37 74
Potassium silicate	139 74
Organic matter	16 9

The following analyses are comparatively recent

Analyses of water of Owens Lake

[Grammes per liter]

[1] Bull U S Geol Survey No 60 1890 p 61

From these analyses and from data similar to those given beyond in connection with Mono Lake it is estimated that Owens Lake contains among other con stituents 3 000 000 tons of potassium sulphate to-

[1] Bailey Gilbert Bull California State Min Bur No 24 1902 pp 94 et seq Chatard, T M Bull U S Geol. Survey No 60 1890 pp 27 101

gether with large quantities of sodium carbonate common salt, and borax These materials are, how ever, present in such dilute solution that they have not been utilized up to the present time The diver sion of Owens River however must gradually result in a notable increase in the alkalinity of Owens Lake and the conditions for the utilization of the potash salts will become more favorable

At Owens Lake the manufacture of sodium car bonate has been carried out on a commercial scale In order to determine the most favorable conditions for the process Chatard subjected a quantity of the water to fractional crystallization and analyzed the salts which were successively deposited Two con cordant series of experiments were made together with a less complete but corroborative set with water from Mono Lake The results of the first group were as follows

Analyses of salts deposited by fractional crystalliza tion of water of Owens Lake[1]

A The natural water of Owens Lake Specifi gravity 1 062 at 2 degrees Salinity 77 098 grammes per liter

B First crop of crystals Water concentrated to one-fifth its original volume Specific gravity of mother liquor 1 312 at 27 9 degrees

C Second crop of crystals Specific gravity of mother liquor 1 312 at 25 degrees

D Third crop of crystals Specific gravity of mother liquor 1 315 at 26 25 degrees

E Fourth crop of crystals Specific gravity of mother liquor 1 327 at 35 75 degrees

F Fifth crop of crystals Specific gravity of mother liquor 1 300 at 13 9 degrees This crop was obtained by chilling the solution in order to de termine the effect of cold

[2] Composition of the anhydrous residue

[3] Chatard supposes that the biborate could not exist in so strongly alkaline a solution as that in their liquor from which this crop was obtained

Mono Lake is situated in Mono County Cal near the Nevada line at an elevation of 6 730 feet the highest level above the ocean of all the saline lakes of the Great Basin Its water is dense and alkaline At this lake the alkaline carbonates are abundant owing to the volcanic rocks of the lake basin as shown by the complete analysis made by T M Chatard as follows

Analysis of water of Mono Lake

	Grammes per liter
Silica	0 0700
Calcium carbonat	0 0810
Magnesium bicarbonat	0 3340
Potassium chloride	1 8342
Sodium chlorid	18 068
Sodium sulphat	9 8690
Sodium carbonat	18 6720
Sodium bicarbonat	4 9015
Sodium biborat	0 2000
Alumina	0 0030
	5 1 4

The results of this analysis show that chloride of sodium and carbonate of sodium constitute nearly 35 per cent each of the total solids Experiments by Chatard on the fractional crystallization of the min eral content of the water gave the results presented below which show the same general rule of depo sition as at Owens Lake The water used in the ex periments had already been evaporated to about one-sixth of its original volume and had a specific gravity of 1 210 The analyses are as follows

Analyses of salts deposited by fractional crystalliza tion of water of Mono Lake

	1	2	3	4	5
Water	15 28	10 98	0 69	4 18	11 31

Totals	99 3	100 03	99 8	100 03	99 85

The lake has an area of 85 5 square miles and an average depth of 61 5 feet From these figures its

volume has been calculated From its volume and the mineral content of its water the amount of the various salines which it contains has been estimated The results which are of interest indicate the presence in the lake of 10 538 100 tons of potassium chloride Such figures show that the saline reserves in this and other incompletely evaporated or playa lakes of the desert regions of California and other public land States are very large and may prove valuable when transportation facilities have been developed and methods for the extraction of the salts perfected Potassium nitrate has been found in the desert region northeast of Salton Riverside County Cal

Alunite

Near the close of the year 1910 Mr A F Custer of Salt Lake City Utah sent to the United States Geological Survey a specimen of alunite (hydrous sulphate of potash and aluminium $K_2SO_4 3Al_2(SO_4)_3$, $6H_2O$) of a very unusual type The occurrence is reported to be located near Richfield Sevier County Utah close to the railroad The deposit varies from 6 to 10 feet in thickness

An occurrence of scientific and economic interest is the association of alunite and gold in the Gold field district of Nevada F L Ransome of the United States Geological Survey believes that the composition of the ores and the changes exhibited in the country rock point to hot ascending solutions as the agent which has produced the alunite On some of the ore dumps the partly soluble sulphate is present in sufficient quantity to suggest its removal by leaching Before undertaking such a step several factors must be considered such as quantity of raw material proximity to market transportation facilities and freight rates

POSSIBLE OCCURRENCE OF POTASH SALTS IN THE UNITED STATES

To make a thorough and complete investigation of the occurrence of potash salts in the United States every known salt deposit should be tested for ordinary rock salt may overlie soluble potash salts as well as underlie them Both these conditions exist at Stassfurt The normal occurrence of salt is however at the base of a series of soluble salines deposited from the evaporation of sea water The deposits of Midland and Isabella counties Mich are of interest in this connection inasmuch as they contain bromine in commercial quantity a fact which indicates partial desiccation of sea water and the occurrence of mother liquors The salt deposits of Mason County W Va and adjacent parts of Ohio likewise contain and are worked for bromine

[1] Econ Geology vol 2 No 7 1907 p 680 Ref Paper U S Geol Survey No 66 1909

The red beds of the southwestern part of the United States in Texas Oklahoma, Kansas, Colorado, New Mexico and possibly other States, contain deposits of gypsum and salt and are worth notice as possible sources of potash salts These beds might profitably be explored in those places where structural conditions seem to favor the accumulation and retention of the salines

ORGANIC SOURCES OF POTASH SALT [1]

The organic sources of potash salts are wood ashes beet-sugar molasses and residues wool scourings (suint) and sea weed

Wood Ashes

Land plants take up considerable quantities of potassium compounds from the soil When the plants are burned about 10 per cent of the weight of the ash is potassium carbonate which may be obtained by lixiviation Potash from wood ashes is now made chiefly in Russia Sweden and America the woods most employed being elm maple and birch Sometimes the stumps and small branches only are burned the trunks being used for timber The ashes are moistened slightly put into tanks having false bottoms on which straw is spread and then lixiviated with warm water The lye so obtained is evaporated (sometimes by the waste heat from the burning wood) in iron pots until it solidifies on cooling The dirty brown mass is then calcined in a reverberatory furnace until all the organic matter is destroyed The product is known as potash or crude pearlash It is white or gray in color and contains about 70 per cent of K_2CO_3, with some potassium sulphate potassium chloride and sodium salts By redissolving the crude potash in water and settling and concentrating the solution until the sulphate and chlorides separate as crystals a concentrated and fairly pure lye is obtained When this is evaporated to dryness and the residue calcined it yields a much purer product known as refined pearlash containing from 95 to 97 per cent of K_2CO_3 It is necessary that low heat be employed in the calcination for the charge fuses at a moderate temperature

Quicklime is often put in the bottom of the tanks before the ashes are introduced On leaching the solution of potassium salts reacts with the lime forming insoluble calcium salts and yielding more or less potassium hydroxide in the lye The resulting product is a mixture of potash and caustic potash

Beet sugar Molasses and Residues

In the manufacture of beet sugar a very impure molasses remains containing among other things a large amount of soluble potassium salts. This molasses is now generally fermented, and in that process the sugary substances are converted into alcohol, which is distilled off, leaving the mineral salts in the liquid residue, called "vinasse" or "schlempe." If this is evaporated to dryness and the mass calcined, the organic potassium salts are decomposed, leaving in the cinder about 35 per cent of potassium carbonate and a large amount of chloride and sulphate together with sodium salts

[1] Taken in part from Thorp F H Outlines of Industrial Chemistry 1901 pp 130 et seq

Wool Scourings (Suint)

Wool scourings furnish some potash in countries where much wool is washed. Sheep s wool as it comes from the animal contains from 30 to 75 per cent of its weight in impurities consisting of dirt, sand dung etc wool grease or "yolk a fatlike substance, made up of cholesterine and compounds in which it is associated with oleic stearic and palmitic acids and suint,' which consists chiefly of potassium salts of oleic stearic and other organic acids, with small quantities of chlorides and sulphate and nitrogenous matter The suint exudes from the animal in the perspiration and is deposited on the wool by evaporation It is soluble in cold water and is thus removed in the scouring process If the wash waters containing wool grease and suint are run into streams, pollution of the water results The desirability of preventing this nuisance as well as the value of the potash has resulted in attempts to dispose of the washings in some economical manner and they are usually evaporated to dryness and calcined When the material is calcined in closed retorts a considerable quantity of ammonia is obtained The cinder is then lixiviated and on evaporation the solution yields first chlorides and sulphates of potassium and sodium and finally a very pure potash which averages a little less than four per cent of the weight of the raw wool scoured

This mode of utilizing wool grease and suint is mainly practiced in France Belgium and Germany, and in these countries it is done chiefly to prevent the pollution of the streams Cheap fuel is very essential to a successful working of the process On a small scale it can not be carried on profitably and the wash waters are often run onto the fields as fertilizer

Potash in Seaweeds

A concentration of potash salts from sea water is reported as being effected by the giant seaweeds of the California coast These plants on drying are said to exude nearly pure potassium chloride and its recovery on a commercial scale has been suggested but so far as known has not yet been actually tried It is understood however that some potash is recovered from kelp elsewhere

A New Method of Exploring the Earth s Interior

By Dr Schames

For information concerning the nature of the earth s interior we have hitherto been dependent entirely upon the study of the propagation of earthquake waves If we suppose a plane to be passed through the earth s center and any two points of its surface as A and B

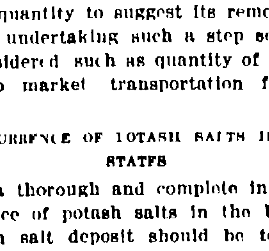

Fig 1—Earthquake Shock Travels from A to B by Three Paths Indicated by the Arrows

(Fig 1) this plane will intersect the surface in a great circle It has been learned by experiment that a shock originating at or beneath the point A is transmitted to B by three distinct waves which reach B at different instants It is assumed that one of these waves is propagated through the earth s interior approximately in the straight line AB and that the other two waves travel through the earth s crust in opposite directions following the curved paths indicated by the arrows The observed differences in the times of arrival of the three waves at B support Wiechert s hypothesis that the earth is composed of a metallic nucleus of density 8 4 surrounded by a shell of rock about 1 000 miles thick of density 3 4

Lowy and Leimbach have recently described two very different and more promising methods of exploring the earth s interior These new methods are based on the properties of electric waves which traverse insulators without diminution of intensity but are partly reflected and partly absorbed by good conductors of electricity Dry soil and rock may be regarded as insulators while subterranean water courses coal seams and deposits of metallic ores and salts are good conductors.

The first of the new methods is based on the reflection of electric waves and is applicable to depths of about 3 000 feet or less Electric waves emitted by an inclined antenna at A (Fig 2) are reflected by a water course coal seam or other conducting mass in the position indicated by M to the point B which is found by exploration with a receiving apparatus

The second method is based on the absorption of electric waves which are emitted by antennæ placed in borings about 1 000 feet deep and are received by apparatus placed in similar borings If waves emitted from the boring A (Fig 3) are received in B but not in C the inference is that the waves are absorbed by a water course or other conductor between A and C By this method the earth can be explored to a depth much greater than that of the borings for owing to the curvature of the earth s surface the middle point of the straight line which joins the bottoms of two borings which are 1 000 feet deep and 200 miles apart lies more than 3 000 feet below the surface Electric waves which have traveled 250 miles through the earth can be detected in the absence of any impediment to their propagation The feasibility of this method has been proved by practical experiments in a German potash mine

It is obvious that these new methods can be employed

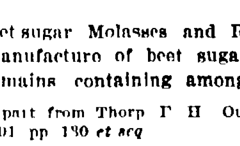

Fig 2—Electric Waves Reflected by Underground Stream

for proving or disproving the existence of Wiechert s metallic earth-core when the reach of subterranean signaling by electric waves has been increased to about 1,250 miles

An application of more immediate practical utility would be the systematic exploration of large territories for underground water The great plain of Hungary could be thus explored by means of 48 borings, each 1 000 feet deep The total cost of the 48 borings would not exceed $110 000 while a single boring, 3 300 feet deep would cost about $7 500 This method of exploration is especially well suited to tropical regions where the soil is drier and consequently a better insulator than elsewhere According to Wohltmann many subterranean water courses must lie hidden be-

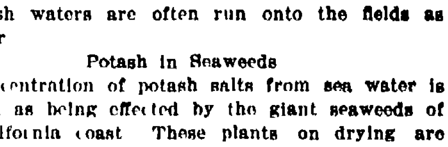

Fig 3—Electric Waves Absorbed by Underground Stream

neath deserts These new methods appear to be eminently well fitted for the discovery of these water courses and indirectly for the conversion of deserts into clusters of green oases watered by artesian wells. —*Umschau*

The Photographic Plate

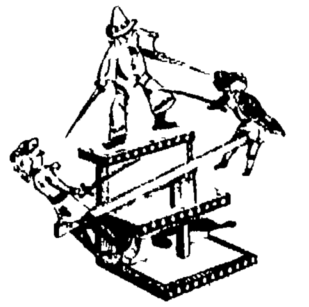
In the *Journal of Physical Chemistry* W D Bancroft states that the silver bromide grain is a complex of silver bromide gelatine, and water The process of ripening consists in changing the composition of the silver bromide grain toward an unknown optimum concentration There is no necessary connection between sensitiveness and coarseness of grain Chemical and optical sensitizers are depolarizers Gelatine acts as an emulsifying agent and as a sensitizer whereas collodion apparently acts only as an emulsifying agent The peptonization of silver bromide is merely a particular case of the general problem of the peptonization of any precipitate. The peculiarities of mixtures of AgCl, AgBr and AgI can all be explained on the assumption that each of these salts can form a continuous series of solid solutions with either of the two This is known to be the case for AgCl and AgBr It seems theoretically possible (by incorporating a suitable depolarizer or sensitizer with the silver bromide grain and using a suitable developer) to make an almost infinitely fast plate having a very fine grain

New Toys*

Interesting French Inventions

A THREE-HANDED DUEL

The novel French toy shown in the illustration may appropriately be called a three-handed duel The two assailants against whom the clown is forced to defend himself are mounted on a see-saw which is operated

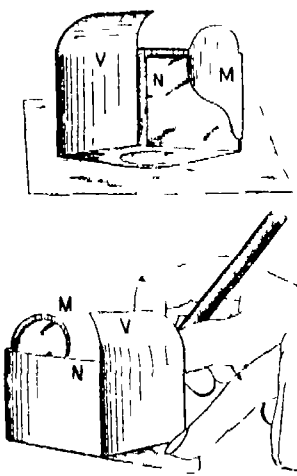


THREE-HANDED DUEL

by pressing alternately the two levers which project from the base The clown is armed with two swords and the combat continues until the owner of the toy wearies of the sport.

THE MAGIC DRAWING BOARD

The difficulty which is encountered in attempting to trace a line or to follow a motion which is seen by reflection from a mirror is strikingly illustrated by a new toy called the magic drawing board In New York such boards have been sold for some time under the name 'Wiggle-waggle Graph As the diagrams show the drawing board is really an incomplete box which lacks one side and has no top The remaining side *N* and the end *M* are lined with mirrors The end *V* is made of sheet zinc and its upper part curves

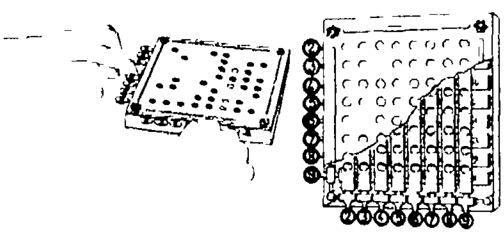


THE MAGIC DRAWING BOARD

over the box and prevents the draftsman who faces this end from seeing directly into the interior A large round hole is cut in the bottom of the box which is also of sheet zinc The box is placed on a sheet of paper on which three equidistant dots are marked just inside the circular aperture The draftsman facing the end *N* sees these dots as well as his pencil point only by double reflection from the mirrors *N* and *M* His task is to join the points by straight lines within a given time The problem may be varied by increasing the number of dots or by requiring the drawing of lines that do not meet but even in its simplest form it requires for its solution a steady hand a quick and correct eye a cool head and much patience and practice.

THE PYTHAGORAS A MATHEMATICAL TOY

The Pythagoras is a toy rather than a calculating machine Its inventor makes no greater claim for it than its utility in teaching children the multiplication table by pleasant and entertaining method The apparatus is a flat, square box the cover of which is perforated by 64 round holes arranged in square order The drawing of the apparatus shows eight keys marked with the digits from 2 to 9 on the left side of the box and also on the front By depressing simultaneously one key of each series the product of the numbers marked on the two keys appears in the round hole which corresponds to their intersection For example if key 5 on the left side and key 7 in front are depressed the number 35 appears in the sixth hole of the fourth row The mechanism by which these results are accomplished is very simple Each of the keys at the left side of the box is connected with a horizontal strip of paper marked with eight of the required sixty four products and each of the front keys is connected with a strip of metal pierced with eight



THE PYTHAGORAS

holes equal in size to the holes in the lid of the box When none of these keys is depressed neither these holes in the metal strips nor the numbers on the strips of paper are vertically beneath the holes in the lid Depressing the left hand key brings the required number as well as seven others under holes in the lid but these are still covered by the metal strips until the depression of one of the front keys brings the hole in one of these strips under the hole in the lid and thus reveals the required product which is directly beneath both of these holes

NEW FRENCH FLYING TOYS

The popular interest in aviation is reflected in the number of flying toys offered for sale in Paris and elsewhere Three of the newest of these toys are here pictured The Aeromains (Fig 1) is a little four bladed screw propeller cut from a thin sheet of celluloid It has a hole at its center and is operated by placing it on a peg and a little celluloid disk at the end of a rod and rolling the rod rapidly between the hands as the illustration shows The rapid rotary motion thus imparted to the light propeller causes it

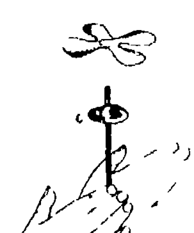


FIG 1—THE AEROMAINS

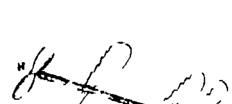

FIG 2—THE DEMOISELLE

to rise in the air and lively sport will be afforded by the attempt to catch it on the rod as it settles down again The Monte-au-ciel (Fig 3) is of similar construction but the propeller is stiffened by a rim and is launched by pulling a cord wound round the rod which occupies the interior of the hollow handle of the toy Hence it rises much higher than the hand driven propeller

The Demoiselle (Fig 2) is a real monoplane with

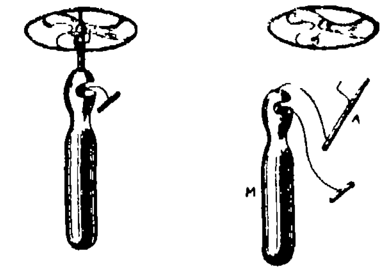

FIG 3—THE MONTE-AU CIEL

a screw propeller *H* which is attached to a stout India rubber cord concealed in the tubular axis This cord is twisted by turning the propeller through about a hundred revolutions The demoiselle is held in the inclined position shown in the illustration with one hand while the propeller is held with the other The propeller and the frame of the machine are then released simultaneously The untwisting of the elastic cords spins the propeller rapidly and the demoiselle if properly launched accomplishes a long flight An interesting aviation contest may be carried out with a number of demoiselles and as many players

A MACHINE FOR WINDING UP TOY AEROPLANES

Toy aeroplanes which are now offered in great number and variety are usually driven by twisted rubber cords The aeroplane is wound up by turning the

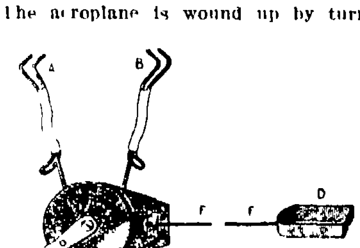

FIG 1

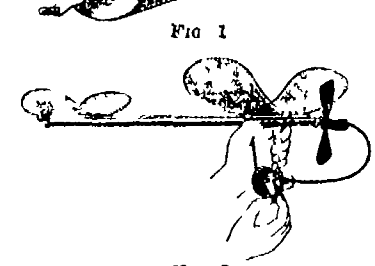

FIG 2

A MACHINE FOR WINDING UP TOY AEROPLANES

propeller backward through from 150 to 300 revolutions according to the length of the elastic cord This operation is tedious and when the aeroplane is nearly wound up it is not easily kept in the proper position for launching

The winding is greatly facilitated and accelerated by the employment of the little machine herewith illustrated The aeroplane is held by grasping its frame with the jaws *A* and *B* (Fig 1) of a pair of pincers attached to the machine which consists essentially of a pinion driven by a crown wheel and crank A flexible transmission *F F* connects the pinion with the spring clamp *D* by which the propeller shaft is grasped The method of using the machine is shown in Fig 2 The flexible transmission is so constructed that it forms a loop and stops the operation when the torsion attains a certain value less than the elastic limit of the India rubber which is thus safeguarded against rupture

* Collected from *La Nature*

Legal Operations of the Department of Agriculture

Cases reported to the Attorney-General for prosecution under the several laws administered by the Department of Agriculture numbered 1,738 twice as many as the year before More than $40 000 in fines and costs were assessed hundreds of tons of misbranded foods and drugs were forfeited

Food and drug cases numbering 990 were reported 766 for criminal action and 224 for seizure proceedings. Of criminal cases, 246 resulted in convictions, 8 in verdicts for defendants, 96 were dismissed, 152 were pending in courts at the close of the year and 252 remained under consideration for future action No leniency was shown in cases involving unfit foods or dangerous drugs. Sixty cases left over from previous years were terminated. The total of fines collected under the food and drugs act during the year was $11 049 31 Of the cases reported for seizure proceedings 132 resulted in forfeiture decrees while 50 were pending at the close of the year In addition 43 shipments were forfeited under seizures of previous years

Since January 15th 1910 when the law work of the Forest Service was placed immediately under the solicitor 105 cases were reported for prosecution under the acts protecting the national forests while 565 cases of contested claims to lands within the forests were disposed of

Under the twenty-eight-hour law 438 cases were reported, more than twice as many as during the preceding year In 139 cases closed $16,500 in penalties was recovered, with $2,919 35 costs, 19 cases out of 158 tried resulted in favor of defendants 29 cases were dismissed for insufficient evidence 559 cases were pending at the close of the year To carry out the present intent of Congress in passing the act which was framed to secure the humane handling of live stock in transit it would seem says the Secretary of Agriculture that an additional provision should be incorporated therein requiring carriers to maintain a reasonable minimum speed on all stock trains

Under the live stock quarantine laws 148 cases were reported 20 cases were disposed of with fines amounting to $2 970 Fifty two violations of the meat inspection law were reported 18 cases gave convictions, 8 were dismissed and 26 are pending Two cases were reported under the Lacey act for the protection of game 1 was abandoned because of difficulty of proving interstate shipment the other is pending Four cases came over from the previous year In 2 the grand jury failed to indict, in the other 2 fines were assessed

The Aims of Astronomy of Precision*

A Resume of Modern Methods

By S S Hough

The science of precise physical measurements is one which does not readily appeal to those not immediately concerned either with the methods or results. An authoritative statement that the sun's distance from the earth is 92 880 000 miles may excite wonder but scarcely more than will the statement that it is approximately 93 000 000 except in the mind of those who are in some measure acquainted with the laborious processes by which the two extra figures are derived. In fact I have not infrequently heard the methods of observation used described by some such epithet as "hair splitting." For this reason I think I cannot do better to-night than to describe to you without entering into technical details of the methods employed some of the aims and objects to which modern astronomy of precision is devoted and which render essential the very highest refinements that human ingenuity can devise.

Perhaps the primary reason why astronomy appeals to the popular imagination in a higher degree than other sciences is that astronomy is *par excellence* the science of prediction. True the days are now past when an astronomer was regarded except by the most ignorant as gifted with supernatural powers and capable of predicting events that can have no conceivable relationship with the objects of his researches, or when an unscrupulous astronomer could utilize his powers of prediction for imposing on the world at large in the face of the criticisms of fellow workers in collateral branches of science. Nevertheless it is only necessary to point to any of the leading almanacs to establish the undoubted claim of astronomy to a considerable predictive capacity in its own legitimate sphere. These almanacs prepared in advance give from day to day the positions of the sun and moon, the phenomena of eclipses, and various other data with an accuracy which can only be called in question by the most refined tests available to astronomers.

How then has astronomy acquired this faculty? The answer to this question is—at least primarily by continuous and patient observation using always the most refined methods of physical measurement available.

A well devised scheme of observation is sooner or later bound to lead to the detection of laws governing physical phenomena if such laws exist. Thus it was the planetary observations of Tycho Brahe which led to the detection of the laws of planetary motion associated with the name of Kepler.

Once such laws have been established and the necessary initial data secured the science of astronomical prediction would for the future devolve on the mathematician rather than the astronomer were it not for two sources of uncertainty with which the astronomer must continue to concern himself. It is evident on one hand that we cannot infuse into our predicted phenomena greater precision than that derived from the initial data themselves dependent on imperfect observations. However well the laws governing planetary motions may be understood the predicted position of a planet to-day depends on its observed position at some earlier epoch or epochs; and the fallibility of the observations made at these earlier epochs will not only pervade all future predictions but will inevitably increase in amount as the epoch of prediction recedes from the epoch of observation. For this reason if the standard of accuracy of prediction is merely to be maintained and the growing requirements of science will scarcely rest contented with this—continuous observation must be maintained and the data on which predictions are based revised from time to time.

I have dealt so far only with the effects of the unavoidable inaccuracies of observations even when pushed to their utmost refinement as influencing results of prediction. A second consideration of even greater importance is the validity of the laws associating the predicted with the observed phenomena. I may illustrate my point again by reference to the laws of Kepler. It is now well known that these laws are only rough approximations to the actual truth and that though they might serve as a useful basis for prediction over a short interval a few years at most would suffice by showing a rapidly increasing departure between the observed and predicted positions of the planets to indicate that these laws require amendment.

That the disclosure of direction which this amendment should take followed so soon on the original discovery of Kepler's laws was due to the genius of Newton who showed that the theory of universal gravitation propounded by him not only adequately accounted for the laws enunciated by Kepler and pointed to their imperfections but served to co-ordinate as due to a single cause even more recondite phenomena such as the leading inequalities in the motion of the moon, the precessional motion of the earth, and the phenomena of the tides. This theory further reduced to order those astronomical vagaries the comets, showing that so long at least as they remained within the precincts of the solar system their motions were governed by it while observations of double stars have established beyond question that even remote parts of the universe are still subject to the same laws.

The dynamical laws propounded by Newton which to-day virtually form the basis of all astronomical prediction enable us to trace back as well as to trace forward the history of the solar system, and to confront modern observations with historical records. Needless to say in but rare instances do these records possess the necessary *elements of precision to strengthen the existing data required* by the astronomer; but there are important exceptions. For instance a very small uncertainty in the "elements," which in conjunction with Newton's laws govern the motion of the moon will produce by lapse of time a large change in the comparatively small area of the earth's surface over which a total eclipse of the sun is visible as such. Thus a record that a particular eclipse was seen as total in a given locality becomes an observation of precision, provided only the chronological date at which the eclipse occurred can be traced with sufficient certainty to insure the identification of the eclipse concerned.

The confrontation of modern with historical observations of such character has served to establish beyond question the high degree of accuracy with which the laws of Newton represent the motions within the solar system and their trustworthiness as a basis of prediction for years perhaps for centuries to come. It is however on various grounds quite certain that these laws in themselves are not absolute far reaching though they are and that they in turn like those of Kepler must be superseded by laws still more exact.

Until such laws are discovered there will always remain an element of uncertainty apart from that due to the initial data affecting all predicted phenomena—an uncertainty which can only be removed when the phenomena cease to be prospective and when they can be confronted with later as well as with earlier observations.

The fact, however that the laws of gravitation yield such a close representation of the observed motions within the solar system throughout historic time renders the detection of a departure from these laws a question of extreme delicacy but none the less essential if prediction is to be secured for long periods in advance.

I have selected my illustrations largely from the solar system chiefly on the grounds that thanks to the Newtonian laws, it is here that in spite of the immense mathematical difficulties which have had to be faced astronomical prediction has attained its greatest triumphs. I wish now to divert attention to the stars. In so far as these form the fiducial points to which the motions of the planets and other members of the solar system are referred it is essential that the positions of a limited number at least should be determined with the highest possible accuracy. Any uncertainty in their positions will undoubtedly be reflected in the positions of the planets, and will constitute one of those sources of error so liable to increase with time and render efforts at prediction if not entirely nugatory at least partially ineffective.

The universe of so called "fixed stars" is not invariable in aspect though its changes for the most part are of so minute a character that they can only be surely detected either by the most delicate measurements or by their cumulative effect over long intervals of time. It is chiefly through a study of these changes that our knowledge of the stellar universe has been acquired in the past and it is largely to similar means that we look for an extension of this knowledge.

Among changes which lend themselves to observation for this purpose we may enumerate:

(1) Changes of the intensity of the light of the stars. The origin of these changes except in a few instances remains obscure. In certain cases, however notably in the case of variable stars of the Algol type a satisfactory explanation of the observed phenomena has been found in the motions of a system governed by laws similar to those operating in our solar system of which the visible star forms a constituent member.

(2) Changes of position due to orbital motion in binary or multiple stars. Where both components of a binary star are visible these changes readily admit of direct measurement. In other cases the existence of a companion is inferred to account for regular periodic changes of position of the visible component, though this companion cannot be seen either on account of intrinsic want of light or on account of its close proximity to the primary and the consequent incapacity of our telescope to render the two visually distinct.

These changes are of interest as affording evidence of the validity of the Newtonian laws in systems other than the solar system.

The changes to which I have so far referred are changes which affect isolated stars or groups of stars, but which do not occur at least to a sensible extent, in the generality of stars.

I come now to the changes of position due to the earth's orbital motion which, on the other hand may be expected to influence all stars in common. Even where, as in the cases I have already spoken of their influence is obscured by orbital motion within the system, when once this orbital motion has been thoroughly examined its laws deduced, and due allowance made for it by computation we might expect to find the effects of the earth's motion still apparent.

The earth in its orbit round the sun approximately describes a circle of 186,000 000 miles in diameter and its successive positions in space at intervals of six months are separated from one another by this extent. But experience has shown that recurring changes in the relative positions of the stars, as viewed at intervals of six months—that is to say, from two different points of the universe separated by this vast distance—can only be detected in the case of a limited number of stars, and *then only by the application of the most delicate methods* of measurement specially designed to bring these changes to light.

To the Cape Observatory and its former director Henderson (1832-4), belongs the credit of first producing trustworthy evidence of the existence of any fixed star, *for which these changes could be unmistakably detected,* and which therefore, was not too remote from the solar system to permit of its distance being at least roughly determined in comparison with the diameter of the earth's orbit. Henderson's discovery has since been fully confirmed by later observers and other stars likely to yield tangible results have now been examined. As illustrative however of the evasiveness of the quantities sought, and the excessive labor by which only they can be derived, though the problem of stellar distance has always been in the forefront of astronomical interest and has attracted the attention of several able observers, the number *of stars for which well-determined parallaxes have* been published up to the present day does not exceed some 400. This number is quite insignificant in comparison even with the number of stars visible to the naked eye without telescopic aid. Moreover the stars investigated have been in general, selected on the grounds of some *a priori* probability of their possessing a measurable parallax either on account of apparent brightness or on account of their large apparent motion and for this reason they can scarcely be regarded as typical of the generality of stars.

In order then to gage the depths of the visible universe it would appear imperative that our base line must in some manner be extended. The distance of 186,000 000 miles through which we are carried in the course of a single half year by the orbital motion of our planet round the sun is so small in comparison with interstellar distances as to give rise to changes in the apparent relative positions of stars which, except in the most pronounced instances are so insignificant in amount as to defy detection even by the most refined processes of measurement we possess.

How then can such an extension of our base line be attained? I have already pointed out that the so called fixed stars are not truly "fixed," but that on close observation it is found that each star has an apparent motion either peculiar to itself or shared by other neighboring stars which with it constitute an independent system. I refer primarily to the visible motion transverse to the line of sight.

If then our sun, as we may reasonably suppose, is itself a member of the stellar universe it may be anticipated that it too will not be at rest, but will be moving forward in space and the visible motions will be those due to the combined effects of the motion of the sun and stars.

That the apparent motions of the stars were not entirely fortuitous but that they could at least partially be co-ordinated throughout the sky as the visible manifestations of a single phenomenon, viz a translatory motion of the sun with its system of planets through interstellar space was first pointed out by Sir William Herschel who further indicated that the point of space to which this motion was directed was situated in the constellation "Hercules."

Before proceeding to the further consideration of this solar motion I wish first to point out to you how its existence at once suggests a means of "extending our base line" for the purpose of gaging these interstellar depths. I have refrained from any numerical estimates of the amount of this motion as this involves philosophical questions into which I do not desire to enter to-night; but in order to fix our ideas it is necessary for me to give you some notion at least of the order of magnitude. It is now possible to state with some certainty that the speed of the sun's motion relatively to the stars as a whole amounts to about twenty kilometers per second, and that the space traversed in a single day therefore amounts to rather more than 1,000 000 miles, that in a year to about 400,000,000 miles. Thus the stars, as seen on two occasions a year apart may be considered as viewed from two points in space separated by this length, and it only requires lapse of time in order to increase the length to an almost indefinite extent.

The great scheme for the photographic mapping of the heavens at present being carried out on an extensive scale by means of the co-operative efforts of the leading observatories of the world will shortly furnish a highly accurate delineation of the skies as seen at the commencement of the twentieth century. This alone has called for concentrated effort extending over some twelve years at least, while it would even now scarcely be safe to say that another ten years will see its completion. An immediate repetition is scarcely to be contemplated, though a subsequent repetition at some future epoch, which may be agreed on by astronomers, forms an essential part of the programme as originally introduced.

When this scheme is completed in its entirety very ample data will be available for the discussion of stellar distribution by the methods I have suggested to you.

In the meantime, however, in such tentative attempts as have been made to fathom the secrets of the universe by means of the study of stellar proper motion, it has been necessary to rely on early recorded exact observations. It will be clear from what I have already explained to you that it is the earliest trustworthy records in comparison with the most up-to-date available which

* From the presidential address delivered before the Royal Society of South Africa

will yield the greatest length of base-line, and consequently the most trustworthy results For this reason the majority of the discussions hitherto attempted have been based on the catalogue of Bradley dependent on observations made by him at Greenwich between the years 1750-62 This catalogue contains the places of some 3,000 stars observed with a precision far surpassing any similar previous observations, and comparing favorably with the best modern catalogues The stars selected by Bradley are fairly uniformly distributed over the portions of the sky accessible to him, viz from the North Pole to 30 deg south of the equator

Unfortunately no early catalogue of stars of even approximately similar precision exists for the remaining region of the sky between 30 deg S dec and the South Pole, and the absence of exact knowledge of these regions for the earlier epochs has always hampered these discussions

The discussions I refer to have generally had as their immediate objectives

(1) The determination of the precessional constant i. e the annual amount by which the earth s axis of rotation changes its position in space and

(2) The determination of the speed of the solar motion and the position of the solar apex i. e the point in the heavens toward which the sun s motion is directed

The discrepancies in these quantities found by different investigators, either starting with different data or utilising different methods for the combination and discussion of the same material had long been a puzzle to astronomers. The key to the situation was at length furnished by Prof Kapteyn of Groningen who in an epoch-making paper read before the British Association in Cape Town, first pointed out that the apparent motions of the stars indicated not merely the existence of a single solar apex but that there were two separate regions of the sky toward which a preference was shown by the directions of motion of the Bradley stars

This was a phenomenon which could not be explained by a simple motion of translation of the sun as evidently the sun s motion could not be directed to two different points simultaneously and the only feasible explanation was that the stars consisted of two groups and that the motion of the sun relatively to one of these groups differed from its motion relatively to the other or that, though the stars appeared intermingled in space they possessed an independent relative motion which might be regarded as located in one group or in the other but which was shared by all the stars peculiar to the group

The theory of the existence of two streams or drifts of stars thus put forward by Kapteyn has since received full confirmation by other investigators notably by Eddington who based his examination on the early observations of Groombridge and by Dyson who limited his discussion to a selected list of stars possessing considerable proper motions

Recent investigations at the Cape have led us to examine in somewhat more minute detail the proper motions of the Bradley stars, with the result that though the phenomena first noticed by Kapteyn stand out as the most prominent feature, certain subsidiary features of no less importance have been brought to light

I have concerned myself hitherto only with the visible motions of the stars transverse to the line of sight, as derived by the older methods of measurement The introduction of the spectroscope into astronomical research has opened up vast new fields into which, so far as they relate to the chemical and physical constitution of the sun and stars it is not my purpose to enter to-night. What I wish rather to emphasize is the value of this instrument as a supplement to the older methods in relation to the geometrical astronomy of position

In accordance with the principle laid down by Döppler the wave-length of light received from a source which is either receding from or approaching a receiver will appear to be modified by an amount dependent in a known manner on the velocity of approach or recession If the receiver takes the form of a spectroscope which permits by any means, direct or indirect of the measurement of the wave lengths and the normal wave lengths of the lines under examination are independently determined by laboratory investigations the difference between the observed and the normal wave lengths will thus afford a means of measuring the velocity of approach or recession of the source of light

Of the precautions necessary to ensure precision it is not my purpose to speak to-night The large spectroscope of the Cape Observatory which we owe to the munificence of the late Mr Frank McClean was from the outset constructed with due regard to these precautions so far as they could be foreseen for the purpose of determining with the greatest accuracy attainable the radial velocities of stars The instrument has been already successfully used and its capabilities have been established in an investigation of the aberration constant of light as depending on the apparent variations in the radial velocities of stars resulting from the earth s orbital motion

From a relatively short series of observations discussed by my colleague Dr Halm this constant has been derived with a precision not inferior to that attained by the best series of older observations and the capabilities of the method are yet far from exhausted

At the present time the instrument is being devoted to a series of observations of all such stars as are accessible in the southern skies the spectra of which present sufficiently pronounced features to admit of measurement primarily with the view of ascertaining what evidence can be derived from a study of the radial velocities in regard to the systematic structure of the universe

A year or two must elapse before the present observing programme is completed but a preliminary discussion of the observations already secured in combination with the published results derived from similar observations in the Northern Hemisphere has revealed the existence of anomalies similar to those found from the study of the transverse motions—anomalies which can only be reconciled with the two-drift hypothesis put forward by Kapteyn by the further hypothesis that though both drifts pervade the whole sky they are not similarly distributed throughout it

At present through scantiness of material from a study of the radial velocities we have been able to do little more than discriminate between the two halves of the sky which contain respectively the greatest and the least proportion of second drift stars It is however a fact of some significance that the former corresponds very closely with that hemisphere which contains the Milky Way suggesting the phenomenon that Kapteyn s second drift might be identified with the galaxy It was with the view of examining this suggestion in the light of the evidence which could be secured from the transverse motions of the Bradley stars that the discussions I have sketched to you to-night were undertaken by Dr Halm.

While they have established almost beyond question the rough features of distribution demanded to reconcile the radial velocity determinations, they further point to an even more detailed correspondence between the distribution of galactic stars and the distribution of stars of the second drift leaving but little doubt as to the identity of this second drift with the galaxy It is this second drift which exhibits evidence of structural units As regards the Milky Way the mere appearance on any fine night affords evidence of a similar character and it is on this account that we have been able to identify the Milky Way with the second drift rather than the first

The significance and origin of this structure are as yet obscure but the more its details are elucidated and the essential features established the nearer are we to an answer to the question What is the Milky Way?

To revert to my original text I have endeavored to point out to you the methods of research by which an answer is sought to this and similar questions and to explain to you the reasons why the highest precision attainable is a *sine qua non* in the conduct of such research Thus it is that the study of the large scale phenomena of the universe resolves itself frequently into a study of the minute detail of instrumental appliances on which must be brought to bear all the knowledge that can be derived from other branches of scientific work The geologist helps us in the selection of stable foundations on which the engineer may erect our large instruments Chemistry and physics in our photography our optical and electrical appliances are of daily application while one of the most valued accessories in almost all methods of precise measurement is the spider s web we devise from zoology

Astronomy in its turn has done much in the past and in the future will doubtless do more to assist the development of collateral sciences Thus the geologist cannot afford to ignore even if he does not accept as conclusive the evidence furnished by astronomy as to the nature of the earth s crust Exact measurements of space and time as conducted in physical laboratories are for the most part conducted by methods first designed to suit the requirement of astronomical precision while in the sun and stars chemical phenomena which may be studied with the aid of the spectroscope are taking place on a scale far surpassing anything that can be produced in the laboratory

The value of free intercourse between workers in the various branches of science is certainly indisputable and I wish to close my address by reference to the opportunities which our society can afford in this respect Devotees even of applied and still more of pure science in a young country are necessarily few in number and scattered A large proportion of these will in the early stages of their career have been in close association with one or the other great centres of scientific activity of the world and to such a feeling of scientific isolation almost amounting to exile and consequent lack of stimulus is almost inevitable Important as are our publications it is even more through our monthly meetings and the promotion of personal intercourse that the society can help in it primary duty of the advancement of natural knowledge in South Africa

Abandonment of the Weekly List of Patents

Early in the present year we transferred to the columns of the SCIENTIFIC AMERICAN SUPPLEMENT *the list of patents which formerly appeared each week in the* SCIENTIFIC AMERICAN *It was felt that the amount of space devoted to the list an amount which increased year after year could be better devoted to interesting reading matter We asked our readers what they thought of the change A number of protests were received but a far greater number of approving comments*

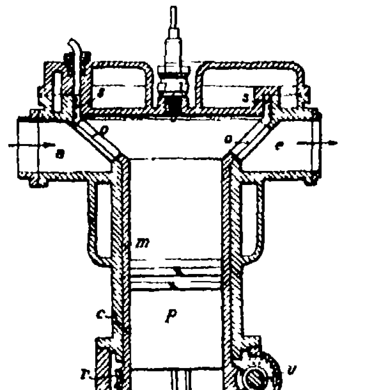
In view of these circumstances the publishers have decided that if the readers of the SCIENTIFIC AMERICAN *did not want the weekly list of patents the readers of the* SCIENTIFIC AMERICAN SUPPLEMENT *were no more in favor of it*

This therefore will be the last list of patents which will appear either in the SCIENTIFIC AMERICAN *or the* SCIENTIFIC AMERICAN SUPPLEMENT

The Renault Valveless Explosion Motor

THE excellent performance of the Knight valveless motor, which has been adopted by the Panhard-Levassor firm and several other automobile builders, has incited other inventors to endeavor to eliminate the admission and exhaust valves, which are costly and fragile, and which diminish the efficiency of the motor by introducing idle spaces.

The Renault firm, of Paris, has recently patented a valveless motor the construction and operation of which are illustrated by the accompanying diagram of one cylinder The piston *p* moves in a cylinder *m* which rotates on its axis inside the fixed cylinder *c* with an angular velocity equal to one-eighth that of the crank shaft The rotation is produced by the endless screw *v* and the helically geared wheel *r* Each cylinder is terminated above by a conical extension This part of the outer cylinder has two openings *a* and *e* which constitute the admission and exhaust ports, and are placed at an angular distance from each other which is determined by the proper regulation of the motor The conical head of the inner cylinder has four openings *o* spaced at intervals of 90 degrees which successively unmask the ports *a* and *e* as the cylinder rotates These openings are bounded laterally by generating lines of the cone and above and below by the horizontal planes which limit the conical portion of the cylinder



THE RENAULT VALVELESS EXPLOSION MOTOR

Leakage from the inner cylinder is prevented by the pieces *ss* The igniter is placed at the center of the removable base of the cylinder—*Le Génie Civil*

TABLE OF CONTENTS

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending March 28, 1911

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents]

Acetyl celluloses compounds, making, Bonhoeffer & Gustrum	987 693
Acid derivatives and making the same, esters of salicylic, Sulzberger & [illegible]	987,771
Adding device, E. E. Scott	987,979
Adding machine computing attachment A L. Landis	987 890
Advertising card W L. Hopkins	987 989
Aerial navigation apparatus J Ostand	987 810
Aeroplane C Kramer	988 118
Air compressor W Krellwitz	987 729, 987 912
Air lift liquid A Long	987 729
Airship J J Slavin	988 039
Airship lifting attachment E. B Latch	988 115
Alloys electrolytically refining A G Betts	987 947
Amalgamator W E. Busby	988 288
Amusement device I Cornelissen	987 850
Animal shelter C J Bear	988 241
Annunciator A. Langen	988 004
Antiskidding device for vehicle wheels, O B Kibby	987 806
Attaching clamp or bond G Adssem	988 001
Automobile engine starting apparatus, Thompson & Hetter	987,980
Automobile farm T J Thorp	988 047
Automobile radiator support Livingston & Fairbank	988 110
Automobile spring C A Tilt	988 2[illegible]9
Automobile top J V Mitchell	988 204
Back spacing mechanism C Spiro	987 701
Bag holder E B Heyd	988 097
Barges anchoring attachment for floating Karr & Rauch	987 886
Barometers and other indicating instruments index for T A Reynolds	987 746
Barrel sanding machine E F Beugler	988 071
Barrel trimming or finishing machine G E Hardie	987 98
Bat former S M Ball	987 789, 987 790
Batteries, machine for making electrical dry W E. Harmon	987 870
Bearing alarm A. H De Lage	988 176
Bearing axle, T. V. Buckwalter	987 864
Bearing, wheel G Spalding	988,219
Bed and seat spring A J Wellman	987 [illegible]81
Bed sofa Kroehler & Pettersen	987 998
Bed wall C O Feltner	988 0[illegible]4
Bedstead folding Olson & Letske	987 736
Belt fastening I I Griffiths	987 716
Beverage dispensing apparatus J H Earl	987 970
Bicycles motor cycles etc stand support and prop for F S Bilsby	987 734
Bit See Expansible bit	
Bit brace attachment O I Hanson	988 [illegible]03
Boiler separator, J E Harrison	988 264
Boiler tube beading tool E Wiet	988 054
Boiler water purifying apparatus etc P Muller	988 014
Bolt and nut lock O E Dietrich	987 70[illegible]
Boom J H McGiffert	988,124
Bottle milk testing H C Troy	988 155
Bottle molding apparatus, Blabing & Sooy	988 166
Bottle non refillable C E W Archer	988 001

The Formation, Growth, and Habit of Crystals*

Modern Views of Crystallography

By Paul Gaubert, D Sc, Assistant in Mineralogy at the Natural History Museum, Paris

A CRYSTAL arouses the interest of the observer not only by the regularity of its forms the perfection of its surfaces and angles its transparency and its brilliancy but also by the manner in which it grows, heals its wounds is dissolved and modified under the influence of the inclosing medium To some authors the crystal from certain points of view appears analogous to living forms and seems to undergo a sort of evolution

Its formation its growth the variations of the faces under the influence of the inclosing medium have been the object of numerous researches which have greatly modified our conceptions regarding them The purpose of this article is to show the present state of our knowledge concerning these diverse and interesting questions of crystallogeny

I

As early as the seventeenth century Leeuwenhoek who examined under the microscope everything that in his time lent itself to this line of observation followed the formation and growth of the crystals of various substances (as sugar tartar sea salt etc) He was led to conclude that the cubic crystals of sea salt are formed of other minute cubes themselves made up from cubes the existence of which one has to accept through analogy with what is seen since they are invisible under any magnifying power Later Baker Ledermüller and others also examined under the microscope the branched and varied forms that appear when a substance crystallizes on a sheet of glass but it is to Nicholas Le Blanc that we owe the first systematic and effective researches in crystal genesis and particularly in the variation of the form In his very interesting work De la Cristallotechnie he gives methods for the preparation of crystals and in particular does he set forth the process of renewing the solution of feeding the growing solids that they may attain a relatively considerable size

In what form do we see the crystal with the aid of the highest magnifying power? Does it present from the first the form that it will have later? The biologists were the first to take up the matter of the formation of the crystalline germ that is, of the form which it presents at the instant when it first becomes visible and most of them have admitted the existence of an embryonic state or a state in which the constitution and form are different from that of the crystal properly called although this idea has been contradicted by Frankenheim to whom we owe numerous crystallogenic observations Vogelsang in 1867 took it up again and made numerous ingenious and varied experiments to show its correctness His observations are generally exact but he has unfortunately misinterpreted them To show the embryonic state of the crystal Vogelsang tried to make the bodies crystallize under special conditions with the purpose of retarding their formation so as to enable him to observe all the steps of development With this purpose in view he added to sulphur solution a viscous body Canada balsam There were produced little spheres to which Vogelsang gave the name of globulites and which were thought to represent an embryonic stage These globulites unite to form particular groups each of which has received a special name and at the expense of which the crystal would be produced only at a later stage

Moreover Vogelsang rests his experimental researches on observations made with crystallites of varied forms existing in a few rocks rich in silica and more or less vitreous and in the slags of blast furnaces but as was later shown by M O Lehmann who made numerous researches on the formation of crystals these globulites are but drops supersaturated with sulphur and consequently have nothing in common with the crystalline state

Brame as well as Vogelsang studied sulphur but in a molten condition He observed little supermelted drops (utricules) to which he attributes a considerable role in crystallization His ideas differ from those of Vogelsang but nothing in his experiments substantiates the existence of an embryonic state.

The observations of M O Lehmann have shown that the crystal possesses from the beginning a form identical with that which it has when it has attained larger dimensions T V Richard and E H. Archibald have employed the cinematograph to follow out the formation of the crystal and obtained only figures of completely formed individuals.

I myself have made a great many experiments, and have always found that the first visible particle had all the properties of the crystal It is nevertheless not to be disputed that in some cases there takes place what Vogelsang and his predecessors have observed with sulphur or other bodies but who worked with supersaturated drops or amorphous particles or little spherulites of unstable form which later underwent modifications into more stable forms and the normal development of which can then be followed

Nevertheless in spite of the observations of Frankenheim O Lehmann and others the idea of the embryonic state of the crystal has not disappeared from science and the hypothesis of Vogelsang, supported by De Schoen Cartaud and others resting on misinterpreted observations still finds some credit.

II.

When the crystal is once formed—that is, becomes visible under the microscope—how does it grow? Several cases may be presented First the mother liquid is in a state of rest, the cooling or evaporation is extremely slow, and the crystalline particles are built up by diffusion alone In this case the growth is too slow to be constantly followed under the microscope In the second case the liquid is cooled or evaporated with such rapidity that the quantity of matter deposited on the crystal produces an enlargement microscopically visible Movements in the liquid are thereby set up It is an established fact that currents called currents of concentration passing over a crystal deposit a thin coating of substance followed by a second and so on until for example one can see on a crystal of lead nitrate having a diameter of half a millimeter as many as twelve of these successive layers deposited If the process were suddenly interrupted and the crystal examined any observed face would not be a plane but would show a sort of step arrangement of which the highest step would indicate the point of contact of the current of deposition

These successive deposits have no interspaces and the crystal may be perfectly transparent If the crystal of lead nitrate is however subjected to the influence of two or of several currents of concentration the corresponding coatings laid upon it start from different points in the periphery and may not be of the same thickness. Ordinarily they do not join exactly at their point of meeting In this way are then produced inclusions and the crystal is no longer transparent but becomes milky On a glass plate it is easy to produce at will a transparent or milky crystal of lead nitrate In the experiment it is necessary to agitate the crystal very slightly with a needle in order to subject it to the influence of one or several currents

These concentration currents produce other peculiarities (vicinal faces etc) which it would take too long to describe in detail I shall confine myself to calling attention to the influence they may have upon the faces of the crystal The introduction of matter to one face only of a crystal causes it to develop unequally and since all crystals of the same bath or magma are not influenced in the same way they may present a number of different forms The crystals formed at the bottom may be different from those which are deposited on the side walls or at the surface

III

If these concentration currents can completely change the habit of a crystal by producing elongation in one direction the nature of the faces is not modified an octahedral crystal always appears in octahedrons But there are two other influences which modify the faces One of them is the rapidity of crystallization the other the constant absorption of foreign matter by the crystal in process of growth Still other factors may intervene, but they are only indirectly concerned

It has long been known that crystals formed rapidly possess simple faces, while those which have grown slowly are more complicated Thus in nature the crystals rich in inclusions sometimes of large size, are poor in faces while the small crystals of the same substance but transparent, are generally limited by a large number of faces. These differences are due to the rate of crystallization the influence of which has been known by the experiments of Frankenheim, Lecoq de Boisbaudran O Lehmann, and myself In rapid crystallization the crystals have faces with simple symbols in slow crystallization these same simple faces persist, but the angles and edges have been truncated and beveled, giving rise to new facets, and I have shown that in certain cases these facets make their appearance always in the same order With varying rates of crystallization the dominant forms obtained in the case where the crystallization was rapid persist with more or less extensive development, but it may be otherwise in the case where the faces are modified by the regular absorption by the crystal during the growth of foreign matter added to the mother liquor This fact is easily made evident, as I have demonstrated by adding a little coloring matter

Rome de l Isle and Berniard have observed that the crystals of sodium chloride formed in urine are regular octahedrons instead of cubes such as crystallize from a pure mother liquor Vanquelin and Fourcroy showed later that this curious modification is due to the urea present. Boydant also established a few phenomena of the same class and tried without success to ascertain why the mere presence of a foreign substance can be thus effective

P Curie developed a remarkable and attractive theory which apparently furnished the key to this curious modification He claims that the capillary action existing between the liquid and the crystal intervenes an effect varying with the nature of the faces belonging to the diverse forms and with the nature of the liquid. Basing his belief on Gauss's theory of capillarity he concludes that such faces develop or require the minimum expenditure of capillary energy The dominant forms must consequently be conditioned by those faces the constant capillarity of which is the least The addition of a foreign substance altering the different capillary constants may consequently induce modifications of form

It appears indeed that the capillary forces must act, but up to this time there is no fact known which proves that they intervene sufficiently to modify the forms in spite of the experiments of M Berent carried out in the laboratory of Sohncke moreover, I shall describe later an observation showing that they are without influence.

IV

The crystals of one substance rarely form synchronously with those of another dissolved in the same mother liquid and it is on this property that chemists base their action when they attempt to purify bodies by repeated crystallizations but there are exceptions as in the well known coloration of hydrated nitrate of strontium by extract of logwood which was accomplished by Senarmont. Since then M Lehmann and I have proved a few other cases of coloration of crystals by artificial organic dyes

By making use of the artificial coloration of crystals so as to indicate the presence of foreign matter which has crystallized with the colorless substance I have been enabled to show that the absorption caused modification in form

The absorption of foreign matter by crystals in process of formation is accomplished in two different ways First the coloring matter enters into the composition of the crystal whatever may be its degree of dilution and is shared between the crystal and the liquid second the coloring matter is taken up by the crystal only when the liquid becomes saturated

The two processes may go on simultaneously The study of certain properties of colored crystals particularly polychroism and the law of division shows that the coloring substance in the first case is found in the crystal in the same state as in the liquid, in the second on the contrary the coloring matter is in the crystalline state and we have to do then with a regular grouping of the crystalline particles of the colorless substance with those of the coloring material added to the mother liquor

Lead nitrate is colored by methylene blue in the second manner it appears in cubic crystals with the triglyphic striæ of pyrite instead of in octahedrons The modifications in the crystals of this salt produced in a mother liquor which holds methylene blue in solution, show that capillarity does not intervene to produce them. Indeed, in a solution depositing lead nitrate and saturated with methylene blue, without, however giving crystals of this latter substance, the crystals of the nitrate are not at all modified They are in octahedrons and colorless, but as soon as the coloring matter begins to crystallize synchronously with them the cube faces appear and finally are formed to the exclusion of all others. Nevertheless, the surface tension can not have been changed since the quantity of methylene blue has remained the same in solution. An interesting fact is the inequality of absorption of the foreign matter dissolved in the mother liquid by the different faces of the crystal. Thus, on the octahedral faces of the lead nitrate the methylene blue is not at all deposited, but only on the faces of the cube and the pentagonal dodecahedron. Similar examples can be cited which explain the ap-

* Translated for the Smithsonian Institution's Annual Report from Revue Scientifique, Paris, 48th year No. 8, January 15th 1910

pearance, frequent in minerals known as hour-glass structure. In the case of cubic crystals of all the possible faces it is only those which absorb the foreign matter which will develop

The idea which first comes to mind is that the molecular structure of the crystal plays an important part in this synchronous crystallization It is not so at all, different foreign substances may be absorbed by different faces and in such cases the habit of the crystal is dependent on those diverse substances If one causes the colorless substance to crystallise in a solution containing two colors each one giving characteristic forms the crystallizations thus obtained will be the two combined forms so that one and the same crystal is composed of pyramids or of prisms of different colors Thus the crystals of urea nitrate colored by methylene blue and picric acid show if the crystallization has been carefully conducted yellow triangular prisms corresponding to the faces *g* and *h* and blue triangular prisms corresponding to the prismatic faces *m* of the monoclinic system

Not only may foreign crystalline matter be absorbed but also the liquid matter added to the mother liquid and even the molecules of the latter may also pass regularly into the crystal to modify its form I have been able to show this fact by crystallising phthalic acid in a solution containing ethyl alcohol[1] This explains why a crystal obtained from different solvents may show different faces

Consequently a crystal very pure in appearance transparent, and without inclusions may contain foreign matter, and in the case where it is the mother liquid which is absorbed its purification is impossible The solvent must be changed.

When the crystals of a determined substance obtained from two different solutions do not present the same forms it is incontrovertible that in one of the cases, perhaps in both cases since we do not always know the *form* of the pure crystal there has been absorption of the molecules of the mother liquor Sometimes it is the water which is absorbed and this water has been regarded as water of crystallization or as water of constitution according to the temperature at which it is driven off

When purification is attempted by recrystallization if the foreign substance which passes into the crystal is present in small quantities in the mother liquid the first or the last crystals formed according to the mode of synchronous crystallization will be the purest In case there is a division of the foreign matter between the crystal and the liquid if the coefficient of its solubility in the crystal and the liquid are known the number of crystallizations demanded for the purification of the crystals may be calculated under proper conditions

V

The natural crystals appear in such varied habits that before Romé de l Isle no one could see the constancy of forms and the genius of Hauy was necessary to establish their derivation It is known that ordinarily the crystals of the same deposit and the same generation are identical and that those of successive deposits or generations may have different dominant forms All these differences may be explained by the rapidity of crystallization but especially by the constant presence of foreign substances Unfortunately it is difficult to determine the nature of the latter since the results of analyses made up to the present time have little value in solving this problem Indeed a very small quantity of matter is required to modify the forms of a crystal sometimes an amount even less than one one thousandth of the weight of the latter is sufficient

In every case whether we have to do with natural or artificial crystals we need to determine their form in the pure state a forn which is constant and which I have called fundamental It may be distinct from the primitive form chosen by crystallographers

In closing I shall observe that the substances prepared in laboratories seem rarely to show the numerous modifications of *form* so frequent in the natural crystals This is due to the fact that the artificial crystals are prepared almost always in the same manner with the same reagents and consequently with the same foreign substances in the mother liquor In nature on the contrary as the analyses of mineral waters show the composition of the solutions which deposit the crystals of a given substance varies from one region to another as much in the quality as in the quantity of the different elements dissolved But all crystals do n t lend themselves with the same facility to these modifications of the faces and just as there exist in nature b lies like alcite which possess the most varied habits there exist also artificial compounds the crystals of which may appear in a great number of forms depending on the condition of crystallization as for example phthalic acid meconic acid nitrate and oxalate of urea

[1] To show this, it is enough to take a colored liq id b t with the exception of bromide there is no liquid which has a proper color at the ordinary temperature

Lord Morley on Science and Literature

Association with Science as a Literary Asset—The Literary Shortcomings of Scientific Men

AN eloquent address on language and litera ure was delivered on January 27th by Lord Morley of Blackburn as president of the English Association Parts of the address dealt with the relation between science and letters with particular reference to the use of scientific knowledge in poetry and the antithesis between documentary fact and artistic style Science aims at concise and truthful expression and while Lord Morley testified to the value of its influence upon literature he doubted whether scientific ideas had inspired even Tennyson to the best verse whether the desire for fact scientifically recorded is not a misfortune in the treatment of modern history and whether concentration upon scientific truth has not a deadening effect upon emotional conceptions and pleasures

In commenting on the address *Nature* remarks Lord Morley s tribute to some scientific master f clear and simple exposition resigns s to his subsequent conclusions Keats could not forgive optics for robbing the rainbow of its wonder and mystery and Lord Mo ley seems to suggest that the literary art which deals with scientific studies and results is not of the highest But poetry is imagery and new images of Nature are made possible by every discovery of the attributes and meaning of the things around us The poetry which neglects advances of natural knowledge becomes conventional in form and substance concerning itself only with the wonders of childhood because it does not understand the higher and grander mysteries which science has failed to penetrate History is concerned with the accumulation and consideration of facts with the view of arriving at correct conclusions from them and in this respect it must be studied by the methods of science though the human factor makes the problems more difficult than when material things only are involved There is however no intrinsic reason why Gibbon s majesty of historic conceptions and the symmetric grandeur of his design should not be combined with such great learning as was displayed by Lord Acton Accurate knowledge must surely not be considered as antithetic to perfection of style

"The instance of Darwin s loss of interest in poetry and music proves little A wide search through the biographies of distinguished men of science will only reveal two or three cases in which devotion to studies of Nature has resulted in the atrophy of æsthetic faculties. Close concentration upon any particular subject often leads to indifference to the aims and work of others but this is as true of art, or poetry or music as it is of science There is less reason for believing that the man of science has usually no taste for literature music or other forms of refined and imaginative expression, than there is for concluding that artists, musicians, and poets have no interest in the attentive study of natural objects and phenomena. If science and documentary evidence are responsible for an age of prose, it is because the poets have been spinning cobwebs from their brains when they ought to have been learning something of the spirit and achievements of science These are they who having never entered upon scientific pursuits are to use Herbert Spencer s words blind to most of the poetry by which they are surrounded

Subjoined are some extracts

Let me offer a few words on the effects of the relations of letters and science We may obviously date a new time *from* 1859 when Darwin s *Origin* of Species appeared and along with two or three other imposing works of that date launched into common currency a new vocabulary We now apply in every sphere high and low trivial or momentous talk about evolution nat ral selection environment heredity survival of the fittest and all the rest The most resolute and trenchant of Darwinians has warned us that new truths begin as rank heresies and end as superstitions and if he were alive to see today all the effects of his victory on daily speech perhaps he would not withdraw his words That great controversy has died down or at least takes new shape leaving after all is said one of the master contributions to knowledge of nature and its laws and to man s view of life and the working of his destinies

Scientific interest has now shifted into new areas of discovery invention and speculation Still the spirit of the time remains the spirit of science and fact and ordered knowledge What has been the effect of knowledge upon form or lang age on literary art? It adds boundless gifts to human conveniences Does it make an inspiring publi for the master of either prose or verse? Darwin himself made no pretensions in authorship He once said to Sir Charles Lyell that a naturalist s life would be a happy one if he had only to observe and never to write Yet he is a writer of excellent form for simple and direct description patient accumulation of persuasive arguments and a noble and transparent candor in stating what makes against him which if not what is called style is better for the reader than the finest style can be One eminent literary critic of my acquaintance finds his little volume on earthworms a most fascinating book even as literature Then although the controversial exigencies of his day affected him with a relish for laying too lustily about him with his powerful flail I know no more lucid effective and manful English than you will find in Huxley What more delightful book of travel than the 'Himalaya Journals of the great naturalist Hooker who carried on his botanical explorations some sixty years ago and happily is still among us?

Buffon as man of science is now I assume little more than a shadow of a name and probably even the most highly educated of us know little more about him than his famous pregnant saying that the style is the man—a saying by the way which really meant no more than that while nature gave the material for narrative it is man who gives the style Yet the French to this day count him among the greatest of their writers for order, unity precision, method clearness in scientific exposition of animated nature along with majestic gifts of natural eloquence. Then com s the grea st f all Whatever the decision may be as to the value of Goethe s sc e itific contribution his at leas is certain that his is the most won dro s the n j e ase of a man who united high original s ient fic power of mind with ranscendent gifts in flight force and beauty of poetic imagination

As for s ience and the poets or ly the other day an attractive little book published by Sir Norman Lockyer shows how Tennyson the co poser of verse unsurpassed for exquisite music in o r English tongue yet followed with unflagging interest the problems of evolution and all that hangs upon them Whether astronomy or geology—terrib e muses as he well might call them—inspired the better elements of his beautiful work we may doubt An English critic has had the courage to say that there is an insoluble element of prose in Dante and Tennyson has hardly shown that the scientific ideas of an age are soluble in musical words Browning his companion poet nearly unive sal in his range was too essentially dramatic t o independent of the scientific influences of his day too careless of expression to be a case much in p int Tennyson said of him he had power of intellect enough for all of them but he has not the glory of words Whether he had or not science was not responsible.

I should like to name in passing the English poet who in Lowell s words has written less and pleased more than any other Gray was an incessant and a serious s dent in learned tongues and his annotations on the System of Nature by Linnæus his contemporary bear witness to his industry and minute observation as nat ralist.

In prose fiction was one writer of commanding mind saturated with the spirit of s ience Who does not feel how George Eliot s reative and literary art was impaired and at last worse than impaired by her daily associations with science? Or would it be truer to say—I often thought it would—that the decline was due to her own ever-deepening sense of the pain of the world and the tragedy of sentient being?

Let us look at the invasion of another province by the spirit of the time The eager curiosity of all these years about the facts of biology chemistry physics and their laws has inevitably quickened the spread both of the same curiosity and the same respect quickened by German example for ascertained facts into the province of history Is the p re scientific impulse—to tell the exact truth with all the necessary reservations—easy to combine with regard for artistic pleasure?

The English writer of our own immediate time with the fullest knowledge and deepest understanding of the fact and spirit of history would I think be pronounced by most critics with a right to judge to be the late Lord Acton Acton s was a leading case where knowledge and profundity was not matched by form His page is overloaded he is often over-subtle he has the fault—or shall I call it the literary crime? —of allusiveness and indirect reference—he is apt to put to his reader a riddle or a poser and then to leave

him in the lurch Here is Acton's own account of the historian's direct debt to the methods of science

If men of science owe anything to us he says, we may learn much from them that is essential For they can show how to test proof how to secure fullness and soundness in induction how to restrain and employ with safety hypothesis and analogy It is they who hold the secret of the mysterious property of the mind by which error ministers to truth, and truth irrecoverably prevails"

Where the themes and issues are those of scientific truth that prose should be unemotional is natural Everybody knows Darwin's own account, how as the laborious years passed he so lost his taste for poetry that he could not endure to read a word of it, Shakespeare became so dull it nauseated him, and music set him thinking too energetically on what he had been working at, instead of giving him pleasure. If all this loss was the price of years of fruitful concentration in the matter, who can wonder if the scientific and documentary age is an age of prose?

The Air-brake as Related to Progress in Locomotion—II*

The History of a Great Invention

By Walter V Turner Chief Engineer, Westinghouse Air Brake Co, Philadelphia, Pa

Continued from Supplement No 1840, page 214

RECENT DEVELOPMENTS IN TRAIN BRAKE APPARATUS

The typical brake equipments which have been mentioned namely Straight air plain automatic quick action automatic and the high speed brake mark epochs during which the respective equipments were each able to successfully meet the traffic requirements existing for the greater part of the periods during which they were supreme but as the demands of service became steadily more severe each in turn gave way to its successor the improved equipment in each case being in its turn satisfactory for such a time as the conditions which brought it into being were not greatly changed

This growth it will be noted was along lines of improving the degree of efficiency of the fundamental functions of the original plain triple valve either by increasing the air pressure carried for braking purposes or by the aid of additions to the valve structure itself or by the attachment of additional devices to existing apparatus or by combination of two or more of the expedients just mentioned

With the high speed brake the practical limit to improvement along such lines was believed to have been reached For some time little or no improvement was thought possible and this was indeed a fact so far as further progress along lines previously followed was concerned for two reasons (1) About all was then being obtained from the old type of brake

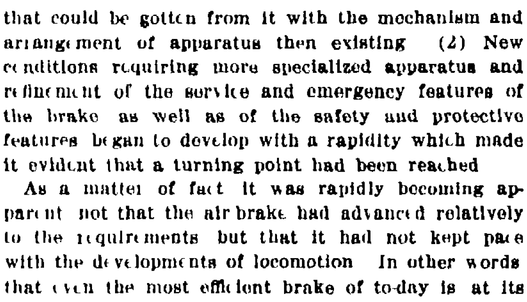

Fig 11 - AMERICAN TYPE OF LOCOMOTIVE 1879

that could be gotten from it with the mechanism and arrangement of apparatus then existing (2) New conditions requiring more specialized apparatus and refinement of the service and emergency features of the brake as well as of the safety and protective features began to develop with a rapidity which made it evident that a turning point had been reached

As a matter of fact it was rapidly becoming apparent not that the air brake had advanced relatively to the requirements but that it had not kept pace with the developments of locomotion In other words that even the most efficient brake of to-day is at its best not able to control and stop a train in the same distance as when the weight and length of the train was less than one-fourth of that to-day That we have done as well as we have will be appreciated when it is considered that the length of the trains and the volume of air employed have rendered this vastly more difficult as to service control and the weight

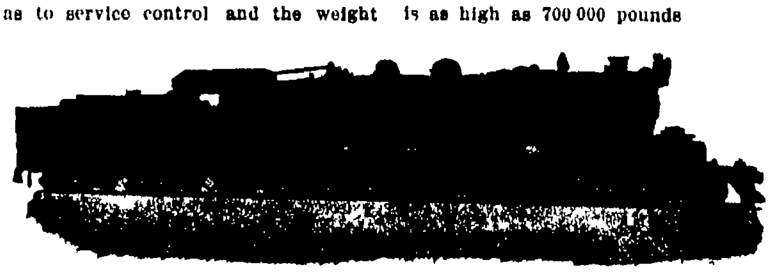

Fig 12 - MALLET ARTICULATED LOCOMOTIVE—ATCHISON TOPEKA & SANTA FE RAILWAY 1909

(which involves many factors) to the extent that it would require at least twice the distance in which to stop if the old brake had to be used with present-day conditions

In addition to the increased weight and speed of trains there were of course increased number of parallel tracks and frequency of trains These always bring with them braking problems quite as difficult of solution and as necessary to be solved as those which preceded them particularly as the tendency is to neutralize or lower the value of many of the

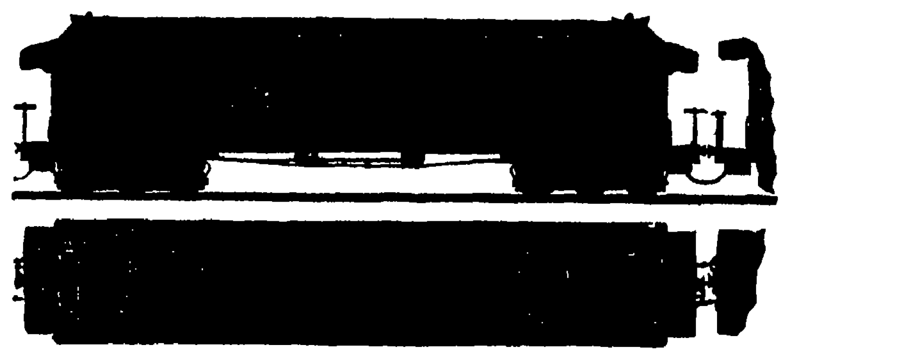

Fig 13—P R R PASSENGER CAR 1872

factors involved in producing and realizing retarding forces

It is difficult for one who has not given the subject careful thought to realize the great changes in railroad equipment and operative requirements which have taken place since the introduction of the air brake but it is only necessary to review briefly these past and present conditions in order to appreciate the necessity for a similar development and improvement of the apparatus used for controlling trains under these new conditions

The following comparative tabulations comparing the conditions existing from 15 to 20 years ago and those of to-day with regard to extent of territory covered capital involved traffic handled and so on will perhaps illustrate the conditions that now have to be faced better than the mere statements which have just been made

Railroad Development From 1889 to 1909

	1889	1909	Increase Per Cent
Miles of line	153 385	234 182	52
Miles of track	136 958	340 000	8 5
Net capital	$ 850 745 000	$13 508 11 000	63 3
Passengers carried	4 2 1 1 000	890 04 000	86 5
Tons freight carried	539 639 000	1 486 000 000	1 5 8
Locomotives number	29 036	5 220	197 0
Freight cars number	829 886	2 113 150	154 6
Employees number	04 43	1 754 000	110 2
Employees compensation	$480 785 504	$1 003,270 000	107 4
Electric railway		50 000	

Locomotives—The weight on drivers has increased since the air brake was invented from 25 000 pounds to 400 000 pounds

The drawbar pull of locomotive has increased since the air brake was invented from 10 000 pounds to 100 000 pounds

The total weight of locomotives at the present time is as high as 700 000 pounds

Working steam pressure has increased since the air brake was invented from 125 pounds to 225 pounds.

Passenger Cars—Weights have increased from 20 000 pounds to 150 000 pounds

Freight Cars—Light weight of car has increased from 12 000 pounds to 50,000 pounds

Capacity has increased in the last twenty years from 40 000 pounds to 150,000 pounds

Passenger Trains—Schedule speeds have increased from 30 miles per hour to 65 miles per hour

The energy contained in a five-car train of cars having an average light weight of 80 000 pounds per car running at a speed of 35 miles per hour, is 6 200,000 foot pounds of cars having average weight of 127 000 pounds running at 65 miles per hour it is 90 000,000 foot pounds or nearly fifteen times as much

Freight Trains—Train length has increased from 15 to 130 cars total weight has increased from 300 to 4 500 tons and in certain places in the country as high as 6 000 tons

To take an actual example illustrating what is involved in the handling of a modern high-speed passenger train the following figures are taken from the official report of the Emergency Brake Tests carried on about a year ago by the Lake Shore & Michigan Southern Railway near Toledo

Lake Shore Emergency Brake Test.

	Weights	
Types of vehicles used	Pounds	Tons.
Locomotive—Pacific type	388 000	194 0
Buffet car	149 000	74 5
Dining car	140 000	70 0
Sleeping car average	125 000	62 5

Energy in Test Trains

Make up of train	2 Loco —10 Cars	1 Loco —6 Cars
Train weight—pounds	2 068 000	1 180 000
Train weight—tons	1 034	590
Energy at 40 M P H foot pounds	116 816 000	66 595 200
Energy at 40 M P H foot tons	58 408	33 298
Energy at 60 M P H foot pounds	262 836 000	149 839 200
Energy at 60 M P H foot tons	131 418	74 920
Energy at 80 M P H foot pounds	467,264 000	266 380 800
Energy at 80 M P H foot tons	233 632	133 190

Kinetic Energy* in Train of 2 Locomotives, 10 Cars of 75 Tons Weight Each—Total Train Weight, 2 276 000 pounds, or 1,138 Tons.

Speed	40 M P H	60 M P H.	80 M P H
Foot pounds	127,811 200	287 575,200	511,244 800
Foot tons	63,906	143 787	255,622

Figs. 11 and 12 present a tangible evidence illustrative of both extremes of the locomotive development indicated in the tabulations just given The view of the American type of locomotive (Fig 11) representing standard practice of 1879 can no doubt be recalled by many and is in marked contrast with the enormous Mallet Compound Locomotives (Fig. 12) now being introduced for heavy grade service in various parts of the country

Similarly the progress in passenger car construction is graphically illustrated by comparing the typical passenger car of 1872 (Fig 13) with the modern all-

* Presented at the meeting of the Mechanical and Engineering Section

*Kinetic energy in train of 2 locomotives, 10 cars of 75 tons weight each—at speed of 80 M P H is sufficient to raise 1 ton to a height of over 48 miles.

steel Pullman cars (Fig 14), which are being built at the present day

All the figures which have been given report the maximum conditions of past and present-day practice As the application of the air brake has made this enormous increase in weight of vehicles speeds and length of trains possible it is fair to assume that the stopping power of the brake should logically be increased in the same proportion so that the stop should be no longer now than formerly

A concrete example will show forcibly just what this increase in weight and speed means to the operating department if it is to accomplish such an admittedly desirable and necessary result Under the former conditions the factor of safety in train handling was none too large and it is therefore imperative that we should be able to control modern trains under present existing conditions at least as safely and efficiently as formerly To do this for five 150 000-pound coaches running at 65 miles per hour it is necessary to provide means for controlling over 105 000 000 foot pounds of energy as compared with about 6 000 000 foot pounds which was all that the brake of the early 70 s was called upon to control with a train of five 30 000 pound cars running at 35 miles per hour When the locomotive used with each train is considered the total energy in the modern train becomes 162 000 000 foot-pounds as compared with 9 800 000 foot pounds for the train of 1870 It is not surprising therefore that the air brake art demands thoughtful consideration from trained and experienced minds if the railroad traffic of to-day is to be handled with a safety and efficiency even equal to that of the days when the total energy to be reckoned with was one sixteenth as great Here again is found another close resemblance between the conditions of acceleration and deceleration for while it is not especially difficult to increase the speed of a train from 30 miles per hour to 40 miles per hour it requires the expenditure of a vastly greater amount of energy to increase its speed from 60 miles per hour to 70 miles per hour In like manner for any given increase in speed the additional amount of work required from the brake increases in geometrical not arithmetical ratio If therefore the improvements for the heavier trains and higher speeds of to-day permit of stopping in about the same distance as could be done with the brake of forty years ago and the trains of that period we should congratulate ourselves for having held our own

The mere power necessary to accomplish this is indicated by the fact that the total maximum force exerted by the push rod of the 6 inch brake cylinder of the early equipment was 1 700 pounds while with the 18 inch brake cylinder used on the heaviest coaches a maximum pressure on the push rod of 26 670 pounds is obtainable

From the foregoing it will be apparent that many features must now be considered which did not exist when the brake was first invented particularly on the physical side of the problem For example the amount of work required per square inch of brake shoe surface is vastly greater This is a condition seldom noticed and yet of great significance, as the following comparison will show

In the report of one of the earliest brake trials in the history of continuous brakes, made on the Midland Railway, near Newark, England, in 1875, and since known as the Newark trials (see London *Engineering* June and July, 1875) the best brake performance recorded was by a train of fifteen 21 000 pound (average) four wheel carriages fitted with a primitive form of the Westinghouse automatic brake one cast iron brake-shoe being used on each wheel The best stop was made from a speed of 52 miles per hour the highest that could be obtained in 18 seconds This corresponds to the performance of 15 5 foot tons (1 ton = 2 000 pounds) of work per brake shoe per second In the classic Westinghouse-Galton tests which followed about three years later the four wheel experimental van used weighed 18 200 pounds and was fitted with two brake shoes per wheel and from 52 miles per hour speed a stop was made by the experimental van alone in 11½ seconds Here the work done was only about 9 foot tons per brake shoe per second

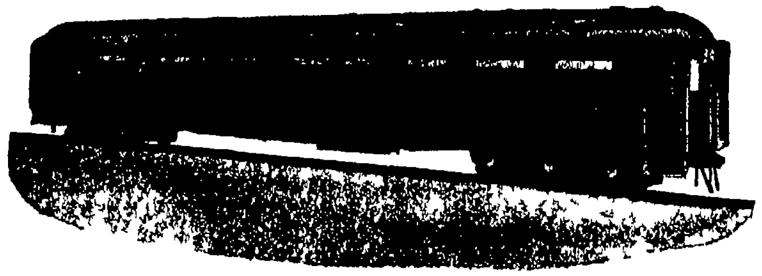

Fig 14—ALL-STEEL SLEEPING CAR 1909

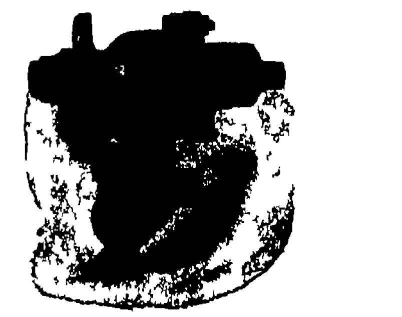

Fig 16—TYPE K FREIGHT TRIPLE VALVE

In 1875 the standard passenger coach used on the Pennsylvania Railroad weighed 39 300 pounds and had four wheel trucks To stop such a car from 52 miles per hour in 18 seconds required only 12 33 foot tons of work per brake shoe per second or less than that required of the brake on the Midland train although the Pennsylvania car weighed 18 300 pounds more This is of course due to the fact that eight brake shoes were available to do the work as compared with four on the Midland train Contrast with the above a modern Pullman car weighing 160 000 pounds and having six wheel trucks Assuming that from a speed of 52 miles per hour that stop could be made in 18 seconds the work done would be 33 5 foot tons per brake-shoe per second or over twice that of the Midland train notwithstanding that there are twelve brake-shoes to do the work instead of four But modern express train speed may be expected to run frequently as high as 75 miles per hour and to make a stop from this speed in say 35 seconds (which would be about the best that could be expected of the modern brake equipment) would require 35 8 foot tons per brake-shoe per second or not much more than when a stop of 52 miles per hour is made in 18 seconds But to have the same absolute safety under modern conditions as existed in 1875 would require the stop to be made in at least the same distance and time and to stop a 160 000 pound car from a speed of 75 miles per hour in 18 seconds would require 69 6 foot tons of work per brake shoe per second or about 4½ times that in the case of the Midland train (What this would be with four wheeled trucks will be appreciated) Even if two brake-shoes per wheel could be used instead of one there would still be over twice as much work to be performed by each brake shoe per second if the trains of to-day at the speeds now attained in high speed service are to be relatively as safe as the trains of thirty years ago Furthermore the use of two brake shoes per wheel is rapidly becoming a necessity not only on account of the great amount of work to be performed by each brake shoe but also because the brake shoe pressure required by modern conditions of high speeds and heavy cars are becoming so great that in emergency applications a heavier pressure is brought to bear on the axle and journals by the brake shoe acting on one side of the wheel only than is imposed by the weight of the car resting on that wheel

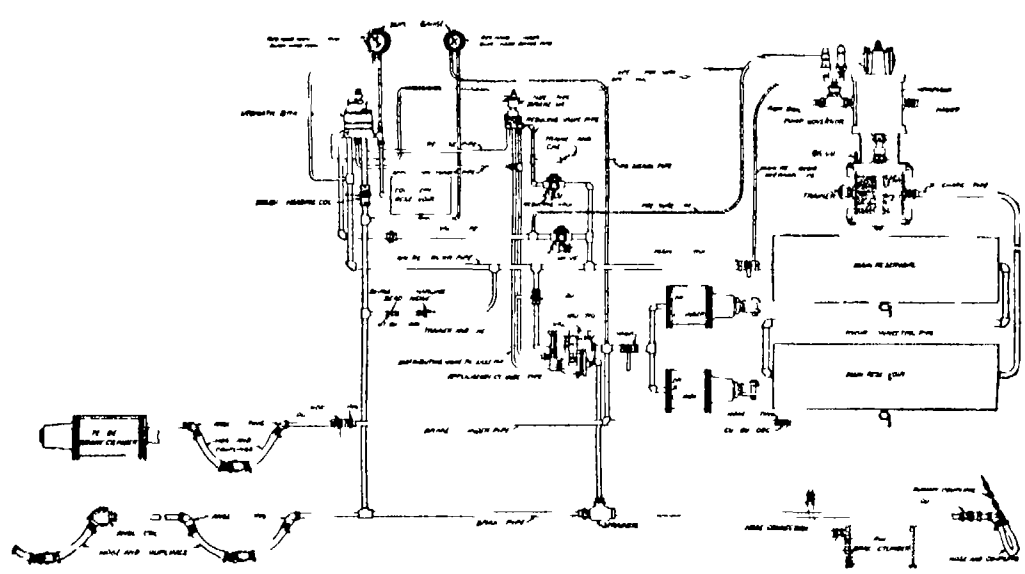

Fig 17 PIPING DIAGRAM ET EQUIPMENT

The tremendous significance of this increase is but faintly appreciated by those who have not had occasion to investigate this aspect of the question The cast iron brake shoe is to day practically as it was thirty years ago This brake shoe must now do four times the amount of work by frictional resistance to the rotation of the wheel as formerly It may be suggested Why not quadruple the pressure per brake shoe But it also must be remembered that when the brake shoe pressure is multiplied by four the actual retarding force is by no means quadrupled for three vital adverse factors are being overlooked viz the effect of increased pressure speed and temperature on the coefficient of friction between the wheel and the shoe Exactly how great an effect these may have depends of course on the conditions of the individual test considered but that it is considerable is proven by the fact that a stop from a speed of 75 miles per hour in 35 to 40 second instead of 18 seconds is considered good although we are to day using about four and a half times as much pressure per brake shoe as at the Newark trials

It should be stated that in the above no account is taken of the rotative energy of the wheels If this is considered it is evident that the figure for the modern conditions will be still more in excess of those of the past on account of the wheels being heavier and there being a greater number per vehicle

Again the difference in air pressure required to apply and release the brakes is by no means as easily obtained to day as when trains were short The air supply required for short trains with small brake cylinders was obtained with compressors of much less

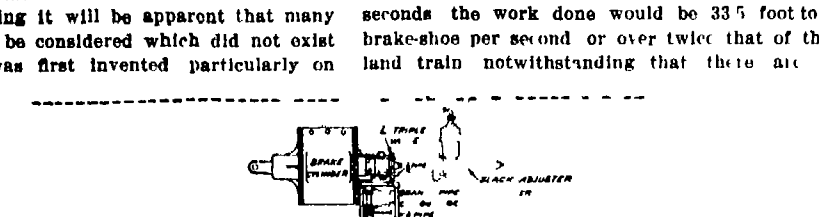

Fig 15—IMPROVED PASSENGER BRAKE EQUIPMENT TYPE LN

capacity than is now necessary to employ, witness, the 6-inch air compressor of the early days of the brake with its capacity of not over 15 cubic feet per minute as compared with the cross compound com pressors now used which have approximately 125 cubic feet capacity The reason for this is apparent, for it required not so very long ago about 25 to 30 cubic feet for a full application now 300 cubic feet is required

In general therefore it may be stated that the brake which would satisfactorily meet the requirements of past conditions falls short of the maximum efficiency which it should be possible to attain in proportion to the increase of the requirements of present day service over those of the past The force of this is apparent when the same comparison is made between the locomotives and cars of the two periods. This review of the conditions and what is involved which is by no means exhaustive will serve to give an idea of the magnitude of the problem How the various stages of this problem have been solved as *they presented themselves* will be shown best by a consideration of the features and functions of the im proved brake apparatus that was developed to meet the conditions just explained

CHARACTERISTICS OF IMPROVED BRAKE EQUIPMENTS

While the fundamental service and emergency fea tures of the quick action brake could not be departed from on account of the necessity for maintaining inter changeability of apparatus and operative function it was clear that in designing a brake to meet these new conditions not only must the fundamental features of the old brake be improved to their highest possible efficiency but new features must be added some of which were inherently impossible if the design were carried on along the lines previously laid down

With this as a point of departure, the develop ment of the newer forms of locomotive passenger and freight brakes was commenced and it may be fairly said that with the incorporation of the new features which will be explained in what follows the air brake entered upon a new era of its history as distinct from that which preceded covering the progress of the art from the development of the plain automatic brake to the high speed brake as that era was distinct from those of the straight air brake and of the hand brake which marked the earlier history of the art

Briefly stated the recognition of the new principles required by the changed conditions referred to led in the case of the passenger brake to the incorpora tion of the following features in addition to those char acteristic of the previous form of equipment (See Fig 15)

1 Quick rise of brake-cylinder pressure so that the braking power may reach its maximum in the short est possible time and thus begin to be effective in reducing the speed when at its highest value—and when the increase in distance run before coming to a stop is greatest for every second's delay

2 Uniform braking power on all cars irrespective of size of equipment and variation in piston travel thus contributing largely to the convenience and com fort of passengers as well as making the brake more reliable and therefore easier to manipulate

3 Maintenance of both service and emergency brake cylinder pressures up to the capacity of the ample storage reservoirs of the cars This is of the greatest advantage in overcoming the ever present and often serious depletion of brake-cylinder pressure by packing leather leakage

4 Predetermined and fixed limiting of maximum service braking power without a safety valve or other blow-off device This maintains the proper margin be tween the power of service and emergency applica tions and tends to reduce wheel sliding without wast ing air and with a minimum of apparatus thus result ing in economy both of operation and maintenance

5 Quick service feature to compensate for in creased length of train and bring about more prompt, uniform and certain application of brakes

6 Quick recharge of the auxiliary reservoirs to offset longer trains and larger cylinders and reser voirs and insure a prompt application of the brakes when desired and prevent the depletion of the auxil iary reservoir pressure

7 Graduated release feature to add to the flexi bility of the brake by making it possible to graduate the brakes off as well as on and so to handle the train more smoothly with a greater saving of time and a reduction in the amount of wheel sliding

8 Much higher brake-cylinder pressure obtained in emergency for the same brake-pipe pressure carried which pressure is maintained and retained during the complete stop thus materially shortening the stops and adding greatly to the safety of the trains

9 Automatic emergency application on depletion of brake-pipe pressure This is a safety and protective feature of great value in that it insures sufficient braking power being automatically obtained to bring the train to a stop in case the system is depleted be low a predetermined pressure either by careless ma nipulation or accidentally

10 Full emergency braking power at any time, thus placing the maximum stopping power the brake has to offer at all times ready for use by the engineer whenever an emergency arises, irrespective of what may have preceded

11 Separation of service and emergency features so that the necessary flexibility for service applications can be obtained without impairing in the slightest the emergency features of the equipment and conversely so that undesired quick action is practically impos sible.

12 High maximum braking power secured with low total leverage, with correspondingly greater over all efficiency of the brake

13 Better mechanical design resulting in more uni form wear of parts and ease of access for removal or repairs

In the case of the freight brake, the change in the conditions which require a change in apparatus were in the direction of greatly increased length of trains, and difference between the light and loaded weights of the cars The features of the new freight brake were therefore developed with particular reference to those considerations as follows (See Fig 16)

1 Ability to apply and release the brakes without fear of shocks under conditions where they are cer tain with the old brake, gives an added value to all rolling stock

2 As only a comparatively light reduction is re quired with the quick service valves to apply all the brakes and with uniform cylinder pressure there is not sufficient braking power developed in any one part of the train to cause the slack to run in or out severely On the other hand with the old brake, a heavy reduction is required to apply the brake at the rear of a long train the effect of which is to bunch the slack severely with consequent running out again as the brakes take hold at the rear and the draft springs recoil As shock is the complement of time and the place where the retarding force is developed it will be seen that shocks, due to brake applications will be greatly reduced with the new valve for while the time required to dissipate the energy of the mov ing train will be the same the distribution of the braking power will be different as it will be divided among all the vehicles in the train instead of first at one end and then at the other

3 Because more applications and release can be made in the same time with the new brake than with the old—much better control and safer operation of the long trains are obtained

4 On account of the uniform release feature and because a maximum or full service application of the brake is seldom required with the new brake, the re lease is more prompt and certain at the rear (which as has been shown is the vital place of a long train) and the number of stuck brakes' flat wheels, and shocks are greatly reduced particularly as no damage can be caused by the engineer opening the throttle before the brakes at the rear have released

5 The uniform recharge feature assists in this, in asmuch as the number of stuck brakes (resulting from a re-application due to over-charging after a re lease) is reduced and more equal response of all the brakes secured for subsequent application.

6 The quick service feature makes possible much shorter stops which is important at all times, but par ticularly where block signals are in use This makes unnecessary quick action applications of the brake ex cept in cases of actual danger

7 The uniform release feature in grade work to a large degree acts as an automatic retaining valve, which is one of the factors in the increased control

8 The uniformity of application and release tends to reduce the serious effects of the wide difference of braking power with loaded and empty cars in the same train

9 That vital factor in train control the personal equation is made more uniform, as less skill and judgment is required to get good results while lack of these cannot result in so much harm

10 As the air required to obtain the same control is only one-third of that required by the old brake, there is much less danger of the supply being inade quate and with brakes in a reasonably operative con dition there is more likelihood of the engineer stall ing or stopping than of "losing his air

11 Much shifting of lading and breaking-in-two now caused independent of the brake, by stopping and starting will be eliminated as slow downs instead of stops can be made

12 More tonnage can be handled and at higher and more uniform speeds, with safety than has heretofore been possible.

13 Accidents, due to broken wheels, will be fewer, as with the new valve each brake does nearer its share of the work; thus, the excessive heating due to hand brakes being used, or a few brakes doing the work, no longer takes place.

14 (*a*) The old valves are greatly helped by the new ones when mixed in a train (*b*) The new fea tures are simply additions to the old valves, the funda mental operative functions and principles remaining the same as in previous forms.

15 With the empty and load brake, greatly in creased tonnage can be handled with equal or even more safety, and for mixed empties and loads in the same train the elimination of damaging stresses due to inequality of braking power on empty and loaded cars. The characteristics of this equipment and its peculiar advantages merit a more extended descrip tion which will follow a little further on

In the case of the locomotive brake the new fea tures characteristic of the improved equipment were naturally in part due to the necessity for bringing the locomotive equipment up to an equal efficiency with the improved passenger and freight brake apparatus as just outlined

In addition, however certain desirable operative fea tures had long been recognized but remained imprac ticable until the establishment of a new basis for de sign afforded an opportunity for including in a com pact and mechanically satisfactory combination of parts all that previous experience had shown to be desirable in an efficient locomotive brake (see Fig 17) Briefly stated these are as follows

1 Either entirely independent or simultaneous operation of the train and locomotive brakes as may be desired thus permitting of much greater degree of convenience and flexibility in handling long trains es pecially on grades, in switching etc

2 Maintenance of brake-cylinder pressure whether partial or full application up to the capacity of the compressor thus insuring that the desired amount of braking power on the engine will be obtained and maintained irrespective of the leakage which is so difficult to prevent in the case of locomotive brake cylinders especially

3 Uniform brake-cylinder pressure in all brake cylinders on the locomotive irrespective of piston travel number of cylinders or leakage thus doing away with the necessity for different size or type of operating mechanism for different sizes of cylinders or types of locomotives as well as insuring against variations in braking power due to differences in pis ton travel, which must always be reckoned with on account of the brake-shoe wear or neglect in adjust ment.

4 Predetermined and desirable increase in emer gency brake-cylinder pressure over the maximum ob tainable in service thus securing for the locomotive brake equipment an advantage long recognized as fundamental for all car brake equipments

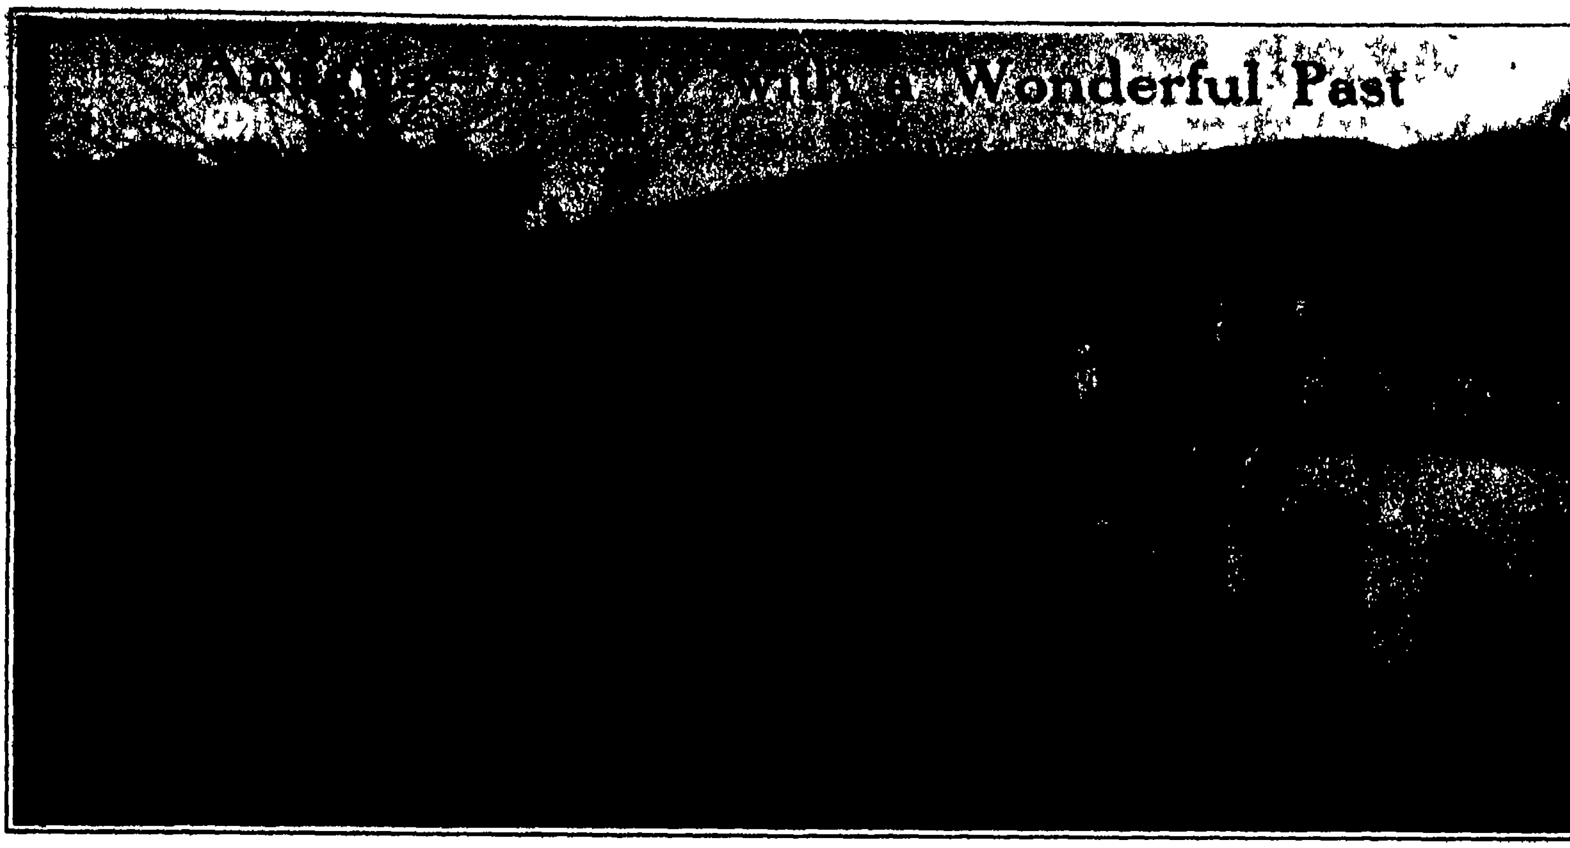
5 Automatic protection against loss of air required for braking due to brake-valve handle being left in lap position by mistake

6 Graduated release feature for the locomotive brakes which will then work in harmony with the new graduated release type of passenger car brake

That the above features are all in the direction of increased convenience economy and safety in the handling of both passenger and freight traffic, is self evident, but when it is further considered that these advantageous improvements have been incorporated in a combination of apparatus less complicated and with fewer number of parts than required by the old equip ment at its best and that the mechanical design and arrangement of parts has been greatly improved with respect to minimizing the wear due to ordinary service and in increased ease of maintenance and repairs it will be seen that the character and degree of the im provements which have been made are in accord with, and not antagonistic to the demands of modern rail road service for apparatus of the highest efficiency coupled with a maximum of economy and a minimum of complexity

(To be concluded)

A new instrument for measuring nocturnal terres trial radiation invented by the late Knut Angström is described by his son, A. K. Angström, Jr, in *Annalen der Physik*, under the name of "condensation-actinometer" Excepting an external cylinder of metal the instrument is made entirely of glass. It consists of a reservoir, exhausted of air, and contain ing ether, into which projects a glass chamber open above to the air and coated with lampblack. The blackened surface radiates heat more rapidly than the rest of the apparatus, and tends to lower the temperature within the reservoir, this cooling is, however, compensated by the condensation of ether, which distills over into a graduated glass tube. The total amount of radiation from the black surface dur ing a given interval is proportional to the amount of ether condensed Its value in thermal units may be obtained by the use of a constant, determined by com paring the instrument with other actinometers.



RUINS OF A CONVENT IN ANTIGUA THE CELLS OF THE NUNS

FOR many years after the signal conquest of the Aztecs by Cortez adventurous gentlemen at arms fired by his success and by the still more potent lure of tales of fabulous riches formed numerous expeditions to penetrate the fastnesses of the New World Pizarro lead his unscrupulous band to plunder the golden land of the Incas Olid conquered Honduras Ponce de Leon searched for the Spring of Eternal Youth Coronada journeyed toward the fabled Seven Cities of Cibola and De Soto endeavored to penetrate the southern wilds to the great Pacific while Cortez himself explored the country from Mexico to what is now Puerto Cortez Honduras but which he named Puerto Caballos from the number of horses lost in landing there

It was however left for Don Pedro Alvarado the most unscrupulous and dashing of his lieutenants to conquer the powerful nations of Quiches Cakchiquels and Mams who dwelt in what is now Guatemala or Quahtemala as the Indians then called it meaning Land covered with trees

About the year 1524 Alvarado led an expedition of one hundred and twenty horsemen one hundred and thirty cross bowmen and one hundred and seventy men-at-arms together with an auxiliary army of nineteen to twenty thousand natives against the allied Quiche forces under the command of Kicab Tenab the Quiche chieftain The often enacted tragedy took place through intrigue false promises ancient tribal animosities and superior armament the native forces were already doomed when the rival armies clashed upon the plains of Quetzaltenango (place of the quetzal the native bird of Guatemala at the present time)

Here under the warm tropical sun the battle waged throughout the day and many were the deeds of valor and desperation performed on both sides Confronted by wonderful weapons in the hands of strange beings mounted on their terrible horses the Indians fought long and well while ever in their front moved the glittering plumes and dripping spear of Tecum the valiant son of Kicab Tenab with his nagual or familiar spirit in the form of a quetzal hovering—according to legend—constantly over his head

Finally the two chieftains of the opposing forces met and all of Alvarado s skill availed him naught against the courage and the nagual of the Indian for as long as the quetzal lived Tecum could not be harmed. At last a Spaniard by the name of Arguete killed the nagual and tradition has it that Tecum then fell dead at Alvarado's feet and the native forces broke and fled The family of Arguete in Spain bears to this day the quetzal upon its coat of arms in memory of that distant encounter upon the plains of Quetzaltenango by which the Spaniard won a new empire and countless thousands lost their birthright, while the Cakchiquels and the Mams were in turn reduced through treachery and the sword

The fate of the Indians was then only too plain—harsh servitude for life under heartless masters They were branded with red hot irons and sold like cattle, one-fifth of the selling price going to the royal treasury of Spain. Alvarado even casually reports burning some Caciques with their towns as he thought In all probability it might have a whole some effect upon the ones left living the effect upon the others being tactfully ignored Stone was quarried and shaped bricks made and wood hewn by the Indians while thousands more of the erstwhile lords of the soil toiled upon the churches and palaces the houses and fortifications of the capital of the newly acquired province of Imperial Spain This with fatal choice Alvarado had located upon the lower slopes of the great volcano of Hunapu in the beautiful valley of the Almoconga high upon the central plateau Little was feared from this grim guardian of the town which reared its head over twelve thousand feet into the clear blue skies as it had long been quiescent and a great lake of water had formed in its crater while two other still higher peaks nearby frowned down upon the misdeeds of the conquerors

So the new capital grew in wealth and importance slumbering in fancied security in the shadow of the great volcanoes while Don Pedro Alvarado having worked long and ardently for the devil in the name of the Lord was made Adelantado Governor and Captain General of all Central America in the year 1530 and ruled in state from the newly founded city After various voyages to Peru Spain and in search of the Spice Islands he was finally killed in Mexico by a falling horse and doubtless laid to rest with all the pomp and ceremony due such a great lord of toiling thousands who slaved because nature had endowed them with a belief in the word of their fellow man a fair country and inferior weapons

Yet through it all the Indians well knew that Sicapua, the god who made the mountains and his brother Cabrakan who made them tremble were merely biding their time to crush the invader and avenge the wrongs of their children And so it came to pass that on a certain terrible night September 11th 1541 but one day after Alvarado s widow Beatriz de la Cueva had been named to serve in his stead the voice of the earthquake was heard throughout the land and mid the rending of the falling walls and the shrieks of the doomed sounded the wild rushing of the waters which poured in an avalanche through a great rent in Hunapu s cone upon the fated town sweeping all before it and leaving but a few solitary ruins where once had stood the glittering capital Many hundreds were killed among them the wife of Don Pedro Alvarado

All that is left to-day are a few sad remains consisting largely of the foundations of a spacious palace and a portion of the crumbling walls of what must have been the old cathedral The natives called the houses clustered about these monuments of the past Cuidad Veihe or the Old Town in contradistinction to Antigua or the second capital

Many traditions were connected by the Spaniards with this great catastrophe for men were then as fond of moralizing as they are now and were less satisfied with apparent reasons when supernatural ones could be applied The widow of Don Pedro Alvarado so runs the legend had given herself wholly up to mourning her noble lord whose amiable traits doubtless grew in direct proportion as the years elapsed. So overcome was she by his loss that she never stirred from the house but spent the long days shut out from the sunshine and the flowers in the darkest room of the palace the walls of which were even painted as black as the clothes she and her tirewomen wore No light nor color no bright blossoms were allowed to intrude upon her sorrow so consuming was it that she even lost that comfort and hope to which all are taught to cling when everything else has failed And so the earthquake came and the great lake burst its confinement to overwhelm the devoted town that by its waters might her sin be washed away and mankind warned for all time against permitting his personal sorrows to supplant the teachings of the church

Hence it transpired that the Spaniards moved their capital four miles distant away alike from the unhallowed spot and from the mountain which had been the agent of their doom that once again might this portion of the New World bear the yoke of Spain and yield to the old its golden flood Complete as had been the revenge of the native gods it was but short lived for the new city was built on a far grander scale than the first one by the unceasing toil of the Indians and once more the white walls glittered in the sunlight beneath the blue skies that overhung the great volcanoes The churches—high vaulted and thick walled sprang up by the score and the Inquisition in its darkest form appeared to wring in unspeakable tortures the lives from unknown thousands The natives, though supposed to be immune were frequently conveniently put out of the way by this means that alone has branded the early Spaniard as decidedly the spiritual inferior as he was undoubtedly the moral and in many material ways of the savages whom he conquered Alas that it should remain for civilized" man to slay by torture that others might be forced to sink to his level of religious degradation and that the frail hand of Isabella of Spain should have left to the world such a bloody legacy The conquerors were not only not contented to grind the vanquished under foot to force them to build their towns and work in the mines and fields to naively burn them alive in their dwellings and subject them to the tender mercies of the Inquisition but they further destroyed the wonderful Mayan manuscripts which contained priceless records of the past in much the same manner as the bigot priest Zumuragua in Mexico piled the Aztecan codices mountain high and applied the torch that thus might the works of the devil" be removed by one of his choicest disciples

Yet in spite of the darkness of its crimes of which only an incomplete record has come down to us the low roofed town in its surrounding of tropical verdure waxed rich and powerful its narrow streets were paved with stone and the sidewalks hardly broad enough for two abutted upon the walls of white buff and blue from which projected the iron barred windows to safely guard the dark-eyed senoritas who gazed upon the passing cavaliers Its plazas and avenidas glittered with life when the music sounded on the moonlit nights and the breeze that stirred the palms and ceibas was heavy with the fragrance of orange blossoms Eight great monasteries five convents and three beaterias housed those of the re-

RUINS OF THE CHURCH [illegible]

ANTIGUA—A CENTRAL AMERICAN CITY WITH A WONDERFUL PAST

ligious orders or whose affiliations were close to Mother Church Two extensive hospitals nursed and comforted the ill in body while three massive jails held securely in their cells and dungeons those whom it was deemed expedient to keep in captivity Yet above all it was Antigua's crowning glory that she boasted over a half a hundred churches within her borders whereby much good seed was scattered broad cast upon the virgin soil

Round about the city like the setting of a diamond clustered seventy picturesque villages each under the charge of a priest and to each of which was assigned the manufacture of some special article In one was found the excellently carved woodwork of which we see specimens to day and for which the native dis plays a singular aptitude in another pottery glazed polished rugose and polychrome while in others iron was fashioned bricks baked or basketry or clothing manufactured For in proud Antigua none of the trades were plied as it was essentially a govern mental religious and social center

Ere the first lights of early dawn had gilded Fuego's brow long lines of merchants could be seen wending their way from the surrounding towns to the great central plaza or open air market there to display their wares to the wakening city and long before sun set the same lines ant like crept toward their homes again

Shaded driveways led through the surrounding country to the fincas and the medicinal baths as even at the present time the valley of the Almocongo is noted for its thermal waters and the rich volcanic ash of its soil

Tribute from the Indians and gold and silver from the mines for many distant leagues poured into its coffers for the suzerainty of Antigua reached from the forests of Yucatan to the gold strewn shores of distant Darien and from the Pacific to the Atlantic Broad paved roads were built from the coast to the interior and many a hidalgo with an eye to the future as well as to the present brought paintings from Spain to grace the stately churches and convents of the proud mistress of all Central America Deep toned bells of bronze cast in the foundries of Toledo or Seville were shipped across the seas to the shores of the New World and then carried up the rivers on barges to later be transported through the forests and over the mountains to their final resting place in the graceful belfries of San Francisco San José and the many other churches that there they might call alike the chosen and the heathen to prayer and save the souls of erring man Yet one bell there was that never reached its destination for after safely passing the dangers of the sea it was lost in the murky waters of the Rio Chamelecon To this day the town near that point is called Campaña which in Spanish means Bell and on certain fiesta nights during the year it is said the solitary wanderer may sometimes hear it slowly ringing beneath the waters

In return for the works of the Old World Antigua sent the heavily ladened galleons with their precious freight to quench the ever quickening thirst of dis tant Spain and so the buccaneers with an equally ab sorbing thirst came that they too might plunder from the plunderer Then the impregnable castle of Amoa was built upon the coast to guard the wealth so in dustriously garnered and it is said that the King of Spain upon once being asked why he stared so in tently through his telescope across the western waters replied I look that I might see Amoa, for truly it has cost enough to make it visible even from here.'

Thus the years rolled by and royal governor suc ceeded royal governor and new eyes looked from behind the window bars where other eyes had peered before at other cavaliers for to all things animate and inanimate there comes a day that must—the end

Long had the gods of the Quiches slumbered and men had forgotten these many years that once they were Yet all this time they had stirred deep down in the heart of the other great volcanoes and sud denly on a never-to-be-forgotten July night in the year 1773 they burst forth again in a mass of flame and smoke upon the sleeping city Deep detonations shook the air and the rumbling of the earthquake once more resounded throughout the land as the out raged gods strode with heavy steps across the trembling earth Belching flames lit the crashing walls and scene of death—churches and palaces, the mansion of the rich and the hovel of the poor lay a crumbling mass Priest and soldier hidalgo and pauper alike were crushed beneath the fallen walls That which the setting sun had viewed the proud mistress of thousands the sunrise found prostrate—but a pile of pitiful ruins The gods of the Quiches once more had triumphed

Yet again among the Spaniards other causes were assigned It was said that there had been dissen tions between the native brothers and the ones from Spain Indeed so bitter had waxed the controversy that the civil authorities were appealed to with the result that certain ones of the Spanish brothers were publicly whipped Therefore it was only a question of hours said the wise before the earthquake came to chasten the wickedness of man Then too there had been scandals connected with the sisters at which men shook their heads—so fortunate indeed is it that professions do not make religion and that its true value is in no way lessened by the acts committed in its name or by those who seek its shelter

Still who can correctly assign a cause for the great ataclysm for did not Antigua gravely aver that a neighboring town had been destroyed because there was no bishop in the place at that time and yet when her own end drew nigh she had no lack of bishops and of priests?

And so it came to pass that the early Spanish capital had been destroyed when the two volcanoes poured forth water and fire and thus it was that the first was solemnly baptised Agu and the latter Fuego and taken with all formality into the church in the hopes that they would reform and eschew their heathen deities and evil ways To this day both Agua and Fuego have faithfully lived up to their re sponsibilities though Santa Maria a number of miles to the north in 1902 blew out her entire side and overwhelmed fincas and cities

Many of the poorer classes even after the second catastrophe clung to their ruined homes and wished to trust to the conversion of the great volcanoes and live where they were born but others there were who had less faith in the intentions of the new converts and others still who owned property upon the site of what is now the City of Guatemala for real estate was cherished in those days even as it is now There-fore it was deemed expedient for many sundry reasons to move the capital twenty-four miles distant to the valley of the Hermita where it now stands. The reluctant ones were dragged forth in spite of un-availing protests, and the remnants of their homes destroyed by the soldiery, that the new city might be-come great and powerful and perchance the values of certain properties be maintained.

So the city of Guatemala has grown at a safer dis-tance from the great peaks of Agua, Fuego and Acatenango completely surrounded by deep barrancas which it was hoped would deaden the earthquake shocks until it again stands without a peer in all Central America.

Of Antigua itself many interesting ruins remain, for though it is now a town of several thousand in-habitants it is essentially a city of the past. The new lives but in the old Everywhere above the lowly dwellings of to-day tower the ruined churches—vast, high arched and domed—with battered belfries in which the old bells still summon the worshippers to prayer in some improvised chapel in the ruins below The vast majority are however roofless and tenanted only by the flickering shadows of the present and the memories of the past Where once swelling anthems pealed and proud hidalgo knelt in prayer, wild flowers grow in tangled profusion and creeping tendrils cling Grass waves knee deep upon many a roof and cloistered courts re-echo but the flutter of beating wings. Far down where the Inquisition flourished the rat alone steals stealthily on its way or weird iguano creeps to light like some poor tor-tured soul The dismal cell of monk or nun stares out upon the world with fallen roof and gaping doors, a feed ng ground for the lowly hog

San Francisco, the greatest church of all contains behind triple bars in a little chapel within its walls the remains of the holy Betancourt, who in his day performed many miracles they will tell you and who it is believed will ere long be canonized Pilgrim-ages are made to this shrine from miles around the penitents going on foot to obtain the full benefit thereof Then it is that Antigua assumes the air of the present and is to be seen in her gayest garb, and that the shrine of Betancourt fairly bristles with small wax images of the man woman and child of the head arm or leg which it is hoped will be cured

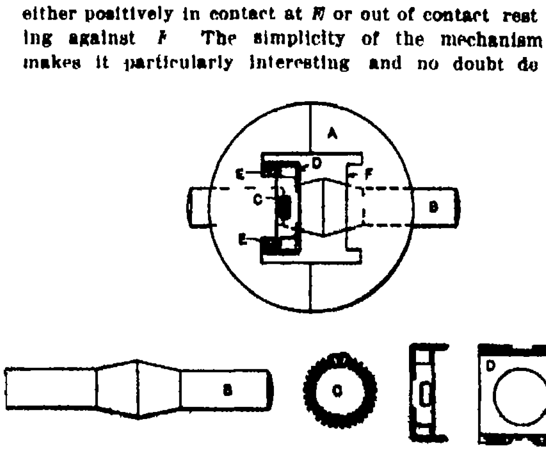
The Indians come from many distant villages for now they have adopted the God of the stranger though still the nagual lives for each and far down down in their hearts at times they feel the old gods stirring

The fiesta summons them to the moss grown walls built by their ancestors yet no longer are they slaves and no longer does the Spaniard rule throughout the land What must be their thoughts as they cluster around their fires during the fiesta nights who can tell? For after all the native gods in winning yet have lost

And thus must we leave Antigua as the silent tropic moon shines down upon the scene of her ancient splendor—upon the walls of her crumbing churches and palaces bathed in the ruddy glare of the flickering camp fires of her former bondsmen while through the dusk loom the sweeping outlines of Agua, Fuego and Acatenango—vast silent and inscrutable—wit-nesses alike of her glory and of her ruin

Ingenious Electric Switch Mechanism

THE accompanying line engraving shows an electric switch mechanism the interesting feature of which is the simplicity of its action In the top view the mechanism is shown assembled and below are shown the three main details the casing A not being shown here Disregarding the casing the switch mechanism consists practically of only three parts First a push bar B extending clear through the switch hav ing its larger diameter in the center and shaped conically from the center for some distance toward each end as clearly shown in the illustration second a coil spring C which encircles the bar previously mentioned in such a manner that the axis of the spring forms a circle around the bar third a moving contact piece D forming a casing over the spring When this contact piece is in the position shown in the upper view it is in contact and forms a circuit at E the contact pieces in the casing A being shown cross secti ned for the sake of clearness The action of the device is simply this When the bar is pushed forward the coil spring rides up on the conical sur face until it reaches the center of the bar all the time preventing the contact piece from releasing from con tact at E until the spring has reached the central and highest part of the bar At this moment it suddenly contracts and moves swiftly along the conical shape on the other side of the highest point of the bar car rying with it the moving contact piece D and releas ing it from its contact at F bringing it against the other side of the casing at F It is not possible to move the contact piece part way and let it slip back again drawing an arc which burns the contacts and eventually destroys them The contact piece must be either positively in contact at E or out of contact rest ing against F The simplicity of the mechanism makes it particularly interesting and no doubt de vices using the principle employed would be success ful in automatic machinery for positive and in stantaneous "knock outs" and stops of various de scriptions —*Machinery*



INGENIOUS ELECTRIC SWITCH MECHANISM

Interesting Plant Discoveries

AN agricultural explorer of the Department has spent the year exploring the plant resources of southwestern Asia. Among the large number of interesting things he has secured is a variety of alfalfa from Erivan which is said to be longer lived than the Turkestan a species of medicago from an altitude of over 4,000 feet whi h is already being utilized in the work of creating new hybrid alfalfa for the northwest a wild almond from the Zarafshan Valley found growing on the dry mountain sides at an altitude of 6 000 feet; a drought resistant cherry for home gardens in the northwest and a collection of apricots with sweet kernels from Samarkand the Afghanian apple and special varieties of pears for trial in the Gulf states; some remarkable olives which have withstood zero temperatures and still borne good crops of fruit; late and early varieties of Caucasian peaches for trial in the southwest seeds collected in the Caucasus from wild plants of the true Paradise apple which is used as a dwarf stock for the purpose of obtaining seedlings not infected with crown gall; scions of a newly pro-duced crab apple, reported to be a better keeper than American crab apples; the new abrikose, a variety of apricot with a skin as smooth as that of a nectarine; a remarkable drought-resistant poplar for the middle west and a wild strawberry, fruiting at the end of February on the dry calcareous cliffs of the Caucasus.

In view of the varying data published concerning the solubility of gold in nitric acid, F. P. Dewey has carried out experiments which show that gold is dis-solved to some extent when treated with the purest highly purified acid. The method employed to deter-mine the amount of gold in the strongest acid solu-tions is described.

Securing Efficiency in Railroad Work

Mr. Harrington Emerson on the Right Way to Do Things

The question of efficiency and economy in the management of industrial enterprises has of late been much discussed, both in the daily press and also in the more technical papers. One contribution to this subject, which commands immediate attention owing to its high character, its direct connection with work actually performed on a large scale, and, last but not least, the numerical examples, drawn from practice, with which it is illustrated is a paper recently read by Harrington Emerson the eminent expert, at the invitation of Harvard University Early in 1904 Mr Emerson was retained by the Santa Fé Railway to inaugurate and direct such reforms as might remedy an inordinate rise which had occurred in the running expenses of the railway during the years immediately preceding The state of affairs which prevailed is well brought out in the following table showing figures collected from the president s annual reports

	Cost per locomotive mile for repairs	Cost of repairs per locomotive	Number of locomotives	New locomotives secured	Cost of repairs per ton of locomotive weight
1897	$0 045				
1899	0 0558	$2 032	1 083		
1900	0 0592	2 096	1 136		
1901	0 082	2 858	1 174	52	
1902	0 0922	3 156	1 312	169	
1903	0 0867	3 042	1 309	130	$38 45
1904	0 1134	3 772	1 433	151	40 23
1905	0 1256	4 165	1 454	36	46 23
				538	

A diagnosis of the causes of this rise revealed a number of influences at work Briefly stated the problems which were confronting the company were of threefold character namely (1) Physical—to cope in prompt and adequate manner with the necessary repairs in shops which had become run down which were mostly antiquated and manned with mechanical employees, most of whom were not only at the time striking, but were very hostile to the company The enormous increase in business which was taking place at this time made it imperative to find means to make the best of the existing equipment as it was quite impossible to build and equip new shops in time to take care of the increased deterioration of the overloaded equipment (2) Financial—to check the alarming increase in expenses (3) Moral—to eliminate radically and permanently the strain and hostility between employee and employer

Before going on to point out more in detail some of the methods followed and results secured by Mr Emerson in the attack of these problems we will pause to consider some of the fundamental principles upon which his plan of campaign has been framed principles which for their convincing simplicity and extreme importance claim our most careful attention and supreme interest

One short sentence with which Mr Emerson heads one of the sections of his paper expresses the essence of the fundamental principle which lies at the bottom of his method This sentence reads "Separate operations are often connected in dependent sequence In exposition of the purport of this sentence we can do no better than quote Mr Emerson s own words He says in part as follows "Lifting a load is one operation carrying it is another If a path is so bad that a good man can only take half the load and walk only half as fast his carrying power is reduced to one-quarter through no fault of his own Thus fifty per cent efficiency as to load and fifty per cent efficiency as to speed results in twenty five per cent mile-pound efficiency If the man is in addition slow and lazy if under any conditions he moves at half speed and takes only half reasonable load, he will carry only a quarter as much and walk only a quarter as fast so that the end efficiency is only 6 25 per cent or only one-sixteenth of the standardised task. Grant a man efficiency of 90 per cent and a condition-efficiency of 80 per cent, hence a combined condition and operation efficiency of 72 per cent, and assuming operations averaging in two-fold dependent sequence and the end result will be 72 per cent of 72 per cent, equal to 51 84 per cent When an investigation shows an end efficiency of 50 per cent, it does not follow that the workers are as low as 90 per cent or that conditions are as low as 80 per cent, since dependent sequences may average three four even five or six or more Assume men at 100 per cent and conditions at 90 per cent in six fold sequence, and the end result is only 53 14 If all the operations in a shop average 95 per cent the shop as a whole may average anything from 95 per cent down It requires but a brief moment s reflection once this matter is brought home to us to realize with what avalanche power the losses due to even comparatively slight defects in the individual steps may rise in a process in which a large number of dependent sequences are involved And obviously processes of this kind in industrial and manufacturing work are the rule rather than the exception Furthermore the improvement which can at times be effected in the efficiency of one single step in the sequence is sometimes vastly greater than anything that has been considered in the figures quoted above For example the cutting power of steel upon steel has in the past been improved from eight pounds an hour to 1 600 pounds that is to say the efficiency has been raised from 0 5 to 100 per cent Dependent sequences are often as many as 50 in a series

Passing on now from this exposition of the fundamental principle underlying Mr Emerson s work we proceed to consider a few instances which show how and with what success the principle has been applied to some concrete cases

The first example which Mr Emerson cites as an apparently trivial and yet thoroughly characteristic step in the extensive reform which took effect at the Santa Fé Railway under his guidance relates to the cost of maintenance for belting in the shops of the company When Mr Emerson s work began it was found that this item being regarded as of altogether minor consequence was left in the care of no particular person with the result as will presently appear that the efficiency in this department was execrably low Remembering our fundamental principle we dare not despise any attentions paid to this detail or any other for belting is more important than it seems it is a link in a chain Every belt failure entails a dependent sequence of loss as the broken belt puts machine and man out of commission delays the work in progress holds locomotives in the shops prevents the moving of trains lessens revenue in an endless This is the house that Jack built series

For the year ending June 30th 1904 the cost of new belting had averaged $1 000 a month and belt failures had averaged 300 a month By careful attention to the quality of belts purchased and to the way in which the work of belt repairing was being handled these figures had been reduced by May 1905 to $163 a month and forty three belt failures respectively The above is merely one perhaps seemingly trivial example of the kind of progress that has been made in every department in which time has hitherto permitted the application of the economic principle illustrated A large number of figures might be quoted to show this, but we must be contented here to pick out a few of the most striking Probably the most extreme instance of the waste which may occur through neglect of the correct economy principles is the showing made under the heading Fuel This represents the largest item of expense on most railroads On the Santa Fé the fuel paid for amounted to an average of 250 pounds for every thousand tons weight of freight trains per mile Actually measured consumption on test runs of freight trains proved to be about 80 pounds instead of 250

According to the *Erie Railroad Magazine* for September 1910 the average amount of coal used per mile by its passenger locomotives is 108 pounds One division was selected for special supervision and its average was soon brought down to 79 5 pounds per mile One locomotive in this division was singled out for a six days test during which its coal consumption was reduced to 35 1 pounds per mile A switch locomotive is reported by Mr W C Hayes of the Erie Railroad in the case of which a fuel consumption of 2 088 pounds under common working conditions was in a test with increased work reduced to 720 pounds

The great contrast between some of the figures taken from common practice and those obtained when proper care has been taken is due to the ten links of dependent sequence between the coal mines and the ash pit The ten links are

Coal charged by the mine but not delivered to the car Coal shrinkage in transit Coal shrinkage in unloading Coal shrinkage in bunker Coal shrinkage in loading Coal wasted in roundhouse before locomotive takes train Coal lost through wasteful firing Coal lost in wasteful running Coal burned while waiting on side tracks Coal lost to ash dump especially when fire is pulled

Of one more department to which Mr Emerson gave special attention we can here speak only very briefly namely the one to which we have referred at the outset as one of the three phases of the problem at issue the moral phase Mr Emerson has shown most clearly that the best efforts are put forth by the men the healthiest feelings on their part toward their employers are bred under a system of properly regulated efficiency rewards Perhaps no better evidence can be brought forth of the spirit thus engendered than by quoting the words of Mr D F Barton foreman of the Topeka shops of the Santa Fé Railroad as he addressed the Railroad Foremen s Association The efficiency system is distinctly co-operative It changes the men from half hearted listless idle indifferent workmen to striving alert active intelligent honest self respecting workers who take an intense interest in the work at hand and are willing to do whatsoever their hand finds to do with all their might Numerically the character of the bonus system as well as its results is brought out with great clearness in the following table

	April 1902	April 1909
Passenger locomotives turned daily	6	7
Freight locomotives turned daily	18	13
Gross tons handled	77 742 800	152 430 860
Mechanics wages per hour	$0 375	$0 42
Average bonus per hour		$0 043
Pay roll	$16 813	$17 813
Bonus paid		$1 849
Number of men	260	223
Locomotive failures	57	11
Miles between failures (all)	4 377	
Miles between failures (passenger trains)		17 683
Miles between failures (freight trains)		29 995
Miles between failures (all)		47 678

The last three items alone in this table showing a total of 4 377 miles between failures in 1902 and 47 678 miles in 1909 after the reform had gone into effect are enough to impress the most skeptical with the enormous importance and value of such methods as are advocated and taught by Mr Emerson We may well pause to consider what such reforms would mean to the individual and to the State if introduced not in merely this or that branch of some single industry but to entire systems and to the whole industry of our country

A New Impact Testing Machine

In a recent number of *Engineering* Mr R. D MacLachlan describes a machine on the principle of a weight falling on a plate and applying an impact tensile load. With such machines it is desirable that the load should be applied directly, so that as little as possible of the energy of the falling weight is lost in the intermediate connections. In the machine described the plate which receives the blow is made very stiff and is screwed directly on to the specimen. Precautions are also taken to insure that the blow from the weight on the specimen is a fair one, [illegible] well as tension stress [illegible] The weight [illegible] is of cast iron, accurately turned to fit the central rod and it weighs 82 04 pounds It is raised by means of a windlass A small key on the tup runs in a key way on the central rod, to insure that there is no rotational motion of the weight when falling The energy absorbed in fracturing the specimen is measured in two ways (1) The velocity of the falling weight is measured (2) the kinetic energy of the weight after fracture is recorded The second method is not considered so satisfactory as that of measuring the change in velocity Preliminary tests are recorded A bar of mild 5/16 inch steel of commercial quality was selected Test pieces were screwed ⅜ inch and turned and accurately ground to ¼ inch diameter for the middle 2 inches The specimens were subjected to different heat treatments with the object of determining the effect of such treatment on the power of the material to resist shock In all cases the elongations due to impact testing are greater than those due to tension testing Increase of temperature during annealing appears to reduce the total extension under the static load and the impact load The effect of cooling the specimens in water is very marked the elongation in both static and impact tests being much reduced The preliminary tests showed that the measurement of the velocity on the drum of the chronograph was not satisfactory A stroboscopic method has been adopted which is a great improvement.

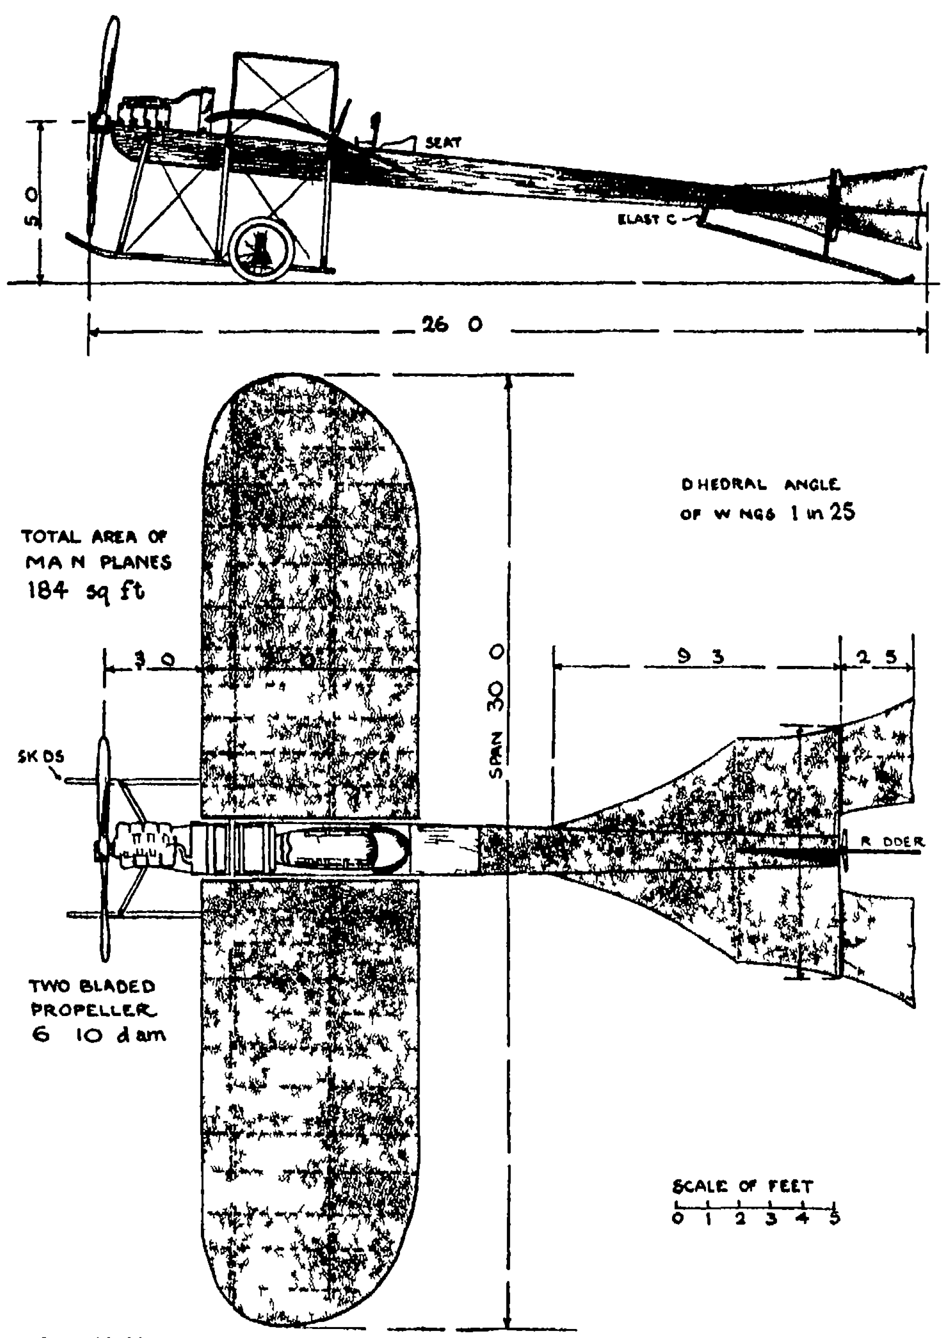
The Hanriot Monoplane

The Construction of a Remarkable French Flying Machine

Wherever it has been seen the Hanriot monoplane has invariably attracted attention and more often than not received favorable criticism of its shipshape appearance. And now that it is about to be brought to the fore in this country under the ægis of a powerful syndicate the interest that it has awakened in the capacity of a mere visitor at some of our flight meetings is likely to mature in a more practical form among those who have an ambition to fly. There are many points of distinct originality in the Hanriot design and construction but it is not always that these features in question are appreciated individually as such by those on whom their *tout ensemble* makes a good impression. First and foremost here is of course the wooden boat-shaped hull that naturally strikes everyone at first sight as the outstanding departure from orthodox practice but there is also the A type frame that supports this body upon the wheel and skid chassis and those who attended the previous Paris Aero Show will doubtless remember that a similar feature of construction characterized the Hanriot monoplane of last year. It was one of the most interesting constructional details that this exhibition brought to light. Simple in design and construction strong in principle it formed a clever solution to a problem that it has not been easy to turn into a really neat job that the method has been generally appreciated may be judged from the fact that several other makers of monoplanes subsequently adopted the essential features of this design.

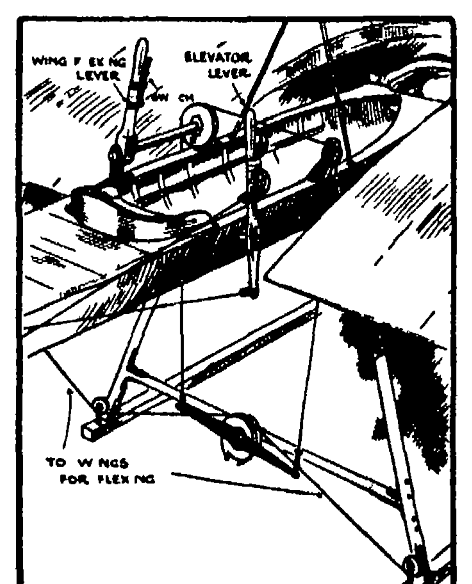
There is also a good deal to be said in favor of the boat body on the Hanriot monoplane and quite apart from any intrinsic merit that this system of construction may possess on its own account there is a distinct advantage in the system in that it dispenses with the use of a tremendous amount of wire that would otherwise be necessary for bracing some equivalent girder member. We have no objection to wire in principle and unquestionably it is a wonderfully strong and light method of building up a frame but on the modern aeroplane there is so much wire that any method of reducing the amount is welcome on this score alone. Wire bracing needs some little attention for it should at least be periodically inspected and if more wire is used than is absolutely necessary it seems to us that there is just the likelihood that it may provoke carelessness with regard to its proper maintenance. By the use of a boat body the Hanriot monoplane is clear of all wire for which a suitable substitute can be provided and those wires that do remain take on in consequence an added importance that should insure their proper attention. It may perhaps seem a little outside the zone of present day conditions to bring forward a criticism of this description but it must after all be remembered that manufacturers essentially hope to obtain a fairly wide sale for their machines and many aeroplanes are quite likely to pass into the hands of users who will not always realize the necessity of persistent attention to small mechanical points while their chief object is to get up into the air. The wider and the more rapid the development of aviation the more is this likely to be the case—as it has been for instance in connection with motor cars—so that in considering the construction of machines, it is necessary even now to take note of features such as these because of the influence that they may have on future design.

The boat body of the Hanriot monoplane is constructed on the lines of a racing skiff, and it is well known that this form of construction produces a very strong and very light girder. The top of the body is entirely decked in, except for a little cockpit containing the pilot's seat. Immediately behind the pilot's seat the deck is thickened so that it is safe for the pilot to stand thereon when mounting and dismounting. No wires of any description interfere with free access to this part of the machine. Three steel strips form a kind of cradle for the support of the body on the A type chassis frame the strips being bolted to the inclined struts of the frame and passing under the body as shown in one of the accompanying sketches. Steel strips are also employed for lashing the main spars of the wings to the body and it will be observed in the same sketch how these spars are mounted on blocks and lashed in place as described. The spars are not horizontal but are set at an angle to one another the dihedral being 7 inches that is to say the extremities of the wings rise 7 inches above the shoulders. The spars in question are 3 inches deep and 1¼ inches wide and they are constructed on the three-ply principle instead of being cut from one piece of wood. This is a departure from common practice that we have not noticed elsewhere, and in view of the criticism that has been levelled against the supposed tendency of monoplane wing spars to buckle this method of construction will doubtless arouse interest. The laminæ of the spars are arranged vertically but again bearing in mind the matter just referred to it is conceivable that some use might be made of this principle with horizontal laminæ to strengthen the spars against the forward pressure. It is the end thrust on a machine that is the difficult force to meet. The vertical forces can be more readily provided for because the presence of the propeller in no way interferes with any system of bracing that may be preferred. In the Hanriot monoplane it is worthy of note that the rear spars of the main wings are individually trussed by a diamond bracing each spar being fitted with a vertical cross strut in the center and the four extremities being tied by diagonal wires. The rear spars are hinged to the frame so that they can rock for wing warping and the hinge pins are tied together by a steel tube so as to relieve the body of undue strain.



From *Flight*

THE HANRIOT MONOPLANE 1910



From *Flight*

DIAGRAMMATIC SKETCH ILLUSTRATING THE SYSTEM OF HAND CONTROL ON THE HANRIOT MONOPLANE

A pivoted foot bar not shown operates the rudder

The control of the Hanriot monoplane is mainly interesting on account of the use of two levers one under the control of the pilot's left hand and the other under the control of his right hand. That on the left moves sideways and operates the wing warping that on the right moves to and fro and controls the elevator that forms a hinged extension of the tail plane. In front of the pilot's seat is a pivoted cross bar that can be rocked by the pressure of his feet. This controls the rudder which is mounted between the halves of the elevator. The fixed tail plane on the Hanriot monoplane is quite flat, and consists of a sheet of fabric tightly stretched by the aid of a couple of transverse spars. The rear portion of the tail plane is deflected a little below the line of the leading portion, to which it has a relative, although small, angle of inclination.

Well forward of the main planes is the engine, which on this machine is an [illegible] E.N.V. This is mounted in the bows of the boat body and is also partly supported by the struts of the A

these, a pair of which are situated immediately beneath the motor. The tractor-screw which is direct driven by the engine, is 2 1 meters in diameter and 1.3 meters in pitch. When at rest on the ground, the machine is carried by a pair of pneumatic tired wheels in front and by a light trailing-skid behind. The wheels are mounted on a steel axle that is reinforced by a wood batten and mounted in vertical guides so that it has a considerable upward travel. Suspension is effected by elastic springs anchored to the main skids and attached to the upper end of a column that rests upon the axle itself.

Working Distances of Wireless Stations

Methods by Which Efficiency is Obtained

By W. C. Getz

In looking through the technical inquiry portions of this and contemporary magazines the reader will find invariably that fully 75 per cent of the questions asked about wireless telegraph are of the "How far will it work" type. At first glance this may seem a logical question to the uninitiated, but upon a moment's reflection the utter worthlessness of any stereotyped or

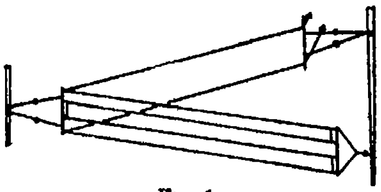


Fig. 1

cut and dried data based on such insufficient information as the height of the aerial or capacity of the spark coil, without a detailed knowledge of the operating conditions and environment, is easily apparent.

While heretofore the editor has probably answered these questions basing his deductions upon performances of similar apparatus that has come under his observation during his greater or less experience in the wireless field, it is now time to bring to the attention of the experimenters, and particularly to the young amateur who has an extremely limited knowledge of electricity and who is therefore more greatly imposed upon by irresponsible firms, the futility of such inquiries and subsequent answers.

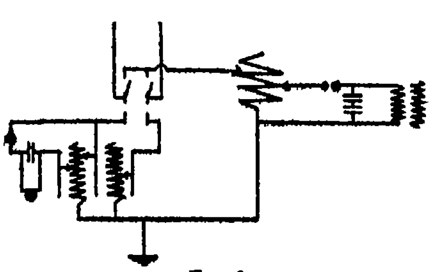

Fig. 2

Such questions as these, while asked in good faith, cannot be answered any easier than a hypothetical question recently asked the editor of a photographic journal—the party writing wishing to know if the editor considered a man weighing 180 pounds and owning a dress suit competent to lecture on "Color Photography," without the editor ever knowing any more about the man than was stated in the inquiry. Individual conditions alter all cases, and it is the purpose of this article to show the great many conditions that enter into the subject of wireless telegraphy, and which, unless carefully studied and complied with, may greatly alter the results from what was expected.

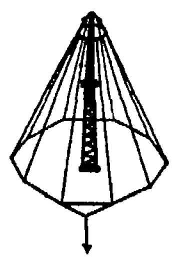

Fig. 3

The efficiency of a wireless station depends on the following general points:

1. System or "hook-up" used.
2. Locality of station.
3. Height of aerial.
4. Capacity of aerial.
5. Sensitiveness of apparatus.
6. Intelligence and care used in connecting and adjusting the necessary apparatus.

Each and every one of these points will cause a difference in the working distance of a station, and as it is hardly possible that there are two stations exactly alike in all of the above points, it is therefore manifest that no formula or rule can be derived that will cover the effective range of any and every station.

A brief discussion of some of the above points may serve to enlighten the experimenter on certain details which may be the cause of some inefficiency of the particular station in which he is interested.

The system or wiring diagram used causes more controversies than any other of the above points enumerated. Fundamentally every wireless circuit contains a variable or constant inductance and a variable or constant capacity. Various combinations of these have been evolved into different systems, each so-called "system" having its stanch adherents who set forth claims of unexcelled superiority in "selectiveness," "long distance," etc., that may be really due to a fortunate combination with the local conditions in any particular case. It is well known to the majority of experimenters that certain "hook-ups" seem to work better at one station than at another, and as no rule can be assigned to cover this, the experimenter getting the best results is usually the one who is not content with one diagram until he has thoroughly tried out

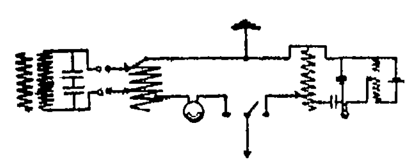

Fig. 4

all. Such diagrams have been issued both in book and blue print form for the past year and a half, and the amateur who neglects obtaining the best and most recent copies of these diagrams is usually the one who never has "results" with any apparatus.

In considering the second point—the locality of the station and its effect on the working distance, we must depend upon the experience of others and base our assumptions accordingly. On water it is conceded that wireless can be worked over twice the distance for a given equipment than can be done over land. While nearby mountains do not cut out the waves as was first assumed, it often happens that in mountainous regions a good ground is hard to obtain. And again ore-bearing mountains if near at hand in some instances have noticeably reduced the efficiency of a wireless set, especially where the ore is of a magnetic nature.

Fig. 5

Water itself does not always form such a good ground, as the resistance of clear water containing mineral or vegetable residue is very high. The best ground is a copper plate or wire netting placed in loam that is permanently moist. A ground plate buried in clay is usually inefficient, and sand unless wet has a very high resistance. A station in the woods will lose much of its transmitting energy if the aerial is near any trees. For this reason when it is necessary to guy the antenna to trees, strain insulators should be cut into the guy wire at equidistant intervals to reduce this leakage factor.

Where static is prevalent the receiving efficiency is somewhat decreased at times owing to the inability of the operator to read through static. By shunting a variable condenser around the detector this annoyance may be greatly reduced, but at the expense of receiv-

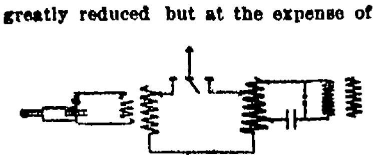

Fig. 6

ing radius. The proximity of power wires sometimes causes electro-magnetic induction in the receiving set. The use of the "loop" form of aerial greatly eliminates this trouble.

The height and form of aerial also varies the distance of operation. There is no rule governing the relation between the aerial height and the effective radius of communication, although Marconi at one time stated the distance was proportional to the square of the height of the antenna for a given set. This of course does not hold good with the present

Fig. 7

type of wireless apparatus, as the instruments now on the market have many times been successfully used over distances one hundred times greater than the aerial height squared.

The main consideration is to have the aerial perfectly insulated. The number and size of the wires used in the antenna depend entirely upon the capacity of the station. When a brush discharge is observed from the aerial, it is generally a safe sign that more aerial wire is required.

The form of aerial, whether straight, cage, flat top, loop, umbrella, etc., can only be determined after a thorough trial is made of each and the results classified, so that the one giving the best results for the individual and particular station is ascertained. The capacity of the aerial varies according to the different forms and dimensions used.

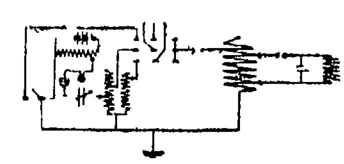

Fig. 8

The relative sensitiveness of the instruments used is a subject that the writer would like to omit, as there is bound to be a difference of opinion on the same, and this is intensified by the fact that every manufacturer differs radically in certain designs and each has an abundance of testimonials to show that his is the only right and efficient way. However, the writer has tried to take a view of strict impartiality, and trusts that if he unknowingly wrongs any one they will write and inform him of the case. As there are now several score concerns making and selling wireless apparatus, and thousands of amateurs are also making their own instruments, certain well known and standard types will be discussed, and the experimenter may govern his conclusions in proportion to which his instruments approach these standards in efficiency.

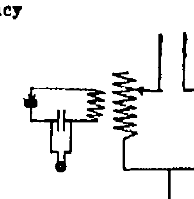

Fig. 9

It is not to be supposed that an instrument costing but a few cents will give as good results as a well made and reasonably but higher priced instrument. For instance, the so-called silicon crystals sold to experimenters by some wireless concerns will not give 50 per cent of the efficiency of the improved silicon detector which is designed and tested for sensitive work. The crystals in the latter are selected from specially imported silicon, and many lumps are rejected before a sufficiently sensitive piece is found. In a like manner the efficiency of any other instrument depends upon the sensitiveness of the individual instrument itself more so by far than on the type of instrument.

On the receiving side the detector is the vital part of the set, without which it is impossible to operate

In the order of their sensitiveness the following types of *standard* detectors have been classified

Class A Electrolytic (silver plate wire 0 0001 inch / 0 00002 inch) perikon

Class B Silicon (improved) pyron Ferron.

Class C Molybdenite

Class D Carborundum Magnetic Electrolytic (silver plate wire 0 001 inch / 0 0001 inch)

Class F Carbon and st el Al iminium and steel Coherers etc

The Perikon detect r is the r st extensively used type for sensitive w rk as it may be easier adjusted and kept in adj stm nt than any other used in practi cal work

The telep h n rec ivers should be of high resistance with a maximum amount of ampere turns per ohm re sistance In this respect enamelled wire is far su perior to silk insulated wire and a number of pro gressive firms are following in the track of the writer who had used enamelled wire for receiver windings for the past several years Low resistance receivers are of no use whatever for sensitive work

The tuner may be of the inductive type or of the familiar auto-transformer or single winding type The latter may have one two or three sliding contacts It has been the writer s experience that excellent re sults were always obtained with th double sliding contact tuner The use of a third sliding contact is now being advocated by certain manufacturers who claim better selectivity with the same The inductive type of tuner is considered to be the most sensitive

Apropos of the discussion now being waged among the several manufacturers regarding the use of enamelled wire on tuners, the writer has used a num ber of tuners wound either with bare, enameled, or cotton insulated wire, and he could not notice any marked difference in the respective efficiencies.

Condensers should have about from 0 001 to 0 005 M F capacity The potentiometers should be at least 300 ohms resistance when two or more cells of bat tery are used

On the transmitting set the relative efficiency of the induction coil or open core transformer and the closed core transformer seems to depend upon the re liability of the builder Both work well when properly and intelligently used Where only direct current is available it is not advisable to use the Wehnelt in terrupter as it gives very poor results on wireless work By no means use it on alternating current, as the best results are obtained when the primary is connected direct to the A C mains, suitable resistance or impedance being inserted in series if necessary

The sending inductance, spark gap and transmit ting condenser can be of any make that uses the gen eral proportions of the standard types. The wire of the sending inductance should not be on less than a three-inch radius and should be No 14 B & S gage wire or larger The spark gaps should have elec trodes of zinc or of some other approved alloy con taining a sufficient amount of zinc to produce the char acteristics that accompany the use of the zinc gap

The current supply for the transmitting side should always be sufficient for the maximum amperage re quired by the transformer or coil when operating in order that the spark may be maintained smooth and regular

The [illegible] and [illegible] of the [illegible] [illegible] really in the [illegible] to accomplish. It [illegible] that he should try [illegible] changes of his [illegible] and capacity and [illegible] the readings of his hot wire meter in the aerial leads with the distinctness in which surrounding stations are able to receive him. If this is done in a system atic manner, each receiving station making a record of the clearness, and condition of spark, etc, thus be ing noted, the actual tuning may be easily and ac curately accomplished.

A small power station tuned properly will probably work four or more times as far as one of double its power but not in tune. The main consideration is to know what you want to try, and then to try it in the simplest and most systematic way possible. The per sonal element of good judgment and care in making the connections good is more responsible for some of the record results accomplished by certain experi menters than the type of apparatus employed.

The following information has been prepared for the use of the experimenter who wishes data on some stations that may have conditions somewhat similar to his particular station and while this is only com piled from the operation of certain particular stations, the facts may be of use in 'doping' out the probable results of apparatus that is to be installed The ex perimenter is again cautioned that his results may differ widely from those given herein and that the only way to get the best results is to experiment with as many hook ups and instruments as you can, until the happy medium is obtained—*Electrician and Mechanic*

Our Soda Lakes

Freaks of nature aside from their importance to the scientific world and as curiosities for the vast army of sightseers to gaze upon sometimes afford humanity a source of supply for many of the neces sities of life The latter is true of the Soda Lakes of Nevada or as they are locally called the Ragtown Ponds The waters of these lakes are strongly alka line and as their name would imply contain large quantities of soda

It should be mentioned that there are but two of the lakes The larger covers an area of 270 acres its greatest dimensions being about a half mile wide by three-quarters of a mile long while the other is con siderably smaller

Aside from the make up of their waters the right to class these lakes with the freaks of nature is based also upon the fact that there are no visible streams tributary to or draining them their entire water sup ply except the small amount derived from direct pre cipitation being supplied from subterranean sources A study of their formation and water supply has been a theme for scientists during the past half century Some claim that the Carson River is the source of supply The bed of this river at its nearest point which is some two miles distant is fifty feet above the surface of the lakes These bodies of water them selves occupy two circular depressions in the earth which geologists claim to be craters of extinct vol canoes and it is said that the water from the river reaches these craters by percolating through the in tervening earth the mineral matter contained therein being unquestionably derived from the deposits of its subterranean passage.

These phenomena lie but a short distance off the old cross-continental trail used by the forty niners in their mad rush to the gold fields of California, and are situated right in the heart of the Carson Desert. The nearest town to these lakes is Leetville but in the days gone by it was known as Ragtown

Nestling in the banks of these strange lakes in deed within a few feet of their very edges are to be found springs sending forth continually streams of the purest cold water free from any taint of soda or alkali Had the early pioneers known that such an elixir of life flowed in that deathlike place how many lives might have been saved

The rim of the greater lake rises eighty feet above the level of the desert but so gradual is the slope that one approaching is not aware of the existence of such a body of water until the very brink is reached Standing on the rim for it can hardly be referred to as a bank one gazes down at the glass surface of the salty water one hundred and sixty five feet below In early days these lakes were believed by many to be bottomless no doubt a belief that still exists among a certain class Of course every body of water must have a bottom and careful measurements have shown the greatest depth of these bodies to be in the neigh borhood of a hundred and fifty feet.

The manufacture of soda from the waters of these lakes was begun a good many years ago, and is car ried on by the simple process of evaporation It is estimated that the two bodies contain more than a million tons of soda—enough to supply the whole world for a good many years to come. Time was when ocean plants supplied the raw material for soda, and it was the French Revolution which effected the first great revolution in the making of that necessary article of every-day use When France was isolated from the world her eminent scientists were called on to save the country from a threatened soda famine and as a result Leblanc invented his process for the manufacture of soda from coal, lime, salt and sulphuric acid

The Asiatic Brick

We should hardly expect to learn much of the arts of civilized life from the tribes of Central Asia, yet, it seems, they make better brick than we turn out. The barbarians employ the same material that we do, and curiously enough the thing that imparts superi ority to their process of brick making is one of the most powerful agents of western civilization—steam.

When the Asiatics have baked their bricks for three days, the opening of the oven is closed with felt which is kept wet, so that the bricks still intensely heated are enveloped in steam.

The process causes a remarkable change in the character of the bricks. From red they turn gray, and at the same time acquire a remarkable degree of toughness and hardness. Although porous, they give out a sound, when struck, like that of clink stone, and they are said to resist the effects of weather much better than do the bricks of Western make.

Necessity was the mother of invention in this case, for the climate in which these ingenious Mongols live is subject to great extremes of temperature, hav ing a disastrous effect upon bricks made by the or dinary process.

Our Typhoid Streams

A Problem of National Importance

By H de Parsons, M E

The pollution of our streams by sewage and trade wastes has become a national issue As the population increases, especially the congestion in our cities, the subject is one of vital interest to the well being and public health of our States Changes produced by settlements have created new conditions Some of these new conditions it is neither possible nor desirable to check, but there is no good reason why one community should misuse a stream to the detriment of another The economic rank of a country is based on its natural resources Of these resources her rivers and waterways are foremost Where can a rich and prosperous country be found which is not well watered? Sewage has to be taken away from the places of generation Its manurial value has not been equal to the cost of securing it Therefore, municipalities construct sewers so as to dispose of the sewage by water carriage with the object of putting it out of sight as quickly as possible As a natural sequence, sewers are built to operate by gravity and to discharge into the nearest convenient stream or body of water so that the sewage may be diluted and carried away with the currents without further attention The result is that some of our rivers are not now sufficient to provide proper dilution, and towns are drinking their own or others sewage

Philadelphia drank its own sewage before it began to filter the water supply from the Delaware River and dearly paid the penalty in a high typhoid death rate. The supplies of many private water companies are polluted and towns are refusing to accept the polluted water offered

The author examined a water shed in New York State where the drainage from a village emptied into the reservoir supplying potable water to adjacent towns Again, in Illinois the water supply for a city was taken from some small brooks and rivulets into which all the adjacent farms with their out buildings emptied their liquid wastes In this case the only effort at purification was a slight aeration of the water by being sprayed over an artificial dam in the reservoir Again in Wisconsin a city was without a municipal water supply and each house had a well in its back yard. These houses drained their sewage into open cess pools located in the same yards

Albany filters its water but even so its typhoid death rate is above the average of cities located amid clean surroundings and its sewage is passed down to other places below on the Hudson

The Ohio River is said by the Sanitary Commission of Ohio to be polluted and unfit to drink and yet it is the only source of supply for the territory lying along its banks in that State Cincinnati drinks Ohio River water and discharges its sewage into the same stream for the use of others on the water shed below The Ohio flows down past Kentucky Covington and other places in this State drink Ohio River water

The government is constructing dams in aid of navigation and in many instances these dams are located without reference to backing up sewage polluted waters into the intakes of water-supply systems

The sewage discharged from one district flows to the next district below on a stream and the process of getting rid of the sewage by dilution is not always safe nor final Sickness caused by germ life in the sewage may readily be brought back to the upper district by intercommunication of the people

It is a mistaken idea that a polluted stream will purify itself If the current is rapid the process of purification will be more energetic than when the current is sluggish But even rapidity of current is not to be relied upon as a safeguard The Niagara River is certainly rapid enough but still the town of Niagara Falls has more than its proper allowance of typhoid The distance between the point of discharge of sewage and the point where the germs are taken up is not so important as the *time* of transit. If the current be swift, the distance that the germs will travel may be very great, as some disease germs have been proven to have comparatively long lives. The pollution of streams by sewage is an active agent in the extinction of human life, and drains the wealth of a community as successfully as the sewers do the houses.

The question of pollution has become a national one, since many of our most valuable streams are interstate in their flow. A village, town, or city, when so situated as to receive the pollution created in another State, is nearly helpless to aid itself Some hold the opinion that the method of disposal of sewage is a local question to be settled by each community This opinion is not well founded Pathogenic micro-organisms are not local People are not localized but travel back and forth Contagious and infectious diseases are not local Disease caused by sewage discharged from one community may break out in another community and be brought back to the first community

Although the pollution of streams is not a local question the laws regulating sewage disposal should not be to drastic They should encourage rather than force communities to prevent pollution and should

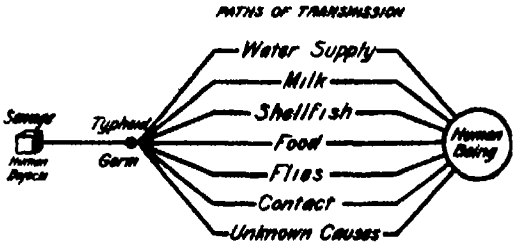

Fig 1—Paths Along Which Disease Germs May Travel From Sewage to Human Beings

be carefully drawn to fit all kinds of local conditions and be made to keep pace with the advances of sanitary engineering A mode of disposal which is suitable for one place may be quite useless in another We should not wait for an epidemic to learn our lesson We need a special authority in health matters and universal co-operation freed from all bureaucratic methods and amenable to scientific advance

Sanitarians have much to learn Our knowledge about disease organisms is still very limited and in view of our ignorance it is certainly unwise to discharge crude sewage into many of our streams Engineers should not erect structures the strength of which they cannot calculate Then why should they plan sewers to discharge into streams which may produce effects they cannot estimate?

The sewers of our cities are the place for every kind of germ harmless as well as pathogenic The sewers discharge them into the streams At first the bacteria diminish rapidly in numbers and then the numbers diminish slowly In the diminished numbers we do not find safety It is the weaker bacteria which perish first the stronger ones live longest Hard particles of sewage break up and liquefy slowly These hard particles may carry bacteria in large numbers for a long time It is a case of the survival of the fittest and of those best protected by coatings of sewage origin The typhoid bacillus as well as other dangerous micro-organisms pass the sewers to our streams. The most virulent survive

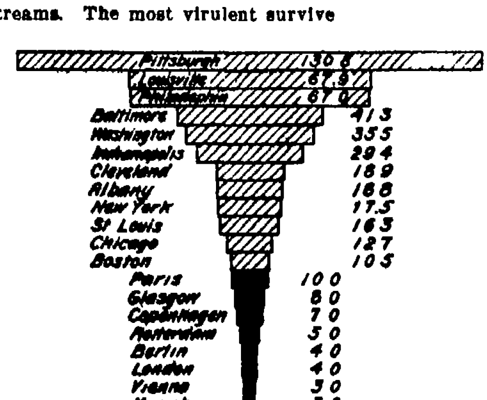

Fig 2—Typhoid Death Rates per 100 000 Population

Bacteria occupy a position in the economy of nature as the lowest known order of life in the vegetable kingdom

The real danger from pollution of streams is the scattering of germs The sources of infection are water supply, milk, shell fish food flies, contact and unknown causes Of these seven paths along which the disease germs may travel from sewage to the human being (see Fig 1) only one is guarded by filtering a water supply The other six are left open It is, therefore reasonable to state that conditions should be maintained at the sewer outfalls which are inimical to germ life, so as to reduce their numbers to a minimum This would place a barrier across every path of transmission.

When disagreeable things occur which are appreciable or apparent our æsthetic feelings are shocked But when similarly disagreeable things are not appreciable or not apparent they often pass unnoticed Thus people will go to theaters and into crowded halls and breathe over and over the same air which others have emitted They make little objection because they cannot see the particles of hair skin bacteria, and other things they breathe It is the same with pollution by sewage They throw it out of sight as quickly and as cheaply as possible without any attempt at purification and they often eat and drink it again unseen Yet these same people are so cleanly in their habits that they would refuse to wear the unwashed underclothes even of a friend to say nothing about wearing those belonging to some person ill with a disease It seems perfectly reasonable therefore that we should guard the discharges from our sewers and protect our streams so that there would be the least risk of causing sickness from drinking or eating our own or others pollution

Typhoid fever is a germ disease The bacilli may come from milk food flies or contact as well as by water The infection is traceable to sewage and the sewage is scattered on water borne in the streams It is a closed cycle disease germs in sewage—sewage in water—disease germs in man It makes little difference how many intermediate stages or steps there may be the result from first to last is the same The autumn months are often called the typhoid season although typhoid as a disease is independent of the divisions of the year Typhoid is a country disease During the later part of the summer the streams are low following the dry season and the sewage is not properly diluted and is often washed up on the banks and deposited in the shallow pools People returning to the cities after their vacations bring back with them the typhoid germs and through lack of careful nursing and neglect of ordinary precautions communicate the disease to others

As a rule the sanitary conditions existing in European summer resorts are much better regulated by the authorities than in America Tent colonies and segregations of little bungalows and cheap shacks so common in the vicinity of American cities during the summer are frequently fine breeding places for typhoid and intestinal diseases A comparison between the typhoid death rates in American and in European cities in countries where pollution is restricted is remarkable and greatly to our discredit. It does not appear that we are a dirtier people than Europeans The difference in the typhoid rates therefore is due to our careless handling of sewage Some present typhoid death rates are shown in Fig 2 and the numbers are the deaths per 100 000 population In England there is a Royal (temporary) Commission on Sewage Disposal which acts as an investigating body and as a central authority which can assist all local boards The whole subject has been closely studied since 1858 and a number of royal commissions have been appointed to aid the country Prior to this date the rivers were grossly polluted and many local nuisances had arisen Out of the Public Health Act of 1872 joint committees or boards were formed from authorities bordering on specific rivers These river boards regulate the pollution allowable in their respective rivers and there exists a certain amount of co-operation between them The work so done has been of untold value to England and the knowledge and experience collected of the greatest assistance to the world Thus for over half a century England has had some form of universal system

In Germany similar ideas are being urged and put into practical operation Each important water shed is guarded by its sanitary authority Generally speaking German rivers are larger than English rivers and this has been an advantage as it has delayed the condition of gross pollution On the other hand German rivers flow through several States and since 1899 there has existed an Imperial Council of Health which acts like a central body to which the States can appeal This may be considered as a preliminary step toward the formation of Imperial River Authorities

In France systematic control of the pollution of the rivers is less advanced than in England or Germany

In America there is no universal restriction of any general value in regard to sewage disposal Our streams are now so polluted that it is practically necessary to use only purified water in our cities But even in our cities where the water is filtered or

otherwise purified the death rate is still higher than the rates in European cities Filtering a water supply only closes one path for the typhoid bacillus to pass from sewage to man It does not protect the suburban or country districts which use unfiltered water

There are many cases of mild typhoid which do not incapacitate the patient for work Any one of these walking cases may give typhoid to another who is in a receptive state Also many typhoid convalescents are allowed their freedom who are still competent to communicate the disease As a result there can always be found residual cases of typhoid which can only be traced to unclean habits The pollution of our streams is largely responsible

As so many of our rivers and drainage areas are interstate it is necessary to have some national authority States cannot sufficiently deal with the questions of pollution as there exists in them such a diversity in laws and regulations Co-operation is wanted among the States and this can best be secured by having the assistance of the federal government that there may be less ignorance and uncertainty as to the mutual obligations of the States Let the government be the central authority through a properly organized bureau Let each State attend to its own work under the standard set by the government In this way the government bureau becomes the authority to which appeals can be made by the States and through which misunderstandings between States can be settled A national association for preventing the pollution of rivers and waterways has been organized by a number of citizens of different States all of whom are interested in sanitary science These gentlemen are carrying on the work for the public good at their own expense with the object of conserving the nation's greatest asset namely pure water It is their object to have the federal government make a study of the question with the hope that the laws of the different States may be made more uniform and that the States may be made to cooperate more closely than they do at present so as to preserve the public health There is surely truth in the saying that He who cures a disease may be the skillfulest but he that prevents it is the safest physician —*Stevens Indicator*

Electrical Notes

An Important German Electric Road —The Dessau Bitterfeld electric section of standard gage railroad is one of the most important in Germany After equipping the section it now remains to adopt the best types of electric locomotive and several firms have built locomotives for this purpose The first ones to be tested are of the Siemens Shuckert make and are designed for express trains running at 60 miles an hour The first trials of these locomotives were made not long since in the presence of an official commission including government delegates and engineers and they expressed themselves as very well satisfied with the results The present locomotives will draw trains up to 380 tons weight.

The Electromagnetic gun Idea —The thought that the giant power of a great electromagnet might be utilized to shoot a heavy projectile from a gun has occurred to many inventors Some years ago Birkeland whose apparatus for extracting nitrogen from the air is now in successful operation throughout the world calculated the power that would be needed for such a cannon and later an officer of the Austrian army made independent calculations with similar results It appears that to throw a projectile of about 90 pounds weight at a velocity of 500 meters a second a current energy of 54 300 kilowatts at 181 volts would be required But the energy is needed only for a fraction of a second Birkeland proposed to obtain it by shooting a powerful electromagnet through a set of coils by means of an explosion, but Spacil the Austrian officer has ventured the opinion that the best way would be to move large coils at a very high speed in a rectilinear direction Not much faith however is placed upon the practicability of such a gun

A Mercury tungsten Arc Lamp —Messrs Urbain and Feige of Paris are experimenting with a new form of arc lamp which uses an arc between mercury and tungsten The arc is made in a vacuum or in an inert gas inside a suitable bulb It was already known that a mercury vapor lamp could be made by using mercury with an iron electrode opposite it so that the vapor produces the light and the iron remains cold An arc is not formed in this case When we wish to make such a lamp burn as an arc lamp the iron is brought very near the mercury about one-eighth of an inch but as the iron melts by the heat of the arc this method cannot be used The authors find that tungsten will stand the heat of the arc so that a lamp can be made on this principle The tungsten glows highly by the heat and gives a strong light, but it does not appear to be consumed so that the lamp has a long life What is of interest is that such a tungsten lamp is very economical At present their experimental lamp works on 12 volts, but it is probable that the voltage can be raised so as to bring it nearer what the usual lamps take by using an inert gas under a higher pressure than is now employed The new lamp gives a very white light.

Science Notes

A New Variety of Rubber in Borneo —A new source of rubber is found in Borneo, according to a paper read on the subject before the Académie des Sciences by Prof Dybowski It comes from the milk of a plant known as *Dycra costulata* and after coagulating the milk forms a white gum known as jelutong When quite dried the matter is almost as hard as rosin, and it contains from 10 to 20 per cent rubber It is said to be superior to the best Congo rubber A factory has been recently put in operation and is now turning out a considerable amount

Berlin University Improvements —At the Berlin University some $200 000 has been expended for different improvements in the buildings especially for the new auditorium The observatory of the university is to be installed at Babelsberg near Potsdam and the work on this building is already begun At the Jena University a new building is being erected which will be devoted to anatomo pathology and it will be under the direction of Prof H Klonka The Krupp company has made a considerable donation to Prof Weichert of the Göttingen University in order to carry on aerodynamic experiments and another to the astronomer Ambronn for constructing a star photographic instrument of a new design

Adhesivity —Harriot has reported to the French Academy of Sciences the discovery of a singular phenomenon which he calls adhesivity When two sheets of brown gold are heated in contact with each other to the temperature at which they become converted into ordinary yellow gold they remain firmly attached to each other There is no action at a distance actual contact is required to produce the adhesion Hence the phenomenon cannot be due to electric or magnetic action Nor can it be due to welding caused by the softening of the metal by heat for contact produces adhesion some time after the two sheets of metal have become cold and brittle Yet adhesion is not produced by the contact of two previously unheated pieces of brown gold or yellow gold A sheet of brown gold heated to its temperature of transformation does not adhere to a sheet which has been heated and cooled several days previously The adhesion is very strong when the temperature of the hot sheet is between 570 and 660 deg F

Medicinal Plants.—The researches presented by Prof Bourquelot to the Paris Academy of Medicine appear to show that the medicinal qualities of plants are greatly modified by drying them for use and this action is much greater than may be supposed The chemical as well as therapeutic qualities are found to be changed by the drying Considerable experimental work was done in order to bring out these facts and it is shown that when the plant is dried there is an interaction of the various bodies it contains so that some of these destroy others and in this way many of the active principles of the plants are destroyed or made insoluble However it is of interest to note that this action can be avoided or at least in part By rapidly sterilizing the plants by dipping them in strong alcohol at the boiling point, the author was able to prevent any further destruction of the soluble ferments Owing to this method he could separate out the chemical principles which existed in the living plant and thus have a great advance in analysis of vegetable substances which is always a difficult matter He also prepared new pharmaceutical substances which will be likely to give very good results for medicinal purposes It will be seen that these results are far reaching and may be very valuable

Frozen Fruit.—The chemical changes produced in fruit by freezing and thawing have been investigated by Otto and Kooper For example analyses were made of ripe sloes and of the same fruit which had been kept 4 days after 5 hours exposure to a temperature of 23 to 25 deg F The loss of weight chiefly water was found to be 13 6 percent The proportion of acids decreased from 9 18 to 6 57 per cent and the tannin from 9 45 to 6 82 per cent, while the proportion of sugar increased from 30 48 to 31 75 per cent, and part of the glucose was converted into the sweeter fructose or fruit sugar The decrease in tannin 's probably due to oxidation by which the tannin is converted into red and brown substances designated as pholobaptenes The fruit lost much of its astringency and acquired an agreeable subacid flavor in medlars which had been frozen and kept 8 days after thawing the sugar decreased from 41 13 to 37 37 per cent the acids from 4 36 to 3 50 per cent, and the nitrogen from 3 08 to 2 68 per cent In Japanese quinces kept 18 days after freezing and thawing, the sugar decreased from 16 91 to 7 60 per cent, the acids from 24 11 to 12.71 per cent, and the tannin from 3 82 to 1 84 per cent.

Engineering Notes

A New Railroad Across Persia.—According to the most recent information the Russian government has approved the project for the Trans-Iranian railroad The cabinet decided upon the construction of a railroading which is to connect Baku in south Russia with India across Persia, and this line will compete with the railroad which runs from Bagdad to the Persian gulf An international company is to build the rail road.

A New System for Purifying St. Petersburg Water —The city of St. Petersburg has had trouble with bad water from the Neva but is soon to start an ozone purifying plant which appears to be the largest in Europe It handles 60 000 cubic yards of water per day and is installed by the Russian Siemens Schuckert electrical firm The system used here is stated to be a combination of the Siemens electric ozoning apparatus together with sterilizing towers designed by the Paris Ozone Company

Grain Silos —Large grain silos have been erected at Bremen at the Mühe establishment They are entirely of metallic construction and use 24 cylindrical chambers of sheet steel having 17 feet diameter and 95 feet height, taking 12 000 tons of grain This gives a very high pressure on the ground so that the constructors use a large foundation bed of reinforced concrete A bottom plate is first laid and this upholds 42 columns of about 4 feet square section Upon this is placed a reinforced concrete planking in order to receive the silos The space between the columns is used to house various apparatus for transporting the grain

A Canal from the Rhine to the Weser.—An extensive piece of work to be carried out in Germany will provide a continuous canal from the Rhine to the Weser The first section is a canal which will lead from the Rhine so as to connect with the Dortmund Ems canal then the boats will follow this latter A new section then branches off and crosses the Weser stream at Minden ending at Hanover In order to increase the flow from the Weser into the present canals there is building a barrage at Waldeck across the Eder valley and thus a basin will be formed which is one of the largest in Europe containing 210 000 000 cubic yards The barrage is about 140 feet in height It is expected to finish the present work in 1913

Peculiarities of Submarines —Equilibrium is almost as difficult to maintain for a submarine vessel as for an aeroplane With modern large submarines it is contended the act of diving is performed when the vessels have headway The bow is depressed by horizontal rudders controlled by skilled men and the vessel moves obliquely downward The desired depth having been attained the steersman must so manage the horizontal rudders that the vessel shall practically maintain its level but in fact its course becomes really an undulating one up and down There must be no movements of men or weights in the vessel without immediate compensation to restore and maintain the balance else the submarine may dive to a disastrous depth Manual has been found better than automatic control

Locomotives Indicating National Character —An ingenious French study of the various types of locomotives in use throughout the word undertaken from a new point of view presents some interesting conclusions One of the most surprising inferences drawn was that genuine art is exhibited in the construction of locomotives They show it is contended from the French standpoint, beauty of line and proportion and true originality of treatment The American locomotive combines elegance practicality convenience and power thus betokening qualities of the race that does its work well The English locomotive it is stated is more trim and snug being smaller but without loss of power The French is lighter and finer in line than either of the two mentioned but is less powerful and effective

GOODWIN'S MODEL MONOPLANE EXHIBITED AT OLYMPIA

This kite shaped double-surface monoplane has its motor between the surfaces. The propeller turns in a slit as shown

Third International Aero Exhibition at Olympia 1911*

THE EXHIBITS ANALYZED

The Olympia Aero Show has unquestionably realized all anticipations of exceptional interest. It is true that the exhibits might have been more numerous, but there were after all twenty different machines on view, ten of which were monoplanes and ten biplanes—which fact in itself is additionally interesting as indicating the balance of opinion that exists at the present time as to the relative merits of the two types. Each type has of course its own particular advantages, which are emphasized or deprecated by individual designers according to their own personal view of what problems are most in need of immediate solution.

At the present show the keynote in design is struck by the prevalence of inclosed bodies, a feature that characterizes the majority of the machines present, and is of itself of the greatest interest and importance. At one time constructors used to be very particular about adopting stream line form for struts and other small members, but practical considerations soon showed that this refinement scarcely warranted—by any increase in efficiency that it afforded—more attention than could be conveniently bestowed upon it in the ordinary course of construction. If struts and spars could conveniently be made of stream line form without undue extra expense, all well and good; if

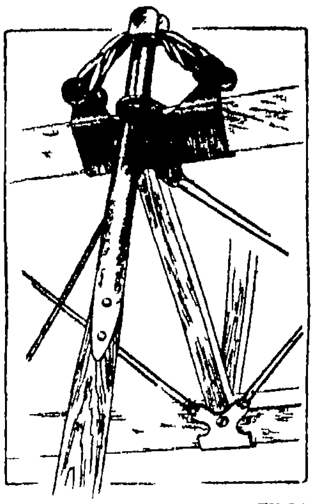
A COMBINED SUBMARINE AND MONOPLANE

This freak model gives an interesting hint of what the future aeroplanes may accomplish

The Valkyrie monoplane in the center foreground. The cigar-shaped Piggott monoplane is at the right in the middle distance. Capt. Cody's huge biplane is shown at the extreme right

GENERAL VIEW OF THE AERO AND MOTOR EXHIBITION AT OLYMPIA

on the other hand it was more convenient to make them rectangular then some leading firms at least made no bones about ignoring the purely scientific side of the problem. As a matter of fact, moreover this elaborate application of pure theory to practice is very apt to ignore practical considerations that are not taken into account in the theoretical hypothesis.



Flight

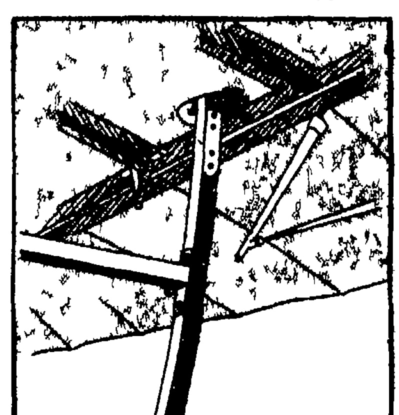
SKETCH ILLUSTRATING THE CRUTCH SUSPENSION OF THE BRISTOL MONOPLANE

For instance aeroplanes nowadays no longer only fly in the calm and indeed the art of aviation has progressed to an extent sufficient to enable pilots to navigate the atmosphere when the wind is blowing at a velocity that represents numerically a fairly high percentage of their own flight speeds. If therefore the wind is not blowing in the line of flight the axes of stream line forms on the machine will be more or less athwart the relative wind and much of the advantage of the special shape will thus be set at nought. While this argument holds good in connection with the struts and other members that are relatively small compared with the machine as a whole it does not necessarily apply with equal force to the question of inclosing the whole of the principal masses in a casing of stream line form. The engine and the pilot offer a very considerable extent of surface that does nothing but oppose the flight of the machine by the resistance of the normal air pressure upon it.

Clearly this is neither the time nor place to deal with the mathematical and technical aspects of this most important subject but suffice it to say that as far as theory is able to indicate at the present time the use of stream line casings offers every opportunity for effecting an important saving. Hitherto of course it has been of less moment to pay very much attention to this matter as other more pressing considerations have called for immediate notice but with the general tendency toward increase in speed—and incidentally in fact that high speed is of first importance in the prospect of winning the *Daily Mail* $50 000 prize—the question of body resistance becomes one of fundamental importance. The inclosing of the engine and pilot in a stream line casing is moreover an altogether different matter from the mere shaping of individual struts.

At Olympia this year the stream line bodies are the predominating feature in design. In the degrees of completeness they range all the way from the new Piggott monoplane which has every part of the body the engine pilot and passenger completely inclosed in a large torpedo-shaped casing with a hemispherical head. This represents the extreme development of the stream line idea, and it will be interesting to watch how far this whole-hearted adoption of a good principle works out in practice. Generally speaking such things are best evolved by degrees, and we do not doubt that it will be necessary to cut a few more holes in the Piggott shell before it satisfies the requirements of the average pilot. It will at any rate, take, we should imagine, some little time to get used to being completely boxed in for even as it is, with orthodox machines, aviators often complain of impeded vision. On the Piggott machine the outlook is entirely through windows made of insoluble gelatine and the passenger and the engine are both situated in front of the pilot. The propeller boss which is conical forms a revolving pointed nose on the otherwise hemispherical head of the body.

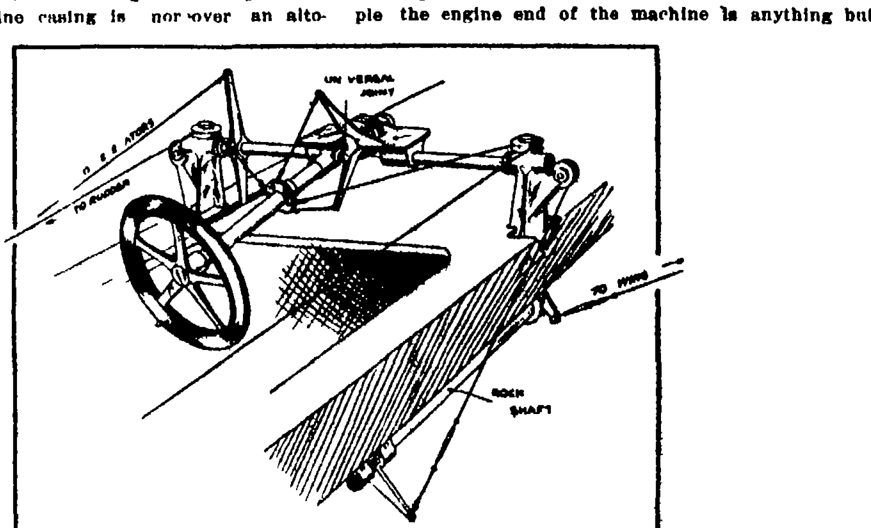
An almost equally pronounced example of inclosed body work is given by the Kny aeroplane constructed by Messrs Mulliner of London and Northampton but in this machine the body is boat-like in form and the pilot and passenger can have at any rate, nothing but sky above them if they care to detach the coaming tower cover plate. Like the Piggott the stream line body of the Kny aeroplane extends to the tail and the latter part of it is fabric-covered. In front, the outer surfacing material is sheet aluminium. On the Piggott machine the surfacing material is entirely fabric. Fabric is also used for enclosing the framework of the Nieuport monoplane, for which Maurice Ducrocq has the agency. In this machine however the rectangular section of the main frame has not been inclosed by any supplementary casing as on the Piggott monoplane and consequently the sides of the body are flat. In appearance, however the Nieuport monoplane distinctly belongs to the class under consideration although possibly its right to such classification is based more on appearance than



Flight

SKETCH SHOWING THE ARRANGEMENT OF THE FRAMEWORK AT THE TAIL OF THE HOWARD WRIGHT MACHINE

actual design for there is little doubt that the small size of the horizontal twin-cylinder engine in front considerably enhances the stream line appearance of the body which if fitted with a more conventional motor might call for less comment on account of its shape. In the Handley Page monoplane for example the engine end of the machine is anything but stream line like in form yet there is no better example of stream-line construction at the Show than is provided by the after-part of its body. It has quite a fish like appearance and is surfaced throughout in highly-polished three-ply mahogany. As the machine is only designed to carry the pilot, its general lines are characterised by short overall length, and so this particular machine has an uncommonly neat appearance.

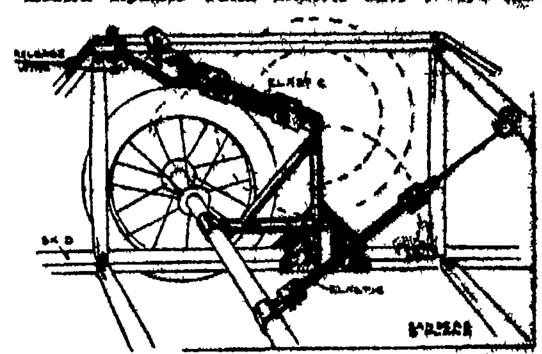


Flight.

SKETCH ILLUSTRATING THE CONTROL ON THE BLACKBURN MONOPLANE

More conventional examples of inclosed body work in which the surface material is simply laid on the frame are [illegible] the Blériot, Martin-Handasyde, Bristol and [illegible] monoplanes, and, strictly speaking, it is to this latter category that the Nieuport also belongs.

The most interesting development of inclosed body work is, however, in connection with some of the modern biplanes which hitherto have always been



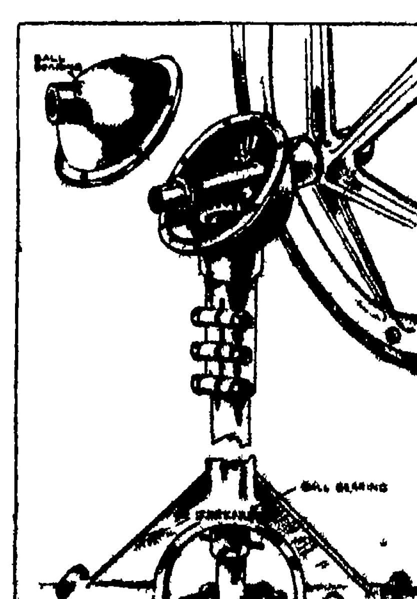
Flight

SKETCH ILLUSTRATING THE MECHANISM OF THE DISAPPEARING AXLE ON THE SANDERS BIPLANE

By releasing a catch the axle and wheels are drawn above the level of the skids, on which latter members the machine can therefore land direct.

characterised by the entire exposure of all the principal masses. The most important—as it was also one of the earliest examples of this system of construction—is the Breguet biplane which may be described as having a monoplane body supporting biplane wings. The body is completely surfaced from head to tail and is of great length. Unfortunately it has a most ungainly appearance, owing to a peculiar discontinuity in its lines but this is perhaps, more pronounced when the pilot is not on board, because the general shape has been based on the aviator's position in the machine and on the amount that his body projects above the level of the frame. A new type of Bristol biplane which is now being built in addition to the Farman pattern is designed on Breguet lines and has the characteristic inclosed body which with the single row of struts in the gap and the engine in front, constitute the outstanding features of the Breguet type.

Various other applications of this principle of inclosed body work to biplane construction are to be found among the modern examples of the Farman type of aeroplane. The Bristol machine of this pattern made by the British and Colonial Aeroplane Co has a kind of car for the pilot and passenger but the engine being a rotary Gnome is exposed. On the genuine Maurice Farman exhibited by the Aeroplane Supply Company a similar casing extends around the engine also which in this case is a stationary Renault, with the propeller mounted on the half-speed cam-shaft. On the Grahame-White biplane the pilot and passenger sit in a dainty little gondola



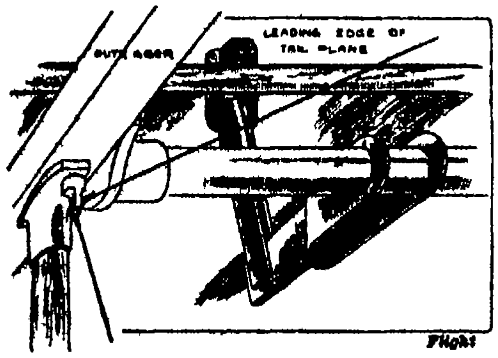
Flight.

THE MARTIN HANDASYDE CONTROL GEAR

On the Howard Wright the aviator carrying the foot-rest is [illegible], and [illegible] of tray, but otherwise everything is exposed as in the original design.

Turning to a consideration of the [illegible] of

[illegible] from the point of view of their general [illegible], it is interesting to compare them by classification into broader and somewhat more fundamental divisions than results from a mere discussion as to whether they are in the latest mode as regards body construction There are twenty machines on view [illegible] of which are biplanes and ten monoplanes Of the ten biplanes five may properly be classified as belonging to the Farman type These include the British built copies by the British and Colonial Aeroplane Company Messrs Howard Wright and Messrs Grahame-White Each has minor peculiarities of its



SKETCH ILLUSTRATING HOW THE ATTITUDE OF THE TAIL IS ADJUSTED BY A HAND WHEEL ON THE SOMMER TYPE HUMBER BIPLANE

own There is also the Maurice Farman which differs from the Henry Farman in the flatter appearance of its planes and in the extended skids, which curve up to support the elevator on the Sommer principle The Sommer type which may be practically considered as a modification of the Farman design is represented at Olympia by the Humber biplane The essential characteristics of the Farman machine which is unquestionably the most popular aeroplane that has yet been built are basically that of the original Voisin from which it was evolved by Henry Farman who flew the Voisin biplane at a time when he was one of the first men to fly at all The Farman machine is a biplane with an elevator in front a tail behind and the propeller immediately behind the main planes As the popular type of engine used on this machine is the Gnome rotary which is always mounted adjacent to the propeller the principal mass is situated aft of the center of pressure and consequently the tail is necessarily of the lifting type because the pilot does not in the accepted position balance the engine by his own weight

On the Breguet biplane where the relative positions of the engine and pilot are reversed the tail becomes practically speaking a non lifting member although in actual practice the tail of the Breguet is a slightly cambered plane Incidentally of course the Breguet system facilitates the use of a monoplane type body because the propeller being in front does not interfere with the continuity of the longitudinal spars in the construction of such a member The inclosing of the body so as to be more or less of stream line form which feature has already been discussed is of course only a natural evolution as the outcome of taking a further step in detail design While on the subject of the Breguet machine it should also be mentioned that quite apart from the question of type this model belongs to a class apart in any case, because it is constructed entirely of steel—timber being now as formerly, the standard material for aeroplane framework. The Bristol-type aeroplane made by the British and Colonial Aeroplane Company is constructed of wood.

Of the three remaining biplanes at Olympia, each belongs to a separate class There is the small Wright racer, with which type Mr Alec Ogilvie competed in the Gordon Bennett race the Cody biplane with which Mr S F Cody won the British Michelin Cup and the Sanders biplane which in some essential features resembles the biplane originally designed by Messrs. Short Brothers.

The Wright biplane in its present form is characterized by the absence of any front elevator and by the use of a non lifting tail Practically the machine is in balance about the center of pressure with the pilot on board and indeed the spiral draught from the propellers is enough to upset this balance through its influence on the tail plane

The Cody biplane is similarly a balanced machine but it differs from the present Wright type in having an elevator The elevator on the Cody machine is a cambered plane and normally carries some of the load for convenience in control although it is not essential from constructional considerations that it should do so The engine on the Cody biplane is carried on the lower plane and within reason both it and the pilot can have their positions altered in order to effect any degree of balance that may be required In practice as has been mentioned Mr Cody prefers that the elevator should be loaded a little as he considers that it facilitates control

The Sanders aeroplane is fundamentally a modification of the original Wright biplane as its only tail member is the rudder and there is an elevator in front This elevator however probably carries proportionately more load than on the original Wright because the very strong Short type girder under carriage is probably heavier than the corresponding outrigger on the original Wright machine These girder skids and the elevator shaft itself are to all intents and purposes the same as those on the Short biplane last year The main planes themselves are characterized by sharply downturned extremities on the upper plane that act as side curtains to prevent leakage and sideslip The engine and propeller on the Sanders biplane are arranged more or less on the same lines as the Cody—that is to say the propeller is mounted midway in the gap and is driven at half engine speed by a single vertical chain The rudder is a triplane in which respect it differs from the biplane rudder on the Wright

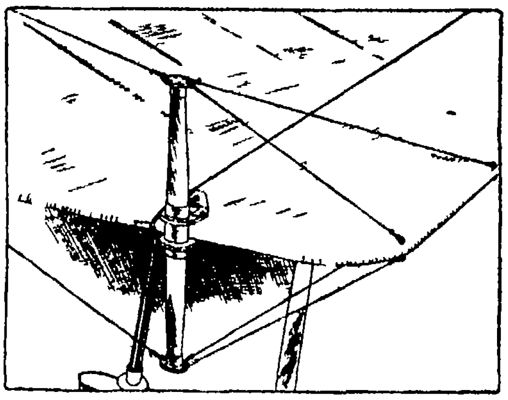
If we attempt to compare the monoplanes on a similar basis it is somewhat more difficult to differentiate between types owing mainly to the gradual merging of the characteristics of the Blériot and Antoinette patterns that have hitherto led the field and been distinct Thus for instance the V section boatlike Antoinette body may be seen combined with Blériot pattern wings which are certainly quite distinct from the planes of the true Antoinette both on account of the fact that they are thinner and also by reason of the absence of individual trussing on the wing spars

A genuine Blériot with its characteristic lifting tail rectangular open girder body and rather low set center of gravity is exhibited by the London representatives of that firm while the Martin Handasyde monoplane may be considered at any rate as regards its appearance as characteristic of the real Antoinette It has the triangular section covered frame, non lifting tail and individually trussed wing spars. As a design however the Martin Handasyde monoplane is full of original detail

Machines like the Blackburn and Bristol monoplanes may be classified as lying between these two distinct types inasmuch as they have Antoinette bodies with wings that certainly bear more resemblance to the Blériot pattern than the Antoinette and are at any rate, trussed only to one central mast.

In the Kny, Piggott, Handley Page and Nieuport monoplanes the body form predominates over all other characteristics but in the principle of the non lifting tail they are alike The Kny has its wing spars individually trussed more or less on the Antoinette principle but in the other machines mentioned the wing spars are not thus reinforced

Properly speaking the real distinction in monoplanes of this classification should be drawn between the tail behind and tail first types and in the latter category the Valkyrie is at present the only example on view This machine is of essentially British design and construction It is characterized by a fixed load

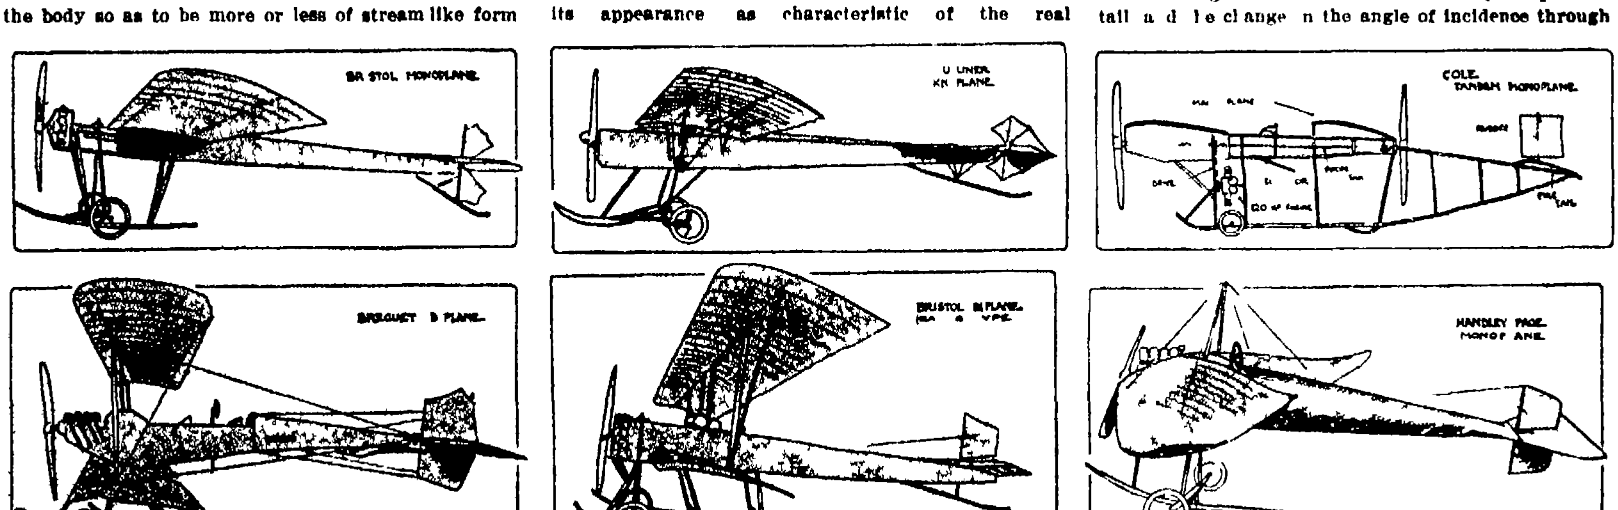


DETAIL SKETCH ILLUSTRATING THE REAR ELEVATING PLANE ON THE FARMAN BIPLANE

carrying leading plane in front of the main plane which leading plane must not be confused with the movable elevator that is also provided In the Valkyrie machine the propeller engine and pilot are likewise all in front of the main plane In the Antoinette monoplane the engine and propeller are both appreciably in front of the main plane and on the Blériot monoplane the engine and propeller are still in front but distinctly closer to the leading edge Inasmuch as the central portion of the Valkyrie main plane is recessed to take the propeller the engine—supposing it to be a Gnome rotary—is not really so much further forward of the leading edge proper than it is on the Antoinette and thus the essential distinction is more or less confined to the change in the position of the pilot Appearances are therefore apt to be a little deceptive in respect to the relative distribution of weight with this particular design

A monoplane that is altogether in a class by itself is the Dunne which is so far as practical flying machines are concerned an evolution of the Dunne biplane The biplane was in itself however originally evolved from still earlier monoplane models A characteristic feature of this machine is the absence of a tail and the V plan form of the wings which also have a varying angle of incidence from root to tip The object of the design is the acquisition of natural stability and the purpose of sloping back the wings is to acquire an overall length for the machine as distinct from the chord dimension This increment in length virtually introduces the principle of a tail and the change in the angle of incidence through out the succeeding sections of the wings confers the principle of the dihedral angle on the relative attitude of the virtual tail portion in respect to the central leading portion of the machine

In fundamental principle the Valkyrie appears to be not dissimilar to the Dunne although there is no structural likeness whatever The leading plane in the Valkyrie however may be likened to the central portion of the Dunne machine and it makes a dihedral angle in respect to the main plane the extremities of which correspond to the rearward tips of the Dunne wings This comparison is, perhaps not altogether



VARIOUS TYPES EXHIBITED AT OLYMPIA

Drawings reproduced from Flight

on I sive as th s br efly drawn but it has been made with I e object of empl asizing that it is in the under lying principle rather than in the form of the machine that types should be compared on a common scientific basis The Handley Page monoplane for example has c s oped back wings arranged with a crescent form of leading edge and the dihedral angle is present in a minor degree by the use of upturned flex b e wing tips Apart from the shape of its wings however the Dunne monoplane is characterized by its underhung load the engine and pilot being situated beneath the wings. In the Sanders biplane which in this respect represents the principle of the early Wright flyer the elevator may be regarded as a for ward tail b t as its attitude can be varied at will s ability is dependent on the action of the pilot

Thus far we have discussed the machines that are already familiar to readers of *Flight* and indeed it is one of the most satisfactory features of the present exhibition that so much of the display is admittedly within the realm of successful practice No one can possibly say that the present exhibition lacks orig inality in aeroplane design and yet it is singularly free from freaks Practically the only purely specu lative designs are the tandem monoplane exhibited by Messrs William Cole and the machine exhibited by Mr F J Bartelt Of these the former is unfin ished and is thus possibly in some degree exempt from criticism, so we would therefore confine our selves to saying that it labors under the disadvantage of having an unprepossessing appearance The design is due to a Frenchman, M Magnodex and attacks a particularly interesting problem in aeroplane con struction The tandem monoplane was on the point of being the first machine to fly in America when Langley was tripped up by ill-fortune in his endeavor to demonstrate a full sized machine of this type before representatives of the American Government. Langley had succeeded in obtaining very successful flights with large power-driven models, and his construction of a man-carrying aeroplane was undertaken at the insti gation of the American Government, as a direct out come of his previous work Faulty launching ways twice brought about temporary disaster to the machine, and the authorities having little faith in those days withdrew their support. Within a few weeks the Wright Brothers had secretly succeeded where Langley failed and in the evolution of their machine the tandem monoplane has been forgotten

The necessity for overall length on a machine as a factor in its stability and the necessity for pro viding an adequate body in order to carry the tail certainly suggest the possibility of developing a useful type in the tandem monoplane since it plausibly [illegible] lifting surface for the [illegible] Whether or no the Cole machine will [illegible] modern prototype of this class we should not like to say In its present form it certainly seems to be following an undesirable principle in attempting to combine such unknown quantities as a tandem monoplane wooden folding wings, twin propellers, and a new type of rotary engine on the same machine

The Bartelt machine is something apart from all accepted types. It consists of a steel structure of biplane appearance with loose, saggy wing surfaces. The wings are mounted at their shoulders on cranks, whereby they rise and fall, while always remaining parallel to the ground. The motion of the cranks being circular the wings, simultaneously with their rise and fall move forwards and backwards—in other words they perform a modified form of paddle action, the object being to derive support by beating the air The wing motion is obtained from chain transmission, and in addition to the supporting reaction, there is said to be a propelling force sufficient to keep the machine going without the small propeller that is such a comparatively insignificant constructional fea ture of the machine as a whole. We are informed that the small scale prototype of the machine exhib ited actually flew with a pilot weighing 8 stone 4 lbs.

The Air-brake as Related to Progress in Locomotion—III*

The History of a Great Invention

By Walter V Turner, Chief Engineer, Westinghouse Air Brake Co, Pittsburg, Pa.

Continued from Supplement No 1841 page 230

To CONSIDER for a moment the quantitative results of the improvements which have been mentioned as evidenced by the comparative stopping distances of trains equipped with the types of brakes referred to The diagram (Fig 18) shows concretely the relative efficiency of the vario is forms of brakes for passenger trains the difference in the length of the lines cor responding approximately to the reduction of distan e required in which to stop a given train of one loco motive and six cars from a speed of 60 miles per hour since the introduction of the air brake If the dia gram were inverted so that it is viewed ipside down a fair idea will be obtained of what the relation between the stops wo ild have been through the re spective periods of train development had there been no change in the air brake since first applied

The tendency of modern rolling stock to lower brake efficiency is further illustrated in Fig 19 The

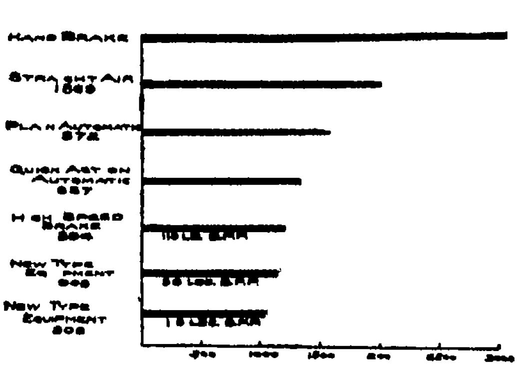


Fig 18—DIAGRAM OF DEVELOPMENT OF AIR BRAKE EFFICIENCY SINCE 1869

retardation curves show the stopping distance from al o t the same initial speed of a train composed of cars weighing 30 000 pounds and braking at 88 per cent and a train of 84 000 pound cars braking at 150 per cent It will be seen that notwithstanding the 60 per cent greater braking power of the heavier train the difference in stop is not greatly in its favor The reason for this is clear when it is considered that the work done during the stop for the light train was 14 foot tons per brake-shoe per second while with the heavy train it was 29 foot tons per brake-shoe per second which shows that under modern con ditions each brake shoe is doing about twice the amount of work required formerly in order to make approximately the same stop which consequently low ered the coefficient of friction and thus tended to equalize the actual retarding forces developed in the two cases

The diagram below the comparative curves shows first the length of stop for light train with the equip ment of its day second what the stop would have been with the heavier train had there been no change in brake equipment to correspond to the increased weight of train third what braking power was actually required to stop the heavy train in the dis tance the light train was stopped with its brake equip ment and fourth what the stop of the light train would be if it were possible to apply to it the brake equipment required for the heavy train This is a significant and all-sufficient example of what is re quired to meet modern conditions as effectively as they were provided for in the past.

CONTROL VALVE EQUIPMENT

With the introduction of heavy sleeping cars and passenger equipment cars carrying heavy motive power apparatus such as self-contained motor cars, not only were the factors above mentioned, which tend to lower brake efficiency aggravated to a marked degree, but limiting conditions were encountered in other directions. The brake force required to control such heavy (155,000 to 170,000 pounds) cars with approximately the same effectiveness [illegible]

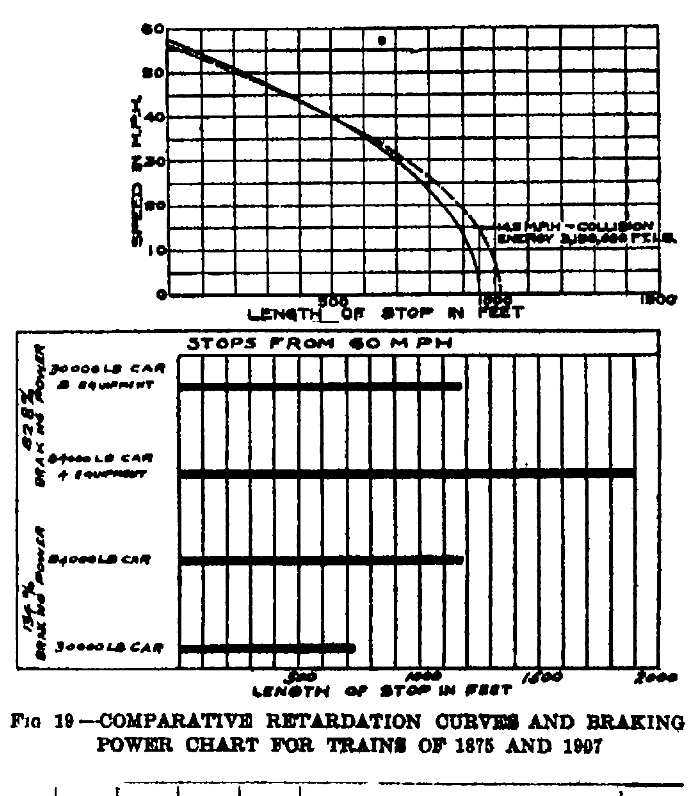

Fig 19—COMPARATIVE RETARDATION CURVES AND BRAKING POWER CHART FOR TRAINS OF 1875 AND 1907

Date	Speed in M P H	Lgth. of stop in feet	Time of stop in sec	Wght of trains, tons	Work in ft tons performed by brakes			B P p c
					Total	Per sec.	Per brake-shoe per sec	
1875	56 0	1080	[illegible] 0	297	[illegible]	1080 4	14.70	[illegible]
1907	67 3	964	18 7	559	61800	3878 9	28 75	150.0

Dotted curve shows stop on Midland Railway 1875, with the Westinghouse Automatic Brake.

Full line curve shows stop made on W J and S. R. R. 1907 with the Westinghouse "LN" Brake.

Had the braking power as shown in the last column of the table and represented by the full-line curve, been 134 per cent instead of 150 per cent, the two stops would have been the same.

* Presented at the meeting of the Mechanical and Engraving Section of the Franklin Institute.

[illegible] with the highest brake-cylinder pressure and greatest multiplication of its power by leverage that could be permitted

The single brake-cylinder had already reached a maximum of 16 inches in diameter and it was generally agreed that a larger size brake-cylinder would be impracticable from a manufacturing, operative and maintenance standpoint.

With 100 to 105 pounds brake-cylinder pressure being obtained from 110 pounds brake-pipe pressure carried there was little hope of raising the cylinder pressure higher and no materal or permanent improvement in the general condition would result even if the full 110 pounds could be realised in the brake-cylinders.

There was no suggestion of an increase in brake-pipe pressure above the present standard it being universally recognized that 110 pounds was about as high as could safely and economically be used with the type of apparatus and fixtures in general service.

The multiplication of the brake-cylinder pressure through the leverage of the foundation brake rigging had been carried in many cases beyond the recommended 9 to 1 maximum simply because it was the most obvious, simplest, and most convenient means of providing the heaviest cars with a proportionate braking power approaching that used on lighter cars The evils of this expedient soon became manifest in dragging brake-shoes slow release and trouble in keeping the brake rigging properly adjusted Most important of all from a safety standpoint, was the effect of this high leverage ratio in multiplying the losses due to lost motion in the rigging or truck members, brake-shoe movement and so on the result of which was evidenced in excessive false piston travel and consequent failure to obtain the maximum brake-cylinder pressure contemplated in the design or still more serious loss in braking power due to the piston traveling so far as to bottom on the cylinder head

These and other mechanical limitations therefore barred further progress in this direction and two alternatives remained viz

1 To increase the effectiveness of the single brake-cylinder as far as possible by using two brake-shoes per wheel (clasp brake)

2 To use two brake-cylinders per car

While the first of these alternatives would undoubtedly be of some assistance there are objections to this design not the least of which is a reasonable doubt whether the acknowledged theoretical advantages of the clasp brake would prove to be practicable and a reasonable certainty that no matter to what extent its theoretical advantages might be realised in practice the maximum increase in efficiency thus afforded could not be sufficient to meet the demands of donditions already existing to say nothing of the possibilities of the future

On the other hand the two-brake-cylinder proposition did not necessarily involve any new or untried principles since two complete equipments of the type already in service might be used one for each end of the car This would provide ample stopping power for existing conditions and lend itself readily to extension as still more severe demands might arise. It was therefore recognized that such an arrangement offered the best solution of the problem of the proper air-brake equipment for passenger cars weighing 130 000 pounds or over Furthermore it was seen that a single valve mechanism to control the admission of air to and release of air from the two-brake-cylinders would possess such marked advantages over a complete double equipment for each car as to make a satisfactory and practicable design of such a valve greatly to be desired. In reality the success and scope of the two-cylinder arrangement depended wholly on the characteristics of the valve device adopted for this purpose.

It was but logical that in the first practical solution [illegible] at the same principle [illegible] operation, as had [illegible] already in use for some years, and giving the best of satisfaction under conditions quite similar to those of the two-cylinder passenger-car equipment While this valve (the distributing valve of the "ET" locomotive brake equipment) was particularly designed to operate in connection with two or more brake-cylinders on locomotives, its distinctive operative features were equally advantageous for passenger car service Consequently when the introduction of 85-ton multiple unit electric motor cars on the N Y N H & H R R electric zone called for a correspondingly effective form of brake apparatus of necessity using two-brake cylinders the valve mechanism adopted was a modification of the distributing valve type the changes being only such as were required to adapt this device to passenger train service From the start its performance under the severe demands of suburban electric service was so satisfactory as to thoroughly establish the advantages of this type of equipment for the high braking efforts and large brake-cylinders required by the heavier classes of cars It is hardly necessary however to go further into detail regard ng its construction or operatio first because the design of its operating mechanism resembles so closely that of the distributing valve and second since it served to mark one stage only in the development of a distinct type of brake apparatus for such service

As already stated with the advent of passenger carrying cars weighing from 135 000 to 150 000 pounds in steam road service and still heavier motor cars carrying extraordinary dead weight loads the limit of an efficient single-cylinder equipment was approached and in some cases exceeded But this was only one phase of the sit ation The demand of high speed heavy train service had steadily advan ed to a point where for adequate control something more was required of a brake than merely maximum retarding power in emergency The ordinary service functions and automatic safety and protective features became hardly secondary in importance Briefly stated the requirements recognized as essential in a satisfactory brake for this modern service are as follows

1. Automatic in action

2 Efficiency not materially affected by unequal piston travel or brake-cylinder leakage

3 Prompt serial service action

4. Graduated release

5 Quick recharge and consequent ready response of brakes to any brake-pipe reduction made at any time.

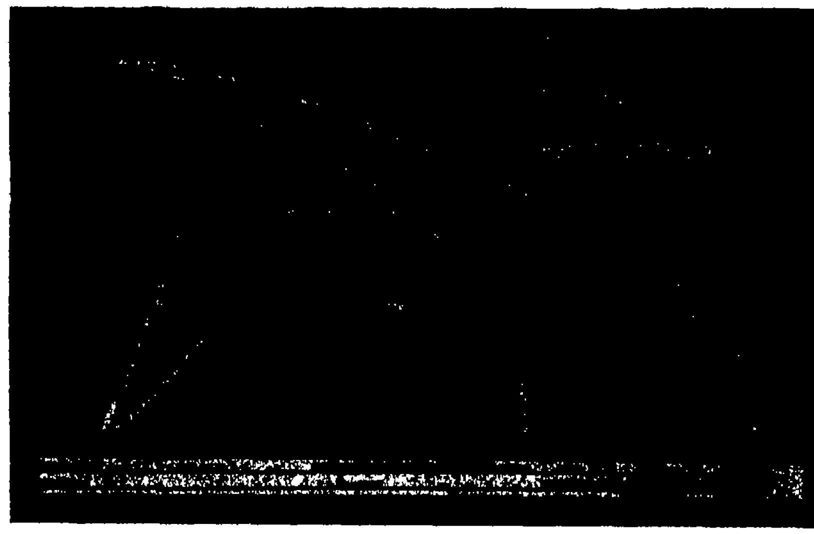
6. Predetermined and fixed flexibility for service operation.

7 Full emergency pressure obtainable at any time after a service application.

8 Full emergency pressure applied automatically after any predetermined brake-pipe reduction has been made after equalization

9 Emergency braking power approximately 100 per cent greater than the maximum obtainable in service applications

10 Maximum brake-cylinder pressure obtained in the least possible time



F G 21—COMPARATIVE TRAIN STOPS CONTROL VALVE AND HIGH SPEED BRAKE EQUIPMENT

11 Maximum brake-cylinder pressure maintained throughout the stop

12 Brake rigging designed for m ximum efficiency

13 Adaptability to all classes and conditions of service

That certain of these req irements demanded radical changes in the valve device used on the car is evident from a comparison with the functions of the previous types already referred to since but one of these required functions was contained in the older equipment These considerations led to the latest development in the art of controlling heavy high speed passenger trains employing what is known as a control valve in the place of a triple valve the fun tions of which have already been mentioned in brief The complete equipment is known as the schedule PC and is illustrated in Fig 20

The relative stopping power of the most efficient of the old order of brake apparatus the high speed brake—and of the control valve apparatus is contrasted in the curves of Fig 21 Both the comparative lengths of stop and the relative rates of rise and a nount of maxim m braking power are shown by the curves It will be noted that the 575 foot shorter stop made with the PC eq ipment resulted not only from the h gher braking power utilized but also from the quicker rate at which this braking power was built up to its maximum value As a result you will note that the speed of the high speed equipment train when passing the point (1 100-foot stake) at which the PC eq ipment train stopped was still as high as 38 miles per hour which means that 40 per cent of its initial kinetic energy (at 60 miles per hour) still remained to be dissipated (harmlessly in this case fortunately) before the train could be stopped

Moreover not only was this speed 38 miles per hour in the case of the high-speed equipment train but it passed the 1,100-foot stake six seconds before the PC equipment train reached that point That is to say the train with the "PC equipment came to a stop at the 1 100-foot stake six seconds after the train equipped with the high-speed equipment passed this

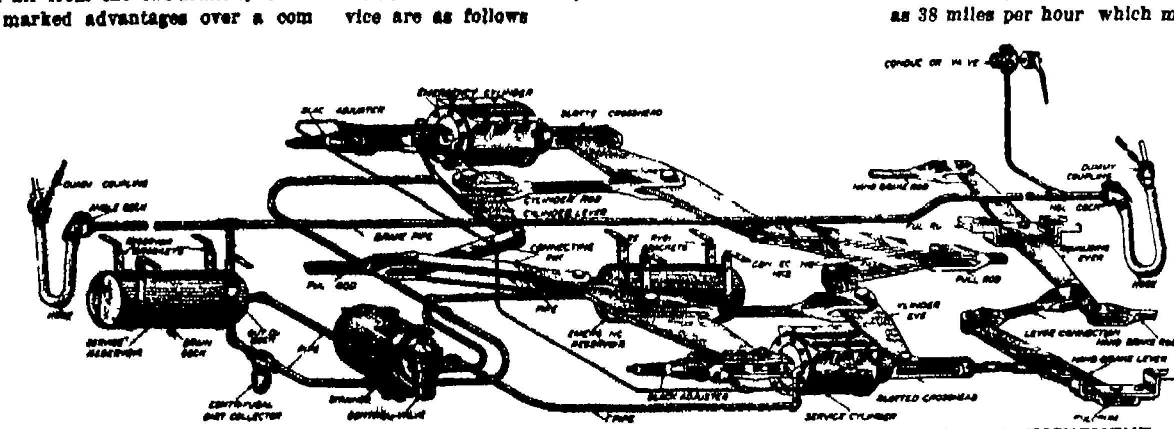


FIG. 20—IMPROVED BRAKE EQUIPMENT FOR HEAVY PASSENGER CARS CONTROL VALVE EQUIPMENT SCHEDULE "PC

point at a speed of 38 miles per hour At the time when the PC equipment train stopped at the 1 100-foot stake the train equipped with the high-speed brake equipment was 275 feet farther on and still running at a speed of 28 miles per hour which corresponds to a kinetic energy 22 per cent of the original amount when train was running at 60 miles per hour

SUMMARY OF DEVELOPMENT IN PASSENGER BRAKES

From what has gone before it will be seen that the existence and development of the passenger brake devices which have been described have come about not spontaneously of themselves or solely for them selves but in response to a definite need or for the purpose of accomplishing certain necessary and desired results the end in view always being the safeguarding of life and property and increasing the facility economy and dispatch with which larger volumes of traffic can be handled

Briefly the conditions to be overcome and the objects to be attained may be summarized as follows

CONDITIONS Increased weights of trains greatly decreasing the relative efficiency of the brake and increasing the energy to be overcome in bringing the train to a standstill Of two trains on the same number of wheels having the same nominal percentage of braking power one being twice the weight of the other the heavier train will run at least one-third further than the other

Higher running speeds increasing the energy to be overcome in making the stop in proportion to the square of the speed and adding directly to the length of stop according to the time required to obtain effective braking power on the train as a whole

Greater frequency of trains which increases the necessity for stopping quickly in a rapidly increasing ratio Not only is it of more importance than ever that the trains be readily controlled within the distances between signals but with double or four track roads there is the added greater possibility of the track on which the train is running being blocked by a break in two or other accident on the opposite track.

Increasing insistence upon the comfort and convenience of passengers and at the same time for greater economy in the handling of traffic the latter being in the nature of things antagonistic to the former without some special provision is made looking to ultimate rather than circumstantial economy

OBJECT OF IMPROVEMENTS —*In Service Applications* —(1) Much more flexible control of the train greatly reducing possibility for shocks (2) More uniform braking power reducing surging in trains and flat wheels (3) Uniform and maintained cylinder pressure notwithstanding variations in piston travel or leaky brake cylinders (4) Constantly recharged auxiliary reservoirs which increase the safety to the highest degree (5) Better protection against excessive braking power in service applications (6) Shorter smoother and more accurate stops

In Emergency Applications —(1) The human factor in the equation is reduced to a low point (2) The increased percentage of braking power and prompt rise of brake-cylinder pressure compensates in a large degree for the decrease of the retarding force due to the increased work the brake shoe now has to perform as compared with the old style brake (3) Trains can be stopped in some where near the same distance as when the cars were lighter (4 *Emergency pressure is available even after a service application has been made to an extent never before attained*

EMPTY AND LOAD BRAKES

Under modern freight traffic conditions as already stated uniformity of retardation on all cars in a train is second in importance only to safety This with mixed loads and empties hauled in the same train, is inherently unobtainable with the type of brake considered thus far It can only be accomplished by providing means whereby a relative braking force more nearly comparable to that of the empty car can be utilized on the partially or fully loaded car

The difference in braking power with the standard brake on loaded and empty cars would no doubt astonish anyone unfamiliar with the facts but can be appreciated from the statement that the same brake-cylinder pressure which gives 60 per cent braking power on an empty car will give only from 17 per cent to 20 per cent when this car is fully loaded

Four possible solutions are evident

1 *Increased Brake-cylinder Pressure for a Given Reduction and on Equalization* —In order to leave the braking power on the empties the same as at present but increase that on the loaded car to the desired amount, it would not be permissible to increase the brake pipe pressure above the 70 pounds at present generally used Even if an increase above 70 pounds *for this purpose* were permissible it would not give any higher braking power for ordinary service reductions but only afford a higher equalization pressure An increase of reservoir volume on the loaded car is therefore another alternative The maximum increase in pressure then available could not be greater than 70 pounds which while only increasing the braking power on the loaded car by 40 per cent (that is from say 20 per cent to 28 per cent braking power) at the most would destroy many fundamental and necessary features of the brake This is only about one-fifth or one-sixth of the increase required for a proper control of a car loaded to from two to four times its light weight This method is therefore impracticable

2 *Increase the Total Leverage Ratio Temporarily on the Loaded Car* —In the first place the total leverage ratio for the heavier modern freight cars and standard equipment is already so high that any such increase as required by the loaded car would be prohibitive Aside from this, however it has been demonstrated by many repeated but futile attempts that none of the various schemes thus far proposed for mechanically changing the leverage to correspond with the increase in car lading (whether automatically with an increase of car weight or manually) can be made practicable for actual road service Once established for the light car the same leverage ratio must be utilized for the loaded car

3 *A combination of increased leverage ratio and auxiliary reservoir volume* might be suggested as a possibility but it would evidently combine the objectionable features of the first and second alternatives just mentioned in such a manner as to aggravate the undesirable effects of each This method therefore fails to afford the relief sought

A fourth possibility remains viz

4 *A Second Brake-cylinder to be Added to the Ordinary Brake Cylinder to Control the Load* —A number of equipments of this type of varying form are being successfully operated on a number of railroads particularly in mountain grade service where the additional braking power thus provided is of advantage in increasing the amount of tonnage handled in a given time down the grade It will be of interest to state in outline only the characteristic features of forms which have proven successful

1 Two brake cylinders per car are used one for the empty car and both used together when the car is loaded to say two-thirds or more of its rated capacity

2 Standard leverage arrangement for the empty" brake cylinder

3. [illegible] [illegible] [illegible], [illegible], [illegible] [illegible] [illegible] [illegible] and [illegible] [illegible] cation of power from the additional "load" cylinder to the "empty" cylinder [illegible] [illegible].

4. Valve mechanism, in addition to that required by the "empty" brake, for controlling the supply of air to and from the added or "load" brake cylinder

5 Semi-automatic change-over valve mechanism for cutting the "load" brake in or out either manually or under certain circumstances, automatically

6. Additional reservoir capacity to furnish the air supply for the "load" brake.

The important problems entering into the operation of brakes on freight trains under present-day intensive traffic duty for which the "empty and load type of apparatus offers an ideal solution may be briefly as follows

1 The necessity for more braking power on loaded cars than afforded by the ordinary form of brake, in order to increase the tonnage which can be handled down long or heavy grades with safety Locomotives of such power are now built, that it is possible in some localities to haul heavier trains to the top of a grade than can be safely controlled down the other side with the standard brake

2 Trains of mixed loads and empties especially long (50 to 100 cars) trains where it is physically impossible or economically impracticable to arrange the empty and loaded cars in the train to the best advantage thus adding greately to the danger of the train parting or damage to the lading and equipment due to inequality of braking power in different parts of the train when the brake is applied at some critical speed or locality

3 Locomotives of great weight but relatively low braking power tending to increase the internal stresses in the train due to unequal retardation on different cars in the train

4 The advent of large capacity cars aggravating the differences in retardation due to lading so that the percentage of braking power on such cars when loaded is reduced to a greater extent than on cars of lower capacity for which the proportion of loaded to light weight is less

5 The requirement of operating both short and long freight trains with practically all air brakes cut in This, on a long train with loads ahead and empties on the rear end presents an operating problem difficult of solution with the old standard brake

PRINCIPLES OF TRAIN BRAKING AND BRAKE DESIGN

Throughout the foregoing description of the development of the various types of brake apparatus occasion has been taken to explain at the same time the operating conditions and service requirements responsible for their being While this has necessarily involved some reference to some of the fundamental principles underlying the proper application and operation of brakes as related to convenience economy and safety in train control there are certain limiting conditions and fixed laws which should be treated more specifically and in detail This is not so much because the present state of the air-brake art exemplifies the application of these laws and principles to the complex demands of modern freight and passenger service but rather because it is only by a careful study and sound working knowledge and appreciation of the significance of these laws that anyone is able to judge positively and accurately on the one hand the adaptability of or necessity for any new air brake device and on the other what are the requirements to which any new device or method must conform in order to adequately and efficiently satisfy the requirements of new service conditions.

(To be continued)

RULES GOVERNING THE COMPETITION FOR THE $15,000 FLYING MACHINE PRIZE OFFERED BY MR EDWIN GOULD

1 A PRIZE of $15 000 has been offered by Mr Edwin Gould for the most perfect and practicable heavier than air flying machine designed and demonstrated in this country and equipped with two or more complete power plants (separate motors and propellers) so connected that any power plant may be operated independently or that they may be used together

CONDITIONS OF ENTRY

2 Competitors for the prize must file with the Contest Committee complete drawings and specifications of their machines, in which the arrangement of the engines and propellers is clearly shown with the mechanism for throwing into or out of gear one or all of the engines and propellers. Such entry should be addressed to the Contest Committee of the Gould-SCIENTIFIC AMERICAN Prize 361 Broadway New York city Each contestant in formally entering his machine must specify its type (monoplane biplane, helicopter etc) give its principal dimensions, the number and sizes of its motors and propellers, its horse-power, fuel-carrying capacity and the nature of its steering and controlling devices.

3 Entries must be received at the office of the SCIENTIFIC AMERICAN on or before June 1st, 1911 Contests will take place July 4th 1911 and following days. At least two machines must be entered in the contest or the prize will not be awarded.

CONTEST COMMITTEE.

4 The committee will consist of a representative of the SCIENTIFIC AMERICAN a representative of the Aero Club of America, and the representative of some technical institute. This committee shall pass upon the practicability and efficiency of all the machines entered in competition, and they shall also act as judges in determining which machine has made the best flights and complied with the tests upon which the winning of the prize is conditional. The decision of this committee shall be final.

CONDITIONS OF THE TEST.

5 Before making a flight each contestant or his agent must prove to the satisfaction of the Contest Committee that he is able to drive each engine and propeller independently of the other or others, and that he is able to couple up all engines and propellers and drive them in unison No machine will be allowed to compete unless it can fulfill these requirements to the satisfaction of the Contest Committee. The prize shall not be awarded unless the competitor can demonstrate that he is able to drive his machine in a continuous flight, over a designated course; and for a period of at least one hour he must run with one of his power plants disconnected; also he must drive his engines during said flight alternately and together Recording tachometers attached to the motors can probably be used to prove such performance

In the judging of the performances of the various machines, the questions of stability, ease of control, and safety will also be taken into consideration by the judges. The machine best fulfilling these conditions shall be awarded the prize.

6. All heavier-than-air machines of any type whatever—aeroplanes, helicopters, ornithopters, etc.—shall be entitled to compete for the prize, but all machines carrying a balloon or gas-containing envelope for purposes of support are excluded from the competition.

7 The flights will be made under reasonable conditions of weather The judges will, at their discretion, order the flights to begin at any time they may see fit provided they consider the weather conditions sufficiently favorable.

8. No entry fee will be charged, but the contestant must pay for the transportation of his machine to and from the field of trial.

9. [illegible]

Wireless Telegraphy and Airships

A Review of Recent Experiments

By the Paris Correspondent of the Scientific American

CAPT FERRIÉ, who is at the head of the Eiffel Tower wireless station, and chief of the government wireless department, has been making experiments for some time upon the question of wireless telegraphy as applied to airships. We give the leading results of this work, which are contained in a paper presented to the Telegraphers Institution of Paris.

For wireless work in connection with airships, we require upon the airship both an antenna or aerial wire, and also a ground connection or its equivalent. We will first refer to the question of the ground wire as this is important. In Fig 1 we have the usual connections for a wireless plant as are used in various stations, and here *A* is the aerial wire and *T* the ground At *E* is the sending apparatus and *R* the receiving apparatus either of which can be connected in.

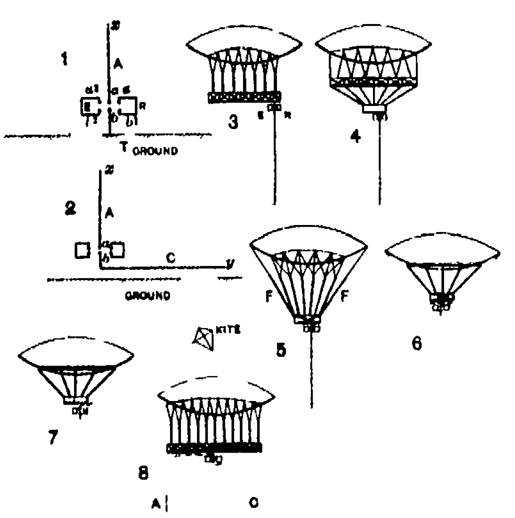
In certain cases we may obtain reasonably good results by replacing the ground wire of the aerial system by a connection with one or more insulated wires stretched above ground and equivalent to the aerial from an electrical standpoint. Such a system is known as a false ground or counter wire It can be used when a good ground connection cannot be made for instance in rocky soil In Fig 2 the ground is replaced by the false ground *C* To transmit we connect the points *a* and *b* respectively with *a*, and *b*, and for receiving with *c* and *b* It is demonstrated both by theory and by practice that while signals are being sent, the tension due to the waves is not constant over the length of the aerial or the combination of this with the false ground or counter wire This tension is greatest at the ends *x* (Fig 1) or *x* and *y* (Fig 2) At these points occur brush discharges which are stronger as the power used in the waves is greater Seeing that greater power is needed when making long distance transmission it follows that such discharges are greater in long-distance work However the brush discharges depend not only upon the energy used in the aerial but also upon the method used in producing the sparks Taking the three cases occasional sparks musical sparks and continuous wave-trains in the first two cases we store up electrical energy in condensers from which we produce a periodic spark discharge When the number of discharges is small the energy spent in each spark is evidently greater than where we have a considerable number of sparks The consequence is that the electric tension in the aerial and especially at the ends *x* or *x* and *y* (Figs. 1 and 2) is weaker as the number of sparks is greater and the brush discharges follow the same law The use of musical sparks whose number is such that the noise produced becomes a musical sound allows of greatly reducing the brush discharge With a continuous wave train we have a still greater diminution but we will not dwell upon this method as it is not yet found to give really practical uses The factor of the brush discharge is an important one in order to prevent explosion of the hydrogen of the balloon as we will further see

To install a wireless plant upon an airship we must evidently use a mounting with counter wire analogous to Fig. 2 On the other hand as it is shown that the brush discharges produced at the ends of the antenna and the counter wire will ignite the hydrogen we must reduce this discharge to a minimum and to do this we use musical sparks. Besides it is required to suppress or mask all sparks which may be formed in the air, especially in the wave-generating apparatus which may cause an explosion in the hydrogen escaping from the balloon. It is also prudent in all cases to quite avoid making a transmission when the balloon valves are opened, or when there is an accidental rent in the envelop Various dispositions for the aerial and the counter-wire are used according to the different types of balloons In all cases we generally form the aerial by a single wire from 100 to 200 meters (328 1 to 656.2 feet) in length which is hung down from the nacelle after having somewhat loaded it so as to avoid difficulty when the airship is moving. As to the counter wire system it can be planned in several different ways.

First: By using the metallic mass of the nacelle and suspension wires. However the balloon proper must be sufficiently distant from the metallic extremities of the steel suspension wires, etc., so that the electric discharges produced at these points have no risk of [illegible] the hydrogen which may come from the balloon. A distance of [illegible] meters ([illegible] feet) is sufficient [illegible] to provide any metal- [illegible] balls so as to [illegible] such [illegible] the Renard type of airship for instance we may use the mounting shown in Fig. 3 The metal parts are shown in heavy lines and the transmitting and receiving apparatus *E R* are here shown outside of the nacelle for clearness In the Gross type (German) we can proceed in an analogous manner (Fig 4) and the counter-wire system is formed by the steel work from which the nacelle is suspended together with the nacelle itself

Second If the linear dimensions of the metallic masses are not sufficient for use as a counter system we can add insulated wires suspended from the balloon body so as to lengthen the former For instance in the Parseval type (German) the counter system can be formed as Fig 5 shows and the extra metal wires *F F* make up a counter system and are quite insulated from the mass of the balloon and well away from it.

Third In airships having a metallic framework like the Zeppelin or a metallic platform as in the Republique, it would be quite imprudent to incorporate such in the wireless circuits It is preferable to make a special counter system by means of metal wires quite insulated from the metallic mass and far enough away from it to avoid any accidental contacts between the live and the dead metal during the signaling for we would give rise to sparks in the metal Moreover as even the dead metal will have oscillations set up in it by induction dangerous discharges might be produced at the pointed parts of the metal It is a good plan to section the metallic cables as much as possible by insulating pieces for the electric discharges will be weaker as the dimensions of the metal parts are less. In Fig 6 we observe such a method which could be used on the Republique type. It is also proposed to form the counter system by a metal wire which is held by a kite and this could be applied to any type of airship but the kite might hinder the proper movement of the airship In cases where we have a very long nacelle the aerial and counter system could be placed in symmetrical positions (Fig 8) at *A* and *C* both of them being insulated from the metallic mass of the nacelle Such a method has the drawback of not giving the same working range in all directions, as the waves radiated from *A* will interfere with those from *C* There will be thus a maximum range in one of the planes and a minimum in the other



DIAGRAMS OF WIRELESS WORK IN CONNECTION WITH AIRSHIPS

As regards the sparks produced by the apparatus itself at the brushes of the dynamos etc it is easy to take the needed precautions by using wire gauze protectors as we find in miners safety lamps For producing the current there is generally used an alternating current dynamo having a musical frequency which can be connected to one of the shafts by a friction clutch A 2 to 4 horse power size is sufficient in general. As to the receiving apparatus there is nothing special to note However the noise of the motor hinders the reception by means of telephones and we sometimes need to use a coherer and a register so that the apparatus becomes more complicated. It is best to keep the telephone method and use a land station which has enough power to give a loud sound in the telephones. Reception of messages by the airship is besides a secondary matter as the crew has all the needed instructions before the start, and it is not likely that any others would need to be sent while *en route* The reception on board is generally confined to some conventional signals to show when messages are received demands for repeating messages etc

In closing we will mention a few points as to the range which airship plants can reach We must distinguish two classes of range first the range at which the airship messages can be received on the ground and second the range from ground to airship The first of these is the most important It depends upon the energy of the waves and the dimensions of the aerial and counter system It thus depends on the plant which can be realized on the airship but it also varies with the lay-out of the ground plant. When this latter has a large aerial the range is evidently larger than what we have with a small antenna such as the military field posts possess The range of receiving may be very long and reach some hundred miles when we use a powerful land station The total weight of a wireless plant on board an airship varies from 200 to 450 pounds according to the method used and also according to the desired range Given the general conditions of the problem as just set forth we will mention some points about the practical results which have been accomplished It will be remembered that during the last military maneuvers in France a series of tests was carried out with the military airship Bayard-Clement with Capt Ferrié on board and operating the wireless plant Although the full data are not yet made public enough is known to give us encouragement in such work It must be remembered that we have here a trial post in which every factor is reduced size weight and power

The current for the airship post is given by a storage battery using ten cells of the automobile pattern These give 20 volts with a maximum output of about 5 amperes For producing the musical sparks using a vibration period of 250 per second there is employed a vibrator which is specially designed by Messrs Bethenod and Ferrié this being a kind of large tuning fork whose vibration is kept up by electromagnets The sparks are protected by wire gauze covering so as to avoid igniting the gas The total weight of the airship plant is 130 pounds We now have some data as to the power and range It was thought hitherto that we required to produce at least 2 kilowatts power on board the airship in order to have a range of 30 or 40 miles However it is found that signals sent from the Bayard-Clement could be very clearly heard on the ground when working at a range of 100 kilometers (62 miles) using a power below 50 watts (1/15th horse-power) and even probably very near 25 watts or but 1/20th horse-power

---

Wood Pulp

Wood fiber has come into general use as a substitute for the cotton rags and other materials formerly employed in the making of paper This fiber is called pulp having taken the name which used to be given to the cotton and linen fiber when it had been prepared by maceration for spreading into sheets of paper The wood fiber used to be prepared not so many years ago by a wholly mechanical process The blocks of wood were ground or rasped [illegible] applied obliquely to the grain The length of fiber depended partly upon the angle at which the [illegible] was held during this process

In place of the old mode of obtaining [illegible] chemical treatment of the wood is now in vogue As formerly the bark is stripped from the wood to secure fibers of uniform quality All discolored or decayed parts are removed for the same reason Then the wood is cut across the grain into thin chips which are carried to the top of the mill and dropped into large drums about fourteen feet in diameter and twenty four feet long

The drums are made strong enough to bear a pressure of from seventy five to two hundred pounds to the square inch When a drum is packed full of chips it is filled with sulphuric acid and other chemicals The wood is converted into a cotton like product which is then pressed dry and mashed It is next mixed with water rolled flat and cut into shape for bundling In this condition it is said to be made up of sixty per cent moisture and forty per cent fiber In this shape it goes to the paper mill Generally speaking it is found better to pay the freight on the contained water than to cheapen the cost of transportation by pressing out the water for the pulp packs hard when it is dry

One cord of spruce wood is estimated to make twelve hundred pounds of dry fiber

The Bruceton Experimental Mine*

Its Plan and Purpose

By George S Rice, Chief Engineer Bureau of Mines

The explosibility of coal dust in air having been successfully demonstrated in the 100-foot gallery of the United States Bureau of Mines at Pittsburg and in the longer galleries at Lievin France and Altofts England the next step in the investigation of coal dust explosions by each of the experiment stations was to determine the exact conditions under which such explosions took place When these conditions were understood tests of various preventive measures could be undertaken with some degree of precision Prevention or at least limitation of explosions in mines was of course the real objective of the stations

The gallery at Lievin a short length of which was erected in 1908 was gradually lengthened to a distance of 8 0 feet the one at Altofts also erected in 1908 was about 900 feet long as originally laid out In both these galleries the limitation of strength prevents safe loading with pure coal dust for more than a distance of 400 to 500 feet on loading beyond this distance the galleries are sometimes ruptured The managements of these stations have expressed the desirability of making tests of coal dust in longer and stronger galleries since it is impossible to solve all the problems surrounding an explosive wave in the short distances now available moreover methods of limiting an explosion which were successful with a loading of coal dust for a length of 300 or 400 feet would probably not be so with a longer loading or a larger explosion

The Director of the Bureau of Mines Dr J A Holmes and his technical staff at an early date appreciated these unavoidable limitations of a surface gallery hence desired to obtain an underground gallery or mine opening which would not only enable the tests to be made on a larger scale than is possible in external galleries but in which experiments could be made under actual mining conditions. In such an underground gallery there would be no restriction as to the extent and violence resulting from explosion experiments provided a suitable location was secured Moreover the methods of limiting and preventing explosions the real objective of all such investigative work could be tried out under real mining conditions

It was foreseen that the greatest difficulties in experimenting in an underground gallery would be

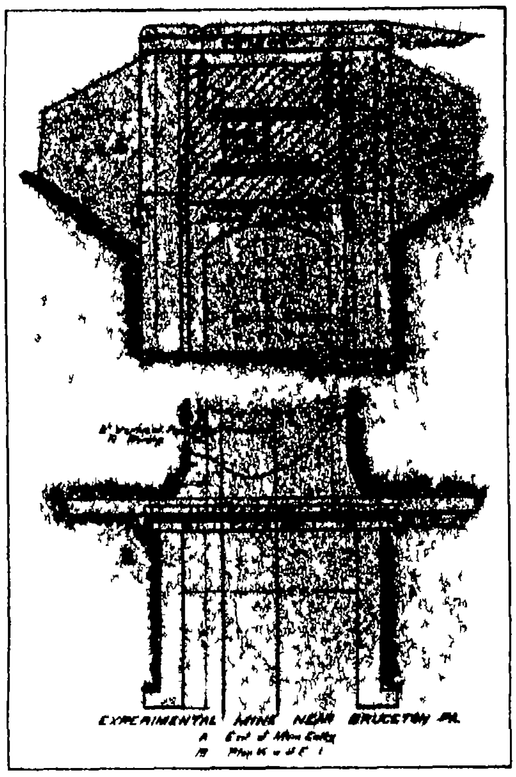
(1) To obtain certain desired natural conditions

(2) Having obtained those to carry out and control the experiments in a scientific way and be able to get complete records in the face of violent explosions

After a long search a location for the experimental gallery or mine has been selected near Bruceton Pa

From 2 500 to 3 000 feet of straight entry can be driven from the outcrop in the Pittsburg seam In some of the mines operating in the seam in the past great explosions have occurred

The entries will probably be either level or slightly rising except for irregularities so that there will be no serious problem of drainage The entries enter from a steep side hill and a cover of from 60 to 160 feet is obtained The openings are well located with reference to explosion effects as there are no houses in the vicinity except those in connection with the plant The mine is fairly close to a railroad (one third mile) so that the coal dug in advancing the entries can be loaded on railroad cars By damming a ravine close at hand water can be obtained for a boiler plant and fire protection Natural gas for experimental purposes and for use in a gas incline engine and fan engine is obtained from a pipe line which passes a few hundred feet from the mouth of the mine Finally the situation is near enough to Pittsburg to allow convenient movement of the engineers and physicists between the testing station there and the mine The location of the mine is twelve miles southwest of Pittsburg on the Wheeling division of the B & O Railroad The coal and necessary surface surrounding the mouth of the mine has been obtained at a nominal rental from the Pittsburg Coal Company



ELEVATION AND PLAN VIEW OF ENTRANCE TO EXPERIMENTAL MINE

PROGRESS AND DEVELOPMENT —After a long continued search for the best location which would give the desired conditions the present site was picked and about the middle of December permission was obtained from the Secretary of the Interior and the director to proceed with the laying out of the mine The surveys already having been made the outcrop was uncovered and two parallel entries with forty feet of pillar between them were started At the time of writing this description these entries have been driven in under cover over 200 feet The right hand one which will be considered the main entry was started in the lower part of the coal seam taking the top of the limestone which is 5 feet below the coal seams as a floor Between the limestone and the coal seam there was at this point a hard shale, the entry was excavated in this and in 3 feet of the lower part of the coal seam leaving up for a roof about 2½ feet of the main seam

After going in about 50 feet in this manner, the floor was gradually raised on an upgrade until the excavation was wholly in the coal seam and the draw slate above it The so-called "draw slate is a soft shale or clay which comes down immediately on mining the coal Above it, as is generally the case in the Pittsburg seam in this district there is 1½ to 2 feet of so-called 'roof coal," which is generally of poor quality and interspersed with layers of shale.

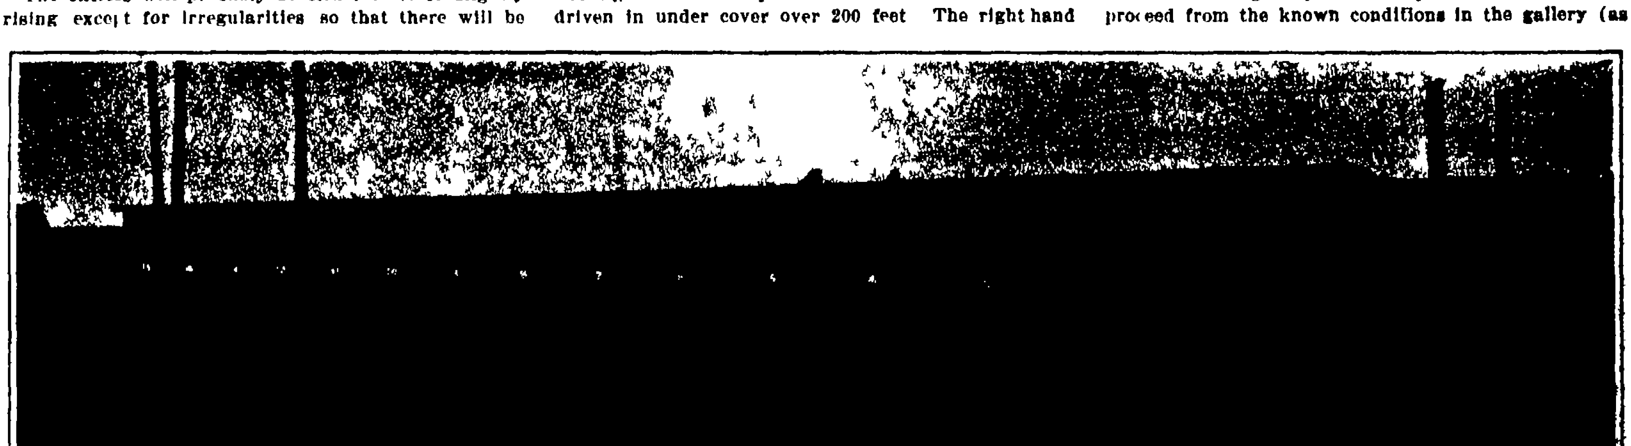
The parallel entry which will be called the air course, was driven wholly in the coal seam It is not intended to use the mouth of this entry in explosion tests. For normal driving, this air course will be the return, and ventilation will be obtained by a small fan driven by a gas engine located at the top of a small upcast shaft near the mouth of the air course This shaft will be offset from the air course about six feet

There will be another entrance to this air course joining it at about 150 feet from the mouth and entering at an angle of about fifty five degrees on the opposite side from the main inlet At the mouth of this side approach there will be placed a short length of concrete gallery with explosion doors and beyond that a round steel gallery 120 feet long 20 feet of which will consist of removable sections that can be rolled out of the way when it is desired to isolate the 100 foot gallery This part will then be identical with the 100 foot steel gallery at the Pittsburg station except in having a branch going off from it at a short distance from the inlet to which a large reversible fan will be connected The object of having this steel gallery which is 6 feet 4 inches in diameter separable from the mine is to render it possible to perform experiments similar to those conducted at Pittsburg The gallery at Pittsburg is so continuously occupied with the testing of explosives that systematic testing of coal dust cannot be undertaken in it When the removable sections before mentioned have been rolled to one side and a steel door lowered in place to cover the connection into the air course experiments can be conducted in the isolated gallery without interfering with operations in the mine

DUST TESTS IN THE MINES —At the start it is intended that coal dust explosions will be originated in the steel gallery and the explosion will enter the air course through the branch pass up same to the last open crosscut through the latter into the main entry and out to the mouth of same The crosscuts will be driven on a circle tangent to the entries This will require one forty five degree turn and one semicircular turn of the explosion wave a condition which seems to cause no obstacle in a real mine explosion nor does it cause difficulty in the Altofts gallery The records of experiments in that gallery show that on the return side that is toward the exhaust fan the dust carried by the air current and the advance compression wave of the explosion has been inflamed and the flame has passed around a number or all of the five right angled turns in that gallery

The purpose of this method of initiating explosions in the outside gallery of the experimental mine is to proceed from the known conditions in the gallery (as developed at the Pittsburg gallery) to the unknown conditions prevailing in mine entries There is also another object that while entries are being driven, it will give double the length of travel for the explosive wave and thus allow the trying out of the mathematical instruments, before passing on to the final explosion experiments which may be originated in the interior of the mine.

FIRE DAMP —Besides making investigations of the explosibility of coal dust in pure air, it is intended to make tests with small percentages of methane in

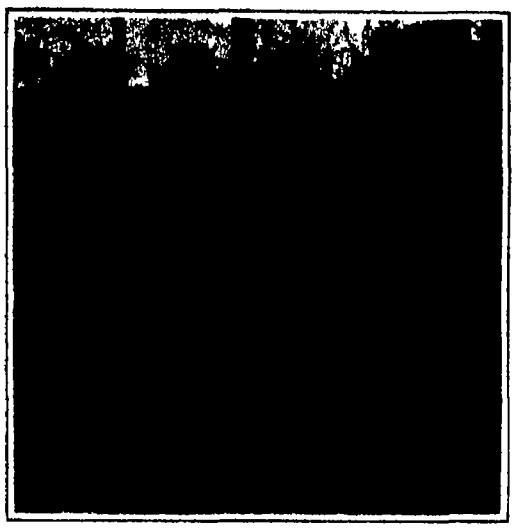


EXPLOSION CHAMBER SHOWING A SERIES OF WINDOWS AND PORTHOLES AT THE SIDE

* This paper has been prepared for West rn Society of Engineers by permission of the Director of the Bureau of Mines.

the air It is generally recognized that a very slight amount of methane, even as low as one-half per cent, may increase the chance of ignition of coal dust and more widely extend an explosion that has once been started

The location of the experimental mine is fortunate in having a natural gas-pipe line near it. This line takes gas from some gas wells in the same ravine It is intended to take a branch from this gas main for use in a gas engine hoist and in a gas engine for driving a small ventilating fan. It will also be used for



ENTRANCE TO THE EXPERIMENTAL MINE NEAR BRUCETON PA.

the purpose above indicated of introducing when desired small quantities of gas into the mine

Natural gas has very nearly the same composition as the marsh gas of the coal seams the difference being that in addition to the methane (CH_4) there is from 10 to 15 per cent of ethane (C_2H_6) This slightly varies the proportion of the mixture of air for its combustion but the difference for practical purposes is negligible

The gas will be piped to certain points and by a system of mixing with the ventilating current will be carried through in whatever proportions may be required approximate percentages will be determined through meter measurements and precise determinations by sampling the air and gas mixture and analyzing It is considered that this line of investigation of the effect of small percentages of methane is most important and the need for it has been expressed by foreign critics of coal dust experimentation now being carried on

Concrete Lining —It is anticipated that great explosive force will be developed at the mouth of the main gallery hence it is intended that the timbering which is now in place shall be supported by reinforced concrete walls and arching The latter will present a smooth surface to the explosive wave and thus prevent great falls at the mouth of the mine the occurrence of which would lead to heavy expense and delay in clearing up after each experiment.

It is the plan to concrete the approach leading from the steel gallery to the air course, and it may become necessary to concrete between this connection to the mouth of the air course, although it is not intended to load that portion of the air course with coal dust It is expected that the explosion wave entering from the gallery entrance will not have gained sufficient momentum at the junction with the air course to break down doors or stoppings erected between that point and the mouth of the air course but will be deflected into the air course toward the face

Method of Driving Entries —The method of driving entries is the usual one employed in the Pittsburg coal seam The coal is undercut and shot down with explosives which in this case are of the permissible type electrically fired The coal is loaded on pit cars which are hauled by mules to the mouth of the mine, thence over an outside tramway with slight descending grade to the head of a rope incline Trips of cars are lowered by the hoist under brake to a trestle and tipple located on a siding of the B & O Railroad

Buildings and Apparatus —It is necessary to have a considerable number of buildings these are now under construction There will be a boiler house with boiler to furnish steam for the several engines including the fan engine A crusher and grinder house will be necessary to grind up the dust for the experiments as much as four tons will be necessary when the mine is fully developed There will be a blacksmith shop containing small equipment for the necessary repairs and an engine house for the incline engine There will be a combined office and observation room for observations and the starting of explosions in connection with which there will be a small laboratory for field analyses of gas and mine air samples Several small buildings including a stable for the mules have already been constructed

Ventilating Fan —The ventilating fan for the experiments must be of such size as to create all the conditions which may surround an explosion in a mine It is desirable to obtain high velocity in restricted areas say 1 500 feet per minute over a considerable distance A capacity of 80 000 cubic feet per minute at a pressure of two inches water gage and 15 000 cubic feet per minute at a pressure of six inches water gage is specified and has been guaranteed by the builders The fan is made reversible so that experiments may be conducted with dust explosions going against the air current as well as dust explosions going with the air current The Altofts gallery fan is not reversible and the explosion portion of the gallery is at the intake end

Pressure and Recording Instruments —The important objects of the experiments are to obtain the speed of the explosion as indicated both by pressure and by flame the variation in pressures at different points along the course of the explosion the temperatures and the samples of the gases immediately preceding the inflammation of the dust or gas and immediately following the inflammation at a given point Such experiments will require apparatus of an extremely sensitive nature

A set similar to those used in the Altofts gallery has been purchased from the Cambridge Scientific Instrument Company of England These were designed primarily for external galleries but it is believed there will be no serious difficulty in arranging them in steel plate boxes sunk into the coal rib It may be found necessary to design new and additional apparatus

An important point in the use of the recording instruments is their driving also the making and breaking of electric circuits To connect these instruments with the outside will require the wiring to be done in such a way that it will not be torn out by the explosions It is proposed to place the wiring in pipes placed in a groove in the coal rib and at the mouth of the mine these pipes will be set in concrete but arranged with suitable boxes at short distances apart, so that the wires may be readily accessible.

It is evident that to make the wires safe under the enormous pressures which are expected which may run up to several hundred pounds or more per square inch will need great care To obtain the currents for the instruments will require a very steady running generator engine set It is expected to obtain a set which will be sufficiently large to allow some lighting with incandescent lamps in and around the mine

Limiting or Preventing Explosions —The real importance of the experiments is not the mere study of explosion waves although of great scientific interest,

BOY MINER AND HIS MULE WHO WERE SAVED TOGETHER FROM A MINE EXPLOSION

but to study methods for preventing or limiting explosions It is therefore proposed to experiment with all the important methods that have been suggested up to date among which may be briefly recited watering by water sprays by exhaust steam sprays and by deliquescent salts (Calcium chloride) and by rock and shale dust in various ways It is believed those experiments tried out in a mine on a sufficiently large scale can effectually demonstrate the relative efficiency of the various methods

Explosives A secondary purpose of the experimental mine and by no means an unimportant one is the study of explosives which have been placed on the permissible list for use in gaseous and dusty coal mines—testing them under actual working conditions in coal

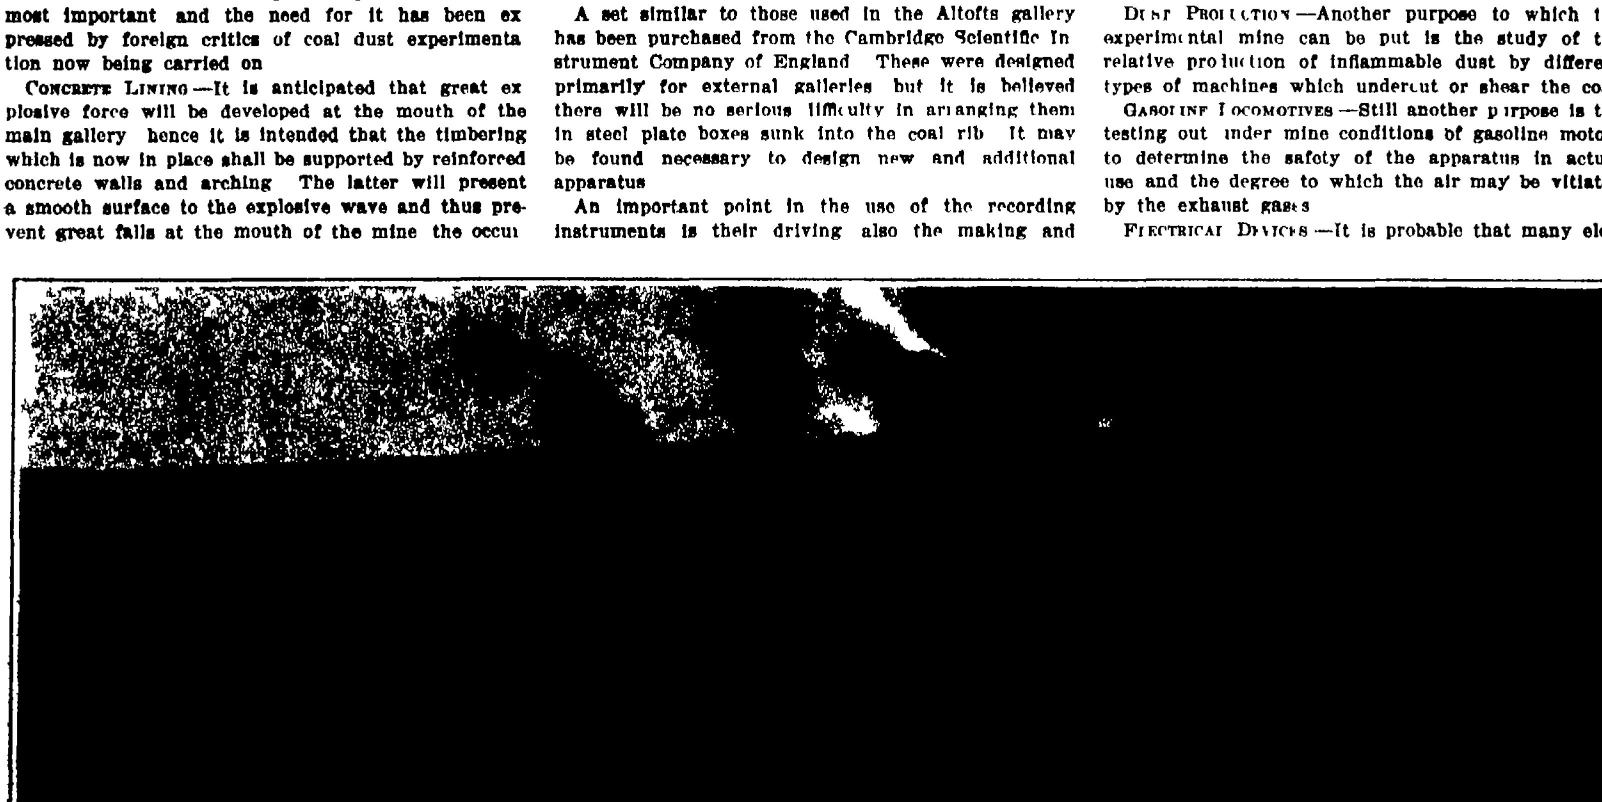
Dust Production —Another purpose to which the experimental mine can be put is the study of the relative production of inflammable dust by different types of machines which undercut or shear the coal

Gasoline Locomotives —Still another purpose is the testing out under mine conditions of gasoline motors to determine the safety of the apparatus in actual use and the degree to which the air may be vitiated by the exhaust gases

Electrical Devices —It is probable that many electrical mining devices can be tried out under actual service together with tests of insulation of wiring

Concrete Also Steel Timbers and Props —The growing scarcity of mine timbers, as well as the danger of fire from their use suggests the importance of testing reinforced concrete timbers and ties also steel props and ties in the experimental mine

The relative advantages of brick arching and reinforced concrete for lining the main entries can also be studied, and under severe conditions



EXPLOSION CHAMBER AT MOMENT OF DISCHARGE

The Production of Light by Living Organisms*

The Chemistry of Biophotogenesis

By F. Alex McDermont,

Division of Chemistry, Hygienic Laboratory, U. S. Public Health and Marine Hospital Service, Washington, D. C.

The term "Biophotogenesis," in its complete sense of the production of light by living organisms, covers a group of phenomena accompanying the vital processes in a wide range of animal and vegetable forms. The fireflies (*Lampyridæ*) are to us the commonest and most brilliant of these biophotogenic forms.

During the summer of 1909 the writer was associated with Professor Joseph H. Kastle of the University of Virginia (then Chief of the Division of Chemistry of the Hygienic Laboratory) in a study of the effect of various chemical reagents on the luminous tissue of the firefly common in this locality (*Photinus pyralis* Linn.), and the results of our work are contained in a paper entitled "Some Observations on the Production of Light by the Firefly," in the *American Journal of Physiology*, Vol. 27, pp. 122-151. At the time this work was started Professor Kastle was engaged in the preparation of his monograph on "The Oxidases and Other Oxygen Catalysts Concerned in Biological Oxidations" (Bulletin No. 59, Hygienic Laboratory), and a latent interest in this subject was awakened by the recurrence of references to the claim of Dubois that the photogenic process in organisms involves the action of an oxidizing ferment or oxidase to which this investigator had given the name "Luciferase." Professor Kastle's prior observations on this point had led him to believe that no oxidase was present, but that peroxidase and catalase were present; he found that aqueous extracts of the luminous tissue of the common firefly failed to turn tincture of guaiacum blue, except in the presence of hydrogen peroxide, and the bluing in the presence of the latter was accompanied by the rapid disengagement of oxygen.

This insect, *Photinus pyralis* Linnaeus, is the one which is so very common in our parks and lawns during the summer. It is a species of the family *Lampyridæ* (fireflies, lightning bugs) of the genus *Coleoptera* (beetles). The luminous apparatus of the male insect—the more commonly seen of the sexes—occupies the entire ventral surfaces of the two abdominal segments next to the last and a portion of the preceding segment. That of the female is a small rectangular area on the third abdominal segment from the last; both sexes have also two very small points of luminous tissue on the last abdominal segment.

The color of the light of this insect is generally stated to be yellow or yellowish green; some of the other local species exhibit a light of a slightly different tone. The light of the *pyralis* has recently been made the subject of a very interesting spectrophotographic study by Drs. Ives and Coblentz at the Bureau of Standards (*Bulletin of the Bureau of Standards*, Vol. 6, pp. 321-316). These observers found the light of this insect to resemble very closely the light of the Cuban cucuyo (*Pyrophorus noctilucus* Linn.), as studied and described by the late Professor S. P. Langley and Professor F. W. Very nearly twenty years ago ("The Cheapest Form of Light," Miscellaneous Collections, Smithsonian Institution, 1901 reprint). Briefly the spectrum of the light of *Photinus pyralis* consists of a structureless unsymmetrical band in the red, yellow, and lower blue portions of the visible spectrum, with a maximum at that portion having the greatest illuminating effect, with the minimum of actinic and thermal effects; it gives no hint of continuation in the infra-red or ultra-violet portions of spectrum. It seems probable that the light of most luminous insects is essentially similar to that of the *pyralis*; two other species of Lampyridæ that I have examined have lights showing spectra of even more limited range than that of the *pyralis*, and in both of these species the color of the light to the eye is more greenish than that of the commoner insect. However, Mr. H. S. Barber of the U. S. National Museum (Proceedings of the Washington Entomological Society, Vol. 9, pp. 41-43) and other observers have reported that various species of tropical *Phengodini* (a group of beetles probably closely allied to the Lampyridæ) give a red light from a photogenic organ in the head; no spectroscopic studies of this light have been made. Max Trautz ("Studien über Chemilumineszenz," *Zeitschrift für physikalische Chemie*, Vol. 53, pp. 1-111) states that the spectrum of the light produced by the oxidation of pyrogallol by means of thirty per cent hydrogen peroxide in the presence of formaldehyde extends from the red to the lower blue, and therefore covers very nearly the same spectral area as that of the light of the firefly. The spectrum of the light of glowing phosphorous also appears to give a spectrum lying within this same area, though of less extent than that of the firefly. Although a little ahead of the subject, I will state here that the light produced by moistening with 3 per cent hydrogen peroxide solution the luminous tissue of the firefly which has been desiccated over sulphuric acid in an atmosphere of hydrogen gives a spectrum of very limited range, extending from the orange to the yellow-green. The spectrum of the light produced by the photogenic bacteria is also of less range than that of the *Lampyridæ*.

It need scarcely be said that the light of the firefly affects the photographic plate, obviously spectrophotographic studies could not otherwise have been made upon it. Dubois has taken photographs by means of the light of the photogenic bacteria and of the cucuyo. In 1896 Muraoka (*Annalen der Chemie und Physik*, Vol. 295, pp. 773-781) announced that he had proved the penetration of metal films by means of the light of the firefly in a manner similar to that of the X-rays. This was very puzzling to physicists in view of the known limited range of the light and the fact that it gave no other evidence of containing ultra-violet or penetrating rays. I have experimented with the local insect (*Photinus pyralis*) and have failed to find the least evidence of penetration of thin sheet copper, aluminium foil or the ordinary black paper with which X-ray plates are wrapped. Some explanation of Muraoka's rather extraordinary results has been offered, based upon some more or less vague bacterial or vapor influence, but when we consider that his results were published only a little while after the discovery of the X-ray it seems possible that Muraoka was just a little over enthusiastic.

Professor Kastle and the writer tried the effect of a large number of chemical substances upon the live insect, the freshly detached luminous organ, and the luminous tissue which had been dried in hydrogen, and for these in detail the reader is referred to the paper in the *American Journal of Physiology*, ante. A great deal of work had already been done along similar lines, some of it dating back to the times of Reaumur and Spallanzani; Ehrenberg, Milne-Edwards and Pflüger have in turn reviewed this literature quite thoroughly.

Some of our results, however, seem worthy of special attention. Taking first the live insect: Injections of solutions of the metallic nitrates, of strychnin and of adrenalin caused the emission of light. Immersion of the insect in methyl and ethyl alcohols, in ether and in chloroform resulted in the production of light. Immersion in pure oxygen appeared to stimulate the photogenic function somewhat, but not as much as might have been expected. Immersion in nitrous oxide caused a considerable increase in the intensity of the light. In the cases of injection and immersion in liquids the reagents kill the insect, but not until they have caused light-emission. Nitrous oxide narcotizes the insect, but in the air it recovers again. Hydrocyanic acid and cyanogen kill the insect, of course, but not until they have caused the emission of light. The luminous organ of one of the local species of *Lampyridæ* has been observed to glow in the mixture of air and prussic acid in the cyanide killing-bottle for over an hour long after the actual death of the insect. Ammonia water causes the evolution of light, either by injection or immersion. Watasé is authority for the statement that if a tissue suspected of being luminous refuses to give light with any other stimulus it will, if a true photogenic tissue, glow on moistening with dilute ammonia water. The injection of 3 per cent hydrogen peroxide solution also caused the evolution of light.

With the freshly detached luminous segments the most notable results were obtained with the vapors of methyl and ethyl alcohols, carbon tetrachloride and bisulphide and mononitrobenzene acting in the presence of air. All of these reagents caused light emission, and the light given out was not the continuous faint glow frequently the result of weak chemical stimuli, but was accompanied by a series of distinct flashes or pulsations of light similar to the normal flashes of the insect. With the detached organ the effect of powerful poisons was in almost every instance to produce the evolution of light, sometimes faint and of short duration, but definite. As examples of poisons acting thus may be cited hydrofluoric acid, iodin cyanide and bromine.

The interesting fact that the photogenic tissue of luminous life-forms preserves after desiccation the power to evolve light on the application of water in the presence of air or oxygen has long been known, and it at once suggests other known instances of the preservation of biologic activity by drying, as exemplified by the yeasts and ferments. By drying the photogenic tissue of *Photinus pyralis* over sulphuric acid in hydrogen or a hydrogen vacuum, we have prepared dry material which has retained its photogenic activity apparently without loss, when kept in sealed tubes for over thirteen months; indeed there seems to be no good reason why, under these circumstances, it should deteriorate. In its conduct toward various chemical substances, the dried tissue after moistening does not differ essentially from the live insect or the freshly detached luminous organ. It glows on moistening in the air, somewhat brighter on moistening in oxygen, and but dimly or not at all when moistened in nitrogen, hydrogen and carbon dioxide. Moistened with 3 per cent hydrogen peroxide instead of water the dried tissue produces a much brighter light than with water alone, accompanied by the decomposition of the peroxide. The spectrum of the light thus produced has already been referred to.

Thus far one substance alone has conducted itself as a positive inhibitor of the photogenic function. This is sulphur dioxide. Carradori observed this fact with the *Luciola italica* over one hundred years ago; Dubois has made a similar observation with regard to the cucuyo. The live insect, the freshly detached luminous organ and the dried tissue placed in this gas all fail to glow, or glow but weakly and momentarily, and are dead to all other stimuli when removed from it. As a rule even those substances which tend to poison the luminous tissue caused the evolution of a dim light at first, but not so with sulphur dioxide in the majority of cases in which we used it.

Mechanical stimuli, such as friction and percussion, and physical stimuli, such as electricity, heat and light, also cause the production of light by the luminous organs of the firefly, whether attached to the living insect or detached. The effects of various temperatures and of electric discharges of various strengths have been extensively studied by other observers. Transferring the detached luminous organs from one gas to another, even though one or both be chemically neutral, may cause light production, apparently due to some osmotic effect. Currents of air and other gases exert an effect on these detached organs which Professor Kastle has compared to the effect of air currents on the strychninized frog. It is obvious from these facts that the luminous tissue is one of great irritability.

Our knowledge of the chemical processes involved in biophotogenesis is very meager. The luminous organ of *Photinus pyralis*, in common with those of the other *Lampyridæ* which have been studied, consists of two layers of cells under the outer transparent chitin. These layers of cells are penetrated by numberless tracheæ, the ends of which appear to be connected by a network of very fine tracheoles, the whole system resembling the finer veining of a leaf. On the inner surface of the organ these tracheæ unite to form larger passages. It is practically certain that during the life of the insect these tracheæ are filled with air. Of the two cell layers, the outer consists of a mass of some special type of nucleated cell of unknown nature penetrated by the aerophore cylinders, while the inner layer is composed of guanine and sodium or ammonium urate, and probably serves as a reflector. These guanine reflecting layers have also been found in the luminous organs of various fish and cephalopods, whose names I will not attempt to inflict on the readers of this paper. The luminous apparatus of these fish and other of the higher sea-forms is quite highly developed, there frequently being a definite lens with a light-producing body back of it, and behind this a guanin reflector, sometimes with a roughly parabolic section.

It is pretty well established that all photogenic organisms require at least two constant chemical factors in order to exhibit their luminous property, viz., the presence of oxygen and of moisture. Bischoff has claimed that the photogenic process in the luminous rhizomorphs (mycelia) is accompanied by the absorption of oxygen and the evolution of carbon dioxide, and other observers have made similar

* From a paper read before the Chemical Society of Washington, October 13th, 1910.

claims for other cases of biophotogenesis, my own observations tend to support these claims, but as yet the evidence is somewhat too meager at least so far as the evolution of carbon dioxide is concerned Dubois's theory assumes the oxidation of a substance of unknown composition to which he has given the name "Luciferine, through the agency of the oxidase Luciferase.' Until more definite data are at hand, it would seem that this theory requires some caution in acceptance The facts so far as known certainly present some analogy to other known biologic processes and it is not at all impossible that his explanation may be correct Watasé expresses the view that in *Noctiluca miliaris* and other simple luminous forms the 'phosphorescence is associated with the contractility of protoplasm as a potential property of all protoplasm whether exhibited or not, and he rather leaves the reader with the impression that he believes that the particles of food materials are actually burned in the living tissues with the production of an incandescent temperature (*Protoplasmic Contractility and Phosphorescence* Biologic Lectures Woods Hole Mass 1898) Jousset de Bellesme in 1880 (*Comptes Rendus de la Academie des Sciences* Paris) stated that he believed the light to be due to the spontaneous combustion of phosphine liberated by the decomposition of protoplasm and Sir Humphry Davy noted that Lavoisier held a similar view The nature of the substance consumed in this biologic oxidation—the *Noctilucin* of Phipson the *Luciferine* of Dubois and the *Photogene* of Molisch—has been variously regarded by different authors Many seem to have regarded it as a fat or a fat-like substance Phipson, who apparently isolated and analysed a culture of photogenic bacteria concluded that it contained nitrogen, Kölliker and Macaire believed it to be an albuminous body Embryologically it appears to be an extension of the fat layer Various observers have found the urates and phosphates of ammonium sodium, potassium and calcium in the luminous tissue and its ash Dubois at one time seems to have rejected the oxidation theory and to have believed that the light was due to the spontaneous crystallization of ammonium urate All attempts to definitely extract and analyze the active substance have failed When the luminous organs are treated with alcohol or ether in an atmosphere of hydrogen the liquid acquires a yellow color but no light-emission occurs when it is exposed to the air or treated with hydrogen peroxide Lecithin does seem to exist in the insect in small amount

An interesting circumstance in this connection is the existence in certain luminous organisms of a substance whose solutions exhibit a brilliant blue fluorescence Dubois found this substance in the cucuyo and Dr Coblentz has found it in *Photinus pyralis Photinus corrucus* and *Photuris pennsylvanica* I have found it in *Photinus scintillans* also Dubois regarded the substance he extracted from the cucuyo as analogous to esculin (a glucoside which is present in the bark of the horse chestnut and whose solutions possess a blue fluorescence) and he regarded it as essential to the photogenic process attributing to the actinic properties of the blue rays in its fluorescent light the actinic power of the emitted light of the insect. Personally I am inclined to regard the fluorescence simply as an incidental property dependent on the structure of some compound frequently met with in insects of this nature much as Jordan regards the fluorescent pigment of *Bacillus fluorescens liquefaciens* Fluorescent extracts of the *pyralis* are produced by extraction with alcohol ether and water but not by chloroform benzene or carbon tetrachloride The fluorescent material is not precipitated by lead acetate mercuric chloride ammonium sulphate nor chlorplatinic acid It appears to be a solid at ordinary temperatures though as emitted by the insect it is contained in a sticky exudation which soon hardens in the air

We cannot say now what possibilities lie before us in the discovery of the secret of the firefly particularly as to the kind of oil he uses in his little lamp Perhaps it will be discovered and turned to practical account The emitted light of the firefly is far from being a good light for general illumination in spite of its luminous efficiency of 96 5 per cent on account of the very limited range of color effects possible under it A single firefly has been variously estimated to give from 1 840 to 1 1600 of a candle power so we would need quite a high firefly power to light our homes and streets by biophotogenic light There are still many gaps in our knowledge of this interesting subject in spite of the large amount of work that has already been done but one by one we hope to close these up and discover the secret of The Cheapest Form of Light

The Camphor Industry*

Japanese and Formosa Methods

Camphor produced from the camphor tree (*Cinnamonum camphora*) has a large use not only as a drug but more especially in the celluloid industry where it is used in the transformation of cellulose nitrate to celluloid It is used extensively in the manufacture of smokeless powder in the making of substitute leathers and generally in the plastic pyroxylin industry

Imports of crude camphor into the United States for the fiscal year ending June 30th 1910 were 3 026 648 pounds valued at $921 926 refined and synthetic camphors added to this 477,269 pounds valued at $179 965

The sources of camphor are practically all foreign Experimental plantations in the United States will not be ready for production within three or four years and while the indications are all toward the success of this venture the commercial production of camphor on a large scale in this country is not to be expected in the immediate future

At present barring the production of synthetic camphor our sources of supply are the East Indian Islands Borneo Sumatra and particularly Japan and Formosa In Japan and Formosa the camphor trade is a government monopoly All camphor and camphor oil produced must be sold to the monopoly bureau The amount of camphor to be placed on the market the price to the producer and to the vendee are fixed by the government

The privilege of engaging in the industry is granted by the government to individuals and companies on application The applicant is required to furnish some evidence of his financial standing A certain territory is allotted to each operator and he must confine his operations to that tract.

The trees are found only in mountainous districts In Formosa they are in the interior, where the collection of camphor is rendered hazardous by the presence of the head hunting tribes which infest the region Conditions have improved in this respect since the Japanese occupation of the island owing largely to the conciliatory policy adopted by the Japanese officials yet in 1909 there were 96 workmen killed by the savages Owing to the danger of attacks by the tribes wages are high being 90 cents gold for a native and $2 for a Japanese

The condition and extent of the forests have been variously estimated It is sometimes stated that the camphor forests are inexhaustible Again it is estimated that the Formosan forests will be exhausted in twenty years. As a matter of fact the truth is between these limits, perhaps forty five years of production at the present rate will use up all the trees now workable.

However, the government and private individuals have been planting young trees. About 15 000 000 trees have been set out since 1901 and with a continuance of the policy of yearly planting it is probable that there will always be a sufficient supply of producing trees.

All camphor trees do not produce camphor. In Borneo for instance it is said that only one tree out of 100 bears camphor crystals The lumber from the trees is valuable however and is much used for building as it is less subject to the ravages of the white ant than most woods If the camphor odor is quite strong the boards may be used for insect proof boxes

In selecting the trees which are to be treated to extract the camphor there is nothing in the outside appearance to guide the searcher Chips are taken from the trees and if the camphor odor is absent the tree is not cut The trees sometimes are 3 or 4 feet in diameter and 180 feet tall If the odor from the chips is sufficiently strong a search is made over the tree for a flaw in which the camphor gum may have collected The tree is cut off below the flaw and the wood split away in order to find the deposit. The flaw may be from 4 to 6 feet long and may contain up to 14 pounds though 7 pounds would be above the average

In Japan and Formosa the body of the tree which contains camphor is cut into chips by the workers who use for this purpose a chisel like knife The finer the chips the more suitable they are for distillation They may be taken from trunk limbs roots or twigs The chips are now distilled in an apparatus of native manufacture which is crude but better than mechanical devices which have been imported from Europe

Over a fireplace is a pan filled with water Above the pan is a very tight circular wooden retort about 3 feet in diameter at the bottom and 1 foot at the top and 5 feet high.

This retort is filled through an opening in the top with the camphor wood chips The opening is then closed by a double lid and earth banked around the lower section of the retort prevents the escape of the camphor fumes. Just above the water pan are thin slats of perforated bamboo through the apertures of which steam passes into the chips above extracting the camphor Near the top of the retort are two bamboo pipes through which the vapors are conducted to a cooling box about 10 feet distant This cooling box is divided into two compartments the lower is filled with cool water and the upper contains a wooden screen upon which the camphor crystallizes Connected with the cooling box is another of exactly similar description called the crystallization box Both are immersed in water which hastens the process of crystallization Distillation requires about 24 hours The chips are then removed through an opening in the lower section of the retort

The two products of the distillation are crude camphor and camphor oil The camphor is crystallised on the screens of the boxes The oil is caught in leads and also skimmed from the water in the cooling boxes.

The camphor and camphor oil thus obtained are shipped to Kobe Japan where the camphor oil is further treated It is heated in small cast iron stills and the fraction having a specific gravity 0 825 to 0.980, which contains 45 to 55 per cent of camphor, is cooled to allow the camphor to crystallize out. When ready the crude camphor is drained out of the oil by filtering through cloth bags

After draining for a few days this product is packed in tubs and after some months gives by rearrangement crystals quite as large and firm as those of the crude camphor produced from the wood

These two grades produced from the wood and from camphor oil when mixed at the monopoly plants constitute what is known as grade B or commercial crude camphor This is used by the American trade

In the government refineries the B grade is somewhat purified and yields the BB grade which is exported along with the B grade to European markets This is also the grade supplied to the seven companies licensed by the government for refining They sublime the camphor producing a clear block of pure camphor

There are two kinds of camphor on the market—the Japanese $C_{10}H_{16}O$ or ordinary camphor and Borneo camphor obtained from *Dryobalanops camphora* $C_{10}H_{17}OH$ The latter is more expensive owing to the demands of the Chinese trade and is seldom in American or European markets It can however be produced by reduction of ordinary camphor The odor of Borneo camphor or borneol is much like that of ordinary camphor but it has in addition a somewhat peppery smell

The tremendous increase in the use of camphor caused an increase in exports from Japan and Formosa from 620 000 pounds in 1868 to 8 427 000 in 1907 and at the same time a rise in price of from $16 42 to $168 50 per 220 pounds Owing to the extraordinary prices industrial chemists were led to investigate the question of producing synthetic camphor with such success that in 1905 and following they were able to compete with the natural product In 1908 the effect upon the market of synthetic camphor was such as to reduce imports of natural camphor nearly one half as compared with 1907

Immediately following however Japan and Formosa were able to quote prices so low that practically all of the firms manufacturing synthetic camphor have been forced to discontinue operations and natural camphor not only has regained its old market but is striving with success to find new ones mainly in the extreme East It is true however that the rapidly increasing price of turpentine may have had something to do with this condition of affairs and also that in a few cases notably that of the Chemische Fabrik a A vorm A. Schering of Berlin it seems possible to make the artificial product and keep its market under present conditions

Many patents have been taken out covering processes for the formation of synthetic camphor but all are attempted improvements on the one original discovery—i e that pinene a hydrocarbon in turpentine could be converted

The methods for effecting the transformation are various but all follow practically the same line Pinene $C_{10}H_{16}$ is treated with HCl or oxalic acid In the first case the pinene hydrochloride is heated under pressure with acetate of lead in acetic acid, causing

* From U. S. Consular Report.

the formation of camphene which has the same empirical formula as pinene $C_{10}H_{16}$ but is of a different structure and is therefore easily oxidized to camphor potassium permanganate being used to produce the change.

In the second case where oxalic acid is used instead of pinene hydrochloride we have a mixture of camphor pinyl formate and pinyl oxalate. This is washed with water and the oxalate and formate are saponified whereby camphor and borneol are formed. The mixture is distilled and the borneol is oxidized by means of chromic acid to camphor. Other modifications are very numerous over 200 patents having been taken out but these two examples are sufficient to show the general lines on which the synthesis is carried out.

The firm of A. Schering of Berlin which has been able to continue the manufacture does not disclose its special methods and laboratory equipment. It is generally understood that it has followed along the lines of original German patents the second case previously mentioned. How much further it can follow a downward move in prices is not known, but competent persons feel that the limit will soon be reached.

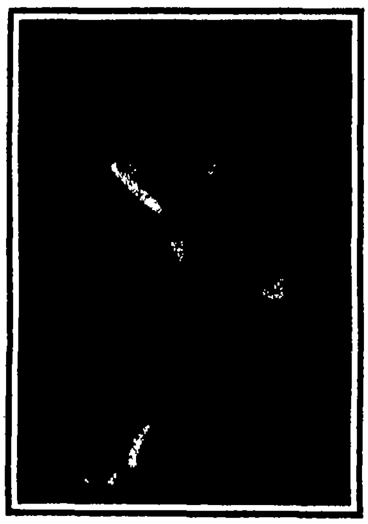
The establishment of the industry in the United States might not be so difficult. The obtaining of turpentine is an easy matter and while not considered so good as the French turpentine the American ranks next in favor with manufacturers.

Another fact in favor of American manufacturers would be the import duty of 6 cents per pound which is levied on both refined and synthetic camphor.

A Quarter Century of Experimental Embryology

Wilhelm Roux and His Work

Twenty-five years have passed since Wilhelm Roux published his first contribution to the mechanics of development, in which he indicated an effective method of analyzing the complex process by which an individual organism is developed and described a series of preliminary experiments. He had previously published observations and a theory of the functional adaptation produced in organs by exercise in performing special functions.



PROF. WILHELM ROUX

Wilhelm Roux who is now professor of anatomy at Halle received on his sixtieth birthday June 9th 1910 an honorary address signed by more than eighty men of science.

The following sketch of the new branch of science by Prof. Albert Halle in the *Illustrirte Zeitung* is based chiefly on its founder's own work.

Experimental embryology or the mechanics of evolution deals with the development of the complex living organism from the apparently simple egg. The only effective method of studying the causal factors of this development is found in selective experiment guided by a mental analysis of the complex phenomena. Roux began by determining the epoch of the first conspicuous change in the egg the establishment of the principal axes of the embryo and subsequently succeeded in discovering the factors which normally produce this change. Some of the initial stages in the development of a frog embryo are shown in Figs. 1 to 5. Roux first proved by experiment that in normal development the deep furrow which appears soon after fertilization and divides the egg into two equal segments (Fig. 3) subsequently becomes the plane of symmetry between the right and left halves of the embryo (Fig. 5). The next question was whether or not the future position of the plane of symmetry is indicated in the egg before fertilization.

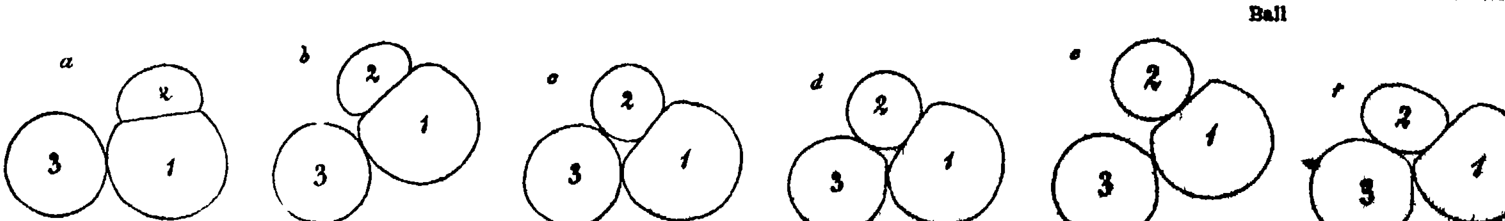
Fig. 26.—Cell-destroying Needle With Heated Brass Ball.



Figs. 19 to 24.—Another Example of Cytotropism, or Elective Affinity of Cells.

The egg of the frog (Figs 1 and 2) is composed of a dark and a light hemisphere The material of the dark hemisphere is employed chiefly in forming the embryo while the light hemisphere consists principally of food for the growing embryo These food stuffs are heavier than the contents of the dark hemisphere. Shortly after fertilization when the egg has become free to rotate in the rim by which it is attached to its environment (Fig 2) it turns so as to bring the dark hemisphere above the rim and the light hemisphere below In the egg of the green water frog this adjustment is not made accurately but the division between the light and dark hemispheres is considerably inclined as is shown by the side view (Fig 1) and the view from above (Fig 2)

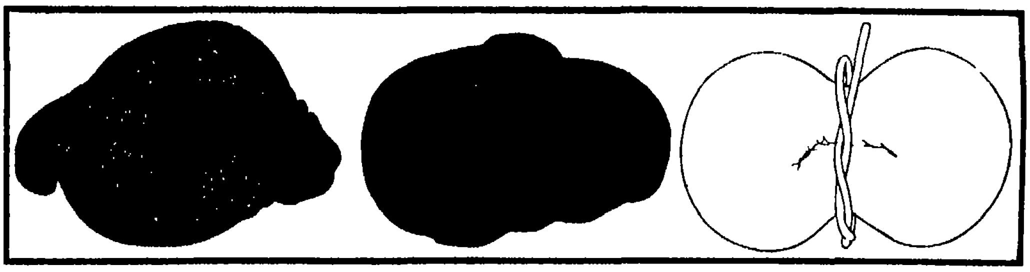


Fig 27—Embryo Developed From Left Half of Frogs Egg

Fig 28—Embryo Developed From Front Half of Frogs Egg

Fig 29—Salamander Egg Constricted to Form a Double Monster

It was found that the first segmentation furrow (Fig 3) divides each hemisphere symmetrically and that the head of the embryo is always formed at that end of the egg (the right end in the illustrations) where the light-colored hemisphere is partly visible from above the opposite end corresponding to the tail of the embryo Unfertilized frogs eggs floating motionless on a solution of albumen also assumed an oblique position Hence the direction of the axis of the embryo and the position of the plane of symmetry appeared to be indicated before fertilization but it was proved by very ingenious experiments that the oblique position first assumed is changed after fertilization so that fertilization is required to determine the exact position of the axis. Then Roux succeeded in fertilizing the egg along an arbitrarily selected meridian by making an incision and thus enabling some spermatozoa to gain a headway of several minutes over the rest This meridian always assumed a vertical position coincident with the first furrow and the plane of symmetry Other experiments showed that this result was due to a re-arrangement of the yolk caused by the spermatozoa and that still greater changes could be produced by holding the egg in arbitrary inclined positions

The dark upper hemisphere had been assumed to correspond to the back of the frog but Pflueger and Roux have proved that the brain and spinal cord are developed from two ridges which originate near the right and left sides of the horizontal equator and descend until they come together at the middle of the light-colored lower hemisphere (Fig 7)

Fig 32—Double Head of Embryo Shown in Fig 31

For the purpose of determining the factors that initiate the process of cell division in the egg Roux divided by means of a glass rod a circular film of oil floating on a mixture of alcohol and water (Figs 8 to 14) He found that nearly all arrangements of cells or segmentation patterns, which occur in the eggs of animals can be imitated in this way and that these patterns differ only in the relative sizes of their segments and the order of arrangement of large and small segments.

"Artificial diminution of some of the segments was found to produce the same result in oil drops and in living eggs, if effected soon after segmentation

Roux also discovered phenomena of attraction which he called cytotropism, between detached cells of the egg When a frog's egg which had developed numerous cells was shredded, immersed in a suitable liquid and examined with a microscope, detached cells were seen to approach each other with an intermittent motion When several cells have come close together the phenomena become more complex Two cells may come together unite closely and then separate and form other associations In Figs 15 to 18 the cell 1 attaches itself to 3 then separates and forms a closer union with 5 In Figs 19 to 24 the approach of cell 3 causes 2 to leave 1 and attach itself to the newcomer

As the nuclei of the spermatozoon and the ovum approach each other in a straight line from a relatively great distance inside the egg Roux endeavored to bring about a similar result with lifeless matter He found that drops of chloroform floating on a saturated solution of carbolic acid approach each other from great distances but that this apparent attraction is caused by repulsion between the drops and the solution and by the one sided protection against this repulsion which each drop affords the other (Fig 25)

More than twenty years ago Roux discovered that when one half of a frogs egg in the first stage of segmentation (Fig 3) was destroyed with a specially constructed heated needle (Fig 26) the remaining segment could develop into a perfect right or left half or even a front half of an embryo The ceiling of Roux s private laboratory is decorated with copies of these monstrosities (Figs 27 and 28) Before this discovery it was assumed that the whole egg was required for the normal development of each part of the embryo

Equally surprising was the discovery that one of these half embryos can supply the missing half and develop into a complete embryo by a process which Roux has named postgeneration Several experimenters then succeeded in producing two complete embryos by separating the two first segments of one egg by various methods and evenly constricting with a thread an egg in an advanced stage of development (Fig. 29) Fig. 31 shows a double salamander with Spemann produced by this latter method Fig 32 the structure of the double head and Fig 30 the normal single form

Conversely it has been found possible to combine two eggs to form a single embryo and to graft two embryos together to form a double monster The parts of these monsters developed independently until they died of inanition (Figs 33 to 38) The operation succeeded even with tadpoles of two different species (Figs 37 and 38)

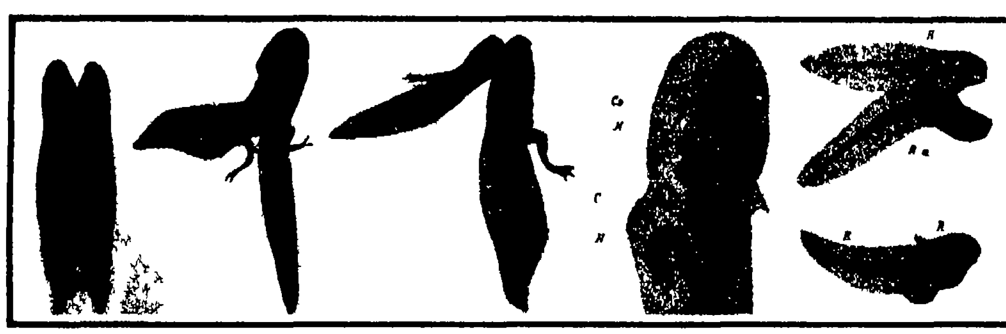
Examples of independent development of parts of

Fig 30—The Embryo of a Normal Salamander

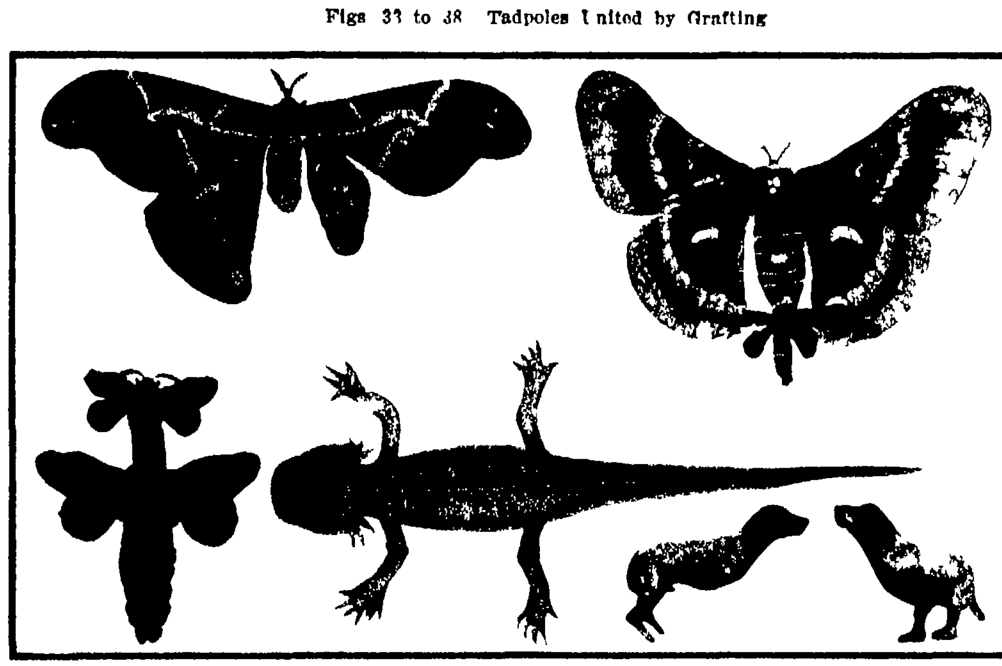
Fig 31 Double Embry Produced by Constricting Salamander Egg

the embryo have been observed also in insects The American biologist Crampton has produced monstrous butterflies of astonishing forms by combining parts of pupæ belonging to different species (Figs 39 to 41)

Barfurth and Tornier have produced amphibia with supernumerary toes by amputating limbs slitting the stumps and keeping the wounds open (Fig 42) Double tails were produced by a similar process The fact that an artificial division produces additional toes or tails and not merely a cleft foot or tail is very important in connection with the causal factors of development



Figs 33 to 38 Tadpoles United by Grafting



Figs 39 to 41—Grafted Butterflies

Fig 42 Axolotl with Supernumerary Toes

Figs 43 and 44—Kangaroo x Dogs

Some of these amazing results plainly indicate that the individual is not developed according to the same fixed plan in all circumstances but that the embryo is able to adapt its development to various conditions For this and other reasons Roux thirty

years ago recognized automatic regulation of function as an essential and characteristic property of living organisms. *In post-embryonal life this regulation is manifested chiefly in recovery from disease and in the functional adaptation to which allusion has already been made.*

A very interesting example of this functional adaptation was observed by Fuld, a pupil of Roux, in the case of dogs born without fore-legs, which stood and hopped in the manner of kangaroos (Figs. 43 and 44). When these dogs had attained their full growth Fuld found that their thigh bones, originally shorter than the lower leg bones, had become longer than the latter, as is the case in kangaroos. These interesting creatures have been jocularly named kanga-Roux dogs. Another pupil of Roux found a similar excessive development of the thigh bone in four members of a Polynesian tribe of crouching habit.

In conclusion I will mention an experiment which may indirectly affect surgical practice. Prof. Kaneko of Japan, working in Roux's institute, inserted silk fibers round the bones of narcotized dogs through and beneath the muscular attachments. The silk became covered by a sheath of cartilage, such as is normally formed over a nerve or a blood vessel which occupies a similar position relatively to a bone in the embryo. Furthermore, Levy has shown that tension can cause the formation of connective tissue along the line of stress.

The important and surprising results obtained by Jacques Loeb, Edmond Wilson and many other workers in this new field cannot be here described. Enough has been said to show the great theoretical importance of this line of research. The art of medicine, especially *in its surgical and orthopedic departments*, will also gain thereby. A beginning has already been made in the "analytical orthopedy" which was theoretically formulated by Roux twenty years ago. In this method the orthopedic capacity of every tissue involved in a malformation is deduced from experiments on animals or from the results of surgical operations, and the knowledge thus obtained is utilized in devising treatments adapted to each tissue. Furthermore, many bold and successful new surgical operations, such as the transplantation of the kidney, are based on the principles laid down in the essay on "The Conflict of Parts in the Organism," which Roux wrote many years ago.

Road Making in the United States

The Present Status of the Use of Bituminous Materials

The development of the use of bituminous materials in the construction and maintenance of roads in the United States since 1908 is worthy of careful *consideration and critical analysis.*

The bituminous materials which have been used in the United States during the past three years may be classified as follows: Fluxed native asphalts, oil asphalts, residual asphaltic and semi-asphaltic oils, light oils, coke-oven tars, coal-gas tars, water-gas tars, and combinations of coal-gas and water-gas tars, combinations of asphaltic materials and tars.

The nomenclature used to designate the various kinds of tars is self-explanatory. In order to avoid misunderstanding, the terms used in connection with asphaltic materials will be defined, the definitions given being abstracts of those proposed by Prevost Hubbard, chemist, United States Office of Public Roads.

Fluxed native asphalts are native asphalts fluxed with a heavy petroleum residuum. Native asphalts are solid or semi-solid native bitumens consisting of a mixture of hydrocarbons of complex structure, *free from any appreciable amount of solid paraffins,* melting upon the application of heat, and evidently produced by nature from petroleums containing little or no solid paraffins. Unrefined native asphalts with few exceptions contain water, vegetable matter, clay, sand, etc.

Oil asphalts are solid or semi-solid products produced by the distillation of semi-asphaltic and asphaltic petroleums.

Residual asphaltic and semi-asphaltic oils are heavy viscous residues produced by the evaporation or distillation of crude asphaltic and semi-asphaltic petroleums until at least all of the burning oils have been removed, and often some of the heavier distillates as well.

The term light oils includes crude and partially refined paraffin petroleums, semi-asphaltic petroleums and asphaltic petroleums.

Paraffin petroleum is an oil the base of which is composed *principally of the paraffin hydrocarbons.*

Semi-asphaltic petroleums are oils containing a semi-asphaltic base, i. e., oils whose residues produced by evaporation or distillation, while composed mainly of asphaltic hydrocarbons, contain also a certain percentage of paraffin wax.

Asphaltic petroleums are oils containing an asphaltic base, i. e., they are capable of producing residues very similar to native asphalts if evaporated or distilled down to the consistency of such asphalts. They contain little or no solid paraffins. Native asphalts are probably produced from such oils by natural processes.

As typical of the practice in the United States will be cited the work of seven State highway departments which have used bituminous materials extensively. The writer wishes at this time publicly to thank the highway departments of the States mentioned below for their co-operation in collating the following information. *The figures given refer to the* total amount of work of the various types indicated which has been accomplished in 1908, 1909 and 1910 by the State highway departments of the States of Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania and Rhode Island. The work has been classified on the basis of the method employed and the kind of material used. Three general methods are referred to, namely, superficial treatment of roads constructed of ordinary macadam or gravel, the construction of bituminous pavements by penetration methods, and the construction of bituminous pavements by mixing methods. The bituminous materials employed have been classified in three groups: first, tars and tar-asphalt compounds; second, fluxed native asphalts, oil asphalts and residual asphaltic and semi-asphaltic oils; third, *light oils.*

The following tables give the amount in square yards of surfaces treated and bituminous pavements constructed by the State highway departments mentioned above during the years 1908, 1909 and 1910.

Superficial Treatment of Roads

	Tars and Tar-asphalt Compounds	Fluxed Native Asphalts, Oil Asphalts and Residual Asphaltic and Semi-asphaltic Oils	Light Oil
	Square Yards	Square Yards	Square Yards
1908	77 000	299 500	
1909	95 500	910 000	4 125 900
1910	183,400	2,454 900	9 890 400

Bituminous Pavements Constructed by Penetration Methods

1908	3 800	25 900	
1909	170 900	2 077 400	
1910	339 800	4 840 900	36 500

Bituminous Pavements Constructed by Mixing Methods

1908	2 100	4 400	
1909	186 000	219 500	
1910	158 000	438,600	

It is interesting to note from the standpoint of the general increase in the use of bituminous materials in the States cited that in 1908 bituminous materials were employed in the construction and maintenance of 416 000 square yards of road surface, in 1909 of 7 734 000 square yards and in 1910 of 18 244 000 square yards. Although the construction of bituminous surfaces and bituminous pavements is in its infancy in the United States, remarkable progress is being accomplished in certain sections. For instance, by the close of the construction season of 1911, if the plans of the State Highway Commission are carried out, the State of New York will have a trunk highway with a bituminous surface extending north from New York city to Albany and thence west to Buffalo, aggregating over 400 miles in length.

In the surface treatment of macadam and gravel roads several lines of development have been especially noticed: first, a more general use of refined coal gas and water gas tars in place of crude tars; second, an extraordinary increase in the various kinds of heavy asphaltic oils combined with sand, gravel or stone chips to form a carpet wearing surface; third, an increase in the use of light oils for the purpose of allaying dust on State roads, and thus to a certain extent preserving the surface of the road by the retention of the top dressing; fourth, a substitution of mechanical distributors of both the pressure spray and gravity flow type in place of hand application methods.

The practice of the past three years has amply demonstrated that the success of superficial tarring is dependent upon the recognition and adoption of those fundamental principles which were laid down by the French engineers in 1903. As those principles have not been adopted in many instances in the United States, they will be given here in brief. First, superficial tarring should be done only during dry and warm weather in order to obtain efficient and economical results; second, the road must have a dry, smooth and durable surface; third, all dust must be thoroughly brushed off in order to facilitate the adherence of the tar; fourth, after the distribution of the coat of tar it is necessary, in order to avoid a slippery surface, to apply a dressing of sand, gravel or stone chips. The practice of some prominent English engineers does not include the adoption of the fourth recommendation cited, as it is maintained that a top dressing is not an essential element of a non-slippery tarred surface.

A well-developed plan of annually treating certain roads of a system with a thin coat of bituminous material is being adopted in certain States. This practice embodies *the recognition of the fundamental principles* of economy and efficiency in modern highway construction, namely, the adaptation of method and material to local conditions.

In connection with the use of bituminous materials by penetration methods certain noteworthy tendencies are apparent. Most important are the employment of distributing apparatus and the formation of broken stone courses in such a manner as to endeavor to secure the maximum uniformity of distribution of material and the definite limitation of penetration.

The average size of stone employed varies from ½ inch or ¾ inch in longest dimensions to 1¼ inch to 1¾ inches. In exceptional cases, however, engineers have adopted the English and French practice of using larger and more uniform sizes of stone for the top course. The unfortunate delays in the application of the penetration method due to damp stone have been overcome in some instances by the employ*ment of mechanical surface heaters.*

A modification of the penetration method is known as the puddling method. The top course in this case is filled with screenings puddled by watering and thoroughly rolled. After the surface drys out it is picked up. The bituminous material is then applied, a coat of chips is spread and the surface rolled. After the surplus chips are brushed off a flush coat of bituminous material is applied. The application of another coat of chips and a final rolling completes the process.

Another modification of the regular penetration method has been employed during 1910. In this method the foundation is thoroughly filled and rolled. A layer of sand is spread upon the foundation course to a depth of about one inch. Refined tar heated to about 250 deg. F. is then applied to the coat of sand. The top course, composed of broken stone varying from ¾ inch to 2¾ inches in diameter, is spread and rolled, the lower voids being filled with the bituminous mastic. After consolidation a second coat of refined tar is applied. As soon as possible after spreading the second coat of tar a layer of stone chips is spread and rolled. A third coat of refined tar is then applied and the surface finished by rolling a covering of screenings or sand.

In the reconstruction of old roads there has been a general employment of the method of picking up the old surface to a depth of 2 inches to 4 inches by the use of mechanical scarifiers, placing a thin coat of new road metal on the loosened surface and then constructing a bituminous pavement by the penetration method.

In both the construction and reconstruction of roads by penetration methods the surface is finished in various ways. One method is to spread a coat of chips or sand after the first coat of bituminous material is applied, roll thoroughly, and after the road has set up sufficiently open it to traffic. Another method is to apply a second coat of bituminous material before the application of a layer of chips. The bituminous material *for the flush coat may or may* not be the same as used for the first coat. A layer of chips or sand is then spread over the flush coat and thoroughly rolled. A third method is essentially the same as the second method cited, except that a layer of chips is applied to the first coat of bituminous material, thoroughly rolled, and the surplus chips brushed off before the application of the flush coat of bituminous material.

From the standpoint of the character of bituminous material used it is of especial interest to note the increased use, particularly in 1909 and 1910, of fluxed natural asphalts and oil asphalts especially manufactured for application to unheated crusher run stone.

* Presented before Section D of the American Association for the Advancement of Science at the Minneapolis Meeting, December 30th, 1910, by Prof. Arthur H. Blanchard, Consulting Highway Engineer, Brown University, Providence, R. I.

In the construction of bituminous pavements by the mixing method a number of improvements and developments should be noted Some attention has been paid to having the stone dry and reasonably clean Although the advantages accruing by using clean and dry stone are recognized the practice has been far from satisfactory only very crude methods having thus far been employed The practice of heating stone on plates has been used to a certain extent with deleterious results. In a few cases mixing machines and tar coating machines have been employed in connection with the construction of bituminous pavements which are to cost not over 90 cents to $1 per square yard The types of the mixers which have been used to date are more or less unsatisfactory especially when bituminous materials are used which are solid at ordinary temperatures or which flow with considerable difficulty when cold During the season of 1911 considerable development should take place in the heating of stone by mechanical dryers and also in the use of new types of mixers especially manufactured for the purpose of mixing bituminous materials with a mineral aggregate

The mixing of broken stone or other aggregate with bituminous materials at a central plant and shipping the finished product by rail has not been developed to any extent in this country The product of one company however has been used quite extensively in three or four States In another case refined asphaltic petroleums have been mixed with sand and gravel and molded into blocks at a central plant The blocks have been laid as the wearing surface and rolled

Bituminous pavements constructed by mixing methods have been finished in different ways In certain instances satisfactory results have been attained by applying a coat of chips or sand to the surface of the course of mixed aggregate and thoroughly rolling the same In other cases a flush coat of bituminous material has been applied before the layer of mineral matter is spread over the surface The bituminous material used for the flush coat in many bituminous pavements is not the same as was used in the mix.

In the above discussion of the mixing method it should be noted that the remarks do not in general apply to bituminous pavements constructed by mixing a carefully graded aggregate and bituminous materials and hence do not refer to many types of bituminous pavements which have been used to a considerable extent in the construction of streets in municipalities.

In various parts of the United States sand gravel and earth have been mixed in place by various processes with bituminous materials in the endeavor to form an impervious dustless and durable road surface This work is being watched with considerable interest as the utilization of local materials for the aggregate in many instances reduces the cost of construction materially The limitation in the weight of traffic to be carried throughout the year under all climatic conditions is one of the most important points under discussion at the present time in connection with the above methods

A new type of construction recently introduced by Logan Waller Page director of the United States Office of Public Roads is known as oil cement concrete In this process fluid residual petroleum is added to the usual ingredients composing concrete

From the standpoint of the nature of the material used again it is noted that there is an increase in the use of refined tar considerable employment of heavy asphaltic compounds and also the employment of combinations of tar and asphalt the most noticeable increase however being in the use of heavy asphaltic oils which can be mixed readily with broken stone as it comes from the crusher

There has been a marked tendency on the part of highway engineers during the past three years to appreciate more fully the importance of the various chemical and physical properties of bituminous materials Many engineers and manufacturers now wisely advocate using different grades of the same type of bituminous material for varying local conditions and for different methods of bituminous construction During 1909 and 1910 bituminous materials for use in the construction and maintenance of road have been purchased in two ways namely by buying direct from the manufacturer a product known under a trade name and by purchasing the material under specifications The old custom of simply purchasing bituminous material under a trade name without investigation of its properties is being replaced by the second method The object of the second method has been to cover one or more of the following points first to secure uniformity in the material furnished for a given contract second to obtain a compound which conforms to certain requirements with reference to the chemical and physical properties of the material which are considered essential third to provide a standard by which it is hoped that a satisfactory material may be duplicated on other contracts The effect of the various physical and chemical properties of bituminous materials on their value as road binders is being investigated by a special committee of the American Society of Civil Engineers Standard methods of testing bituminous materials is the subject of investigation by a sub-committee of the American Society for Testing Materials

In this country as well as in Europe considerable confusion results owing to the lack of uniformity among engineers chemists and manufacturers relative to the nomenclature of bituminous materials Until a recognized nomenclature is adopted it will be advisable to define methods and materials in order to avoid misinterpretation of information furnished relative to the construction and maintenance of bituminous surfaces and bituminous pavements

Frosting, Etching, and Coloring of Incandescent Lamps

Hints for the Manufacturer and Amateur

In the *National Light Association Bulletin* the lamp committee of the association submits the following information as the result of inquiries from member companies and believing that it will be of general interest

Frosting Lamps—Frosted lamps improve lighting results by giving better diffusion and more agreeable lighting A properly frosted bulb cuts off comparatively little light averaging from three per cent to seven per cent, or from one-half to one candle power on a sixteen-candle power lamp

Lamp bulbs may be superficially frosted by dipping in a compound which any company can readily purchase from various manufacturers This frosting is not permanent however nor as satisfactory as the etched frost given to the lamps by the manufacturers which is effected either by sand blast or by acid Both processes give very similar results but for incandescent lamps the acid method is generally used

The acid method employs a solution consisting of hydrofluoric acid and carbonate of ammonium thoroughly mixed in a proportion of about ten quarts of acid to eight pounds of carbonate This is contained in a leaden vat large enough for the admission of a rack full of lamps Placed alongside the acid tub is a rinsing vat The lamps are inserted in rubber sockets in a wooden holding rack and after an initial dip in the rinsing vat to clean them they are immersed in the acid solution for about half a minute and again washed in the rinsing tub If extra heavy frosting is required lamps may be re-dipped as many times as necessary Where it is required to frost only a portion of the lamp rubber hoods are placed over the lamps to a point where the frosting is to stop The acid frost operation is dangerous and requires considerable experience in order to obtain successful results Utmost care must be used in handling the hydrofluoric acid compounds as not only will severe burns result if the solution comes in contact with the human skin but the fumes are injurious to the eyes and respiratory organs This work should be done in a specially ventilated room, and the operator should be thoroughly protected by rubber gloves and apron

Frosted lamps may be cleaned by dipping them in very hot water and rubbing them thoroughly dry with tissue paper Where this is not sufficient a little soap should be used with the hot water Tungsten lamps should always be burning while being cleaned

Etching Letters or Symbols on Lamps—The acid etching of letters or symbols on lamps is not attended with the objections and difficulties of the complete frosting process, and can be readily employed by any company to mark its lamps permanently

The question of identifying lamps as the company's property is a matter that has been given more or less attention—more particularly perhaps by the larger companies in order to protect themselves against fraud and theft of lamps especially since the advent of the metallized filament and tungsten lamps which are much more expensive than carbon filament lamps

A simple and comparatively inexpensive method which may be used by the companies rather than by the manufacturer of lamps is to etch the bulbs either with the name of the company with a letter or with a symbol

This etching is generally done on the bulb near the base and by this means the lamp may be readily identified as the etching is a permanent and positive mark which it is difficult to remove in any way

It is undesirable to have the identification marks placed on lamps by the manufacturers being necessarily expensive and when so etched the lamps become special and unsuitable for shipment to other than the one particular company It is suggested therefore to the smaller companies that should they meet with difficulty or loss in the theft of lamps the following method of identification can be adopted with comparatively small attendant cost to be used locally in their own stockroom or at any convenient point

A rubber stamp a solution of etching fluid and a heater with a perforated sheet metal top are practically all the requisites necessary for this process The heater is perforated in order that the heat may come in instant contact with the lamps and cause them to warm up quickly

A tray full of lamps is placed in this heater with the operator on one side In front of the operator are the stamps a rubber pad and a small brush with which to spread the fluid on the pad When the lamps become warm they are taken from the tray stamped and replaced as rapidly as possible When they have attained a temperature of 150 deg F the tray is removed and the operation is finished

The formula for the making of etching fluid is as follows

To one pound of ammonium fluoride crystals add thirteen ounces of fifty two per cent hydrofluoric acid and eight ounces of water Stir this solution occasionally and let it stand over night when it should be strained Then strain the clear part of the solution through medium coarse muslin Care should be taken in the selection of the ammonium fluoride crystals, which should be of fairly large size Sheet lead or hard rubber vessels should be used as containers for the etching fluid

Coloring of Lamps—Naturally colored lamps of which the glass is permanently colored are the only ones that are thoroughly weatherproof As such lamps are rather expensive superficially colored or dipped lamps are now generally employed Suitable coloring mixtures can be obtained from a number of manufacturers and the lamps can be readily dipped by any operating company In this work the old or dim lamps removed from the circuits may be used The plan generally followed is to burn the lamp in a vertical position with tip down at about two thirds or three fourths of its normal candle power When the lamps have become slightly warm take a cup of the dipping solution and raise it slowly until the lamp is submerged therein up to its base then lower slowly allowing the excess of liquid to drain off into the cup and proceed to the next lamp Lamps should be burned until the coating becomes thoroughly dry and firm

Blue green and purple are not desirable as these colors absorb so much of the light that the lamps are hardly distinguishable at a distance

---

The Luminosity of the Sun

There have recently been published in France some stupendous figures with reference to the luminosity of the sun as calculated by Nordmann of the Paris Observatory

By him the solar heat is placed at 6 482 deg C The sun's total candle power is represented by him in a string of figures beginning with 18 followed by 27 noughts This inconceivable sum is equivalent to 1 994 000 for every square inch of the sun's surface Again some idea of the amount of light these figures represent may be had from the fact that the most powerful electric arc light has an illuminating power of only 20 000 candles

Prof Nordmann states that from every bit of the sun's surface the size of a finger nail there issues a quantity of light that would be sufficient to illuminate the entire Avenue de l'Opéra for a whole night In asmuch as the sun's surface is estimated to be some 200 000 000 square miles its total luminosity may be placed at 51 000 000 000 000 times that of the street mentioned

This French observer has also undertaken the task of measuring the light and heat of various large stars some of which are stated to be even more powerful illuminants than the sun For example Sirius is found by him to be about thirty times hotter than the sun i e 190 000 deg C while the Polar Star is a comparatively cold body of merely 8 200 degrees

Psychanalysis

Getting at the Facts of Mental Life

A New Field of Research

PSYCHANALYSIS is a new word which in terms comprehensible to the lay mind has been defined says *Science and Discovery* as the science of reading the inmost secrets of the heart and soul in spite of—sometimes without the least suspicion on the part of—the person who is the subject of investigation The word psychanalysis has been much used in the medical and psychological organs of late with reference to the remarkable discoveries in pathology of mental ills by the distinguished Dr Freud of Vienna But the practical application of psychanalysis as a means of getting at the facts of mental life is most indebted to Dr Jung the famed specialist in psychological therapeutics whose cures are making a sensation in Germany It has been said of him in the London *Lancet* that his cases read like reports from a new psychological world The fullest account of the Jung method is given by the able associate in psychiatry at Columbia University Dr F W Scripture There are three methods of getting at the facts of mental life explains Dr Scripture The first is that of simple observation This leads to treatment by the physician by the usual medical procedure The second method of getting at the facts of mental life is by that of experimental psychology Its aim is a most careful and accurate analysis of a patient s mental condition by tests and records This has been much exploited in lay and technical publications in late years The third method—involving medical reports from a quiet new psychological world—is that of psychanalysis

To take up Dr Scripture s exposition suppose a patient presents himself with a paresis of the right arm which began years ago There is not the slightest symptom of anything organically wrong It is evidently a hysterical paralysis Or suppose a man appears complaining that he is tortured beyond endurance by a fear that he can not perspire He never has the slightest difficulty and he knows the fear to be foolish Yet this fear is so constant and overpowering that he has been obliged to give up work Again a patient comes to the office saying that for years he has been tortured by a fear of touching filth He washes his hands a hundred times a day

Such cases are beyond the methods of observation In our own mental life there is nothing like such conditions They are so far beyond our understanding that they seem weird or incomprehensible The patient with the fear of filth told Dr Scripture that he knew it to be nonsensical and that he spent hours in discussing it with himself It is one of the great est feats of the method of phychanalysis that it has found the mental mechanism of such cases

To analyze a case of the sort recourse is had by Dr Jung to his so called association method In this a word is spoken and the patient is required to say at once what he first thought of The time taken is measured with a stop watch After a hundred such associations the patient is required to tell again what he thought of in each case Whenever the time of association is unusually long when there is evidence of forgetfulness when the patient does not respond at all to the word called out when his association is superficial—in short whenever the association is of unusual character—the word called out touched upon some topic on which the person was highly sensitive A sensitive topic in one case was an experience on the water and a record of it works out in this style

Word Spoken	Association	Time	Memory	Sensitive Topic or Compl
head	hair	1 4	x	
green	meadow	1 6	x	
water	deep	5 0	swim	'
stick	knife	1 6	x	
long	table	1 2	x	
ship	sink	3 4	steamer	'
ask	answer	1 6	x	
wool	knit	1 6	x	
obstinate	friendly	1 4	x	
lake	water	4 0	blue	'
sick	well	1 8	x	
ink	black	1 2	x	
swim	can	3 8	water	'

Applied to the man with the paretic arm the association tests showed that the words in the list where the most disturbance occurred (long time forgetfulness) were proud pure arm bird death sin The words he thought of as associations most frequently were love and like 8 times not 6 I marriage 3 arm 3 lake 3 Now just try to put these words together as a picture of his mental condition I am (or was) proud that I am (or was) pure I have sinned I would prefer death I do not love my wife (marriage) The words arm bird lake remain unexplained Nevertheless a moral catastrophe is revealed

This will be more evident to the lay mind from an other case—that of a happily married woman subject to explosions of jealousy with outbreaks of violence and of running away from the house. These out breaks she carefully concealed from the rest of the family She wreaked her temper on her husband, who was a model man In the association tests the strongest disturbances occurred with the words happiness anxiety religion choose marry part, death die In her associations she uses like 13 times man 10 child 7 necessary 7 beautiful 6 I 4

It was possible to guess the story from these results alone but it was easier to confront her with the record and show her conclusively that she has revealed something compromising to her happiness, that she is anxious about something that religious questions are troubling her The patient owned up that she was not happy with her husband that she is anxious about the future and does not know what to do that she is married outside of her religion and to a man whom she chose against the wishes of her parents and that she is debating whether she shall part with him or die

Another method of phychanalysis is that of running associations This was introduced by Freud

The patient is told to let his mind wander with perfect freedom and to tell his thoughts as they arise The method is useful in the most varied ways It must first be made clear to the patient that his cure depends upon telling the truth no matter how private may be the thought that arises he must tell it frankly to the physician

This method I will illustrate by the case reported by a clergyman of Zurich He noticed in a composition written by one of his pupils a boy of eleven years indications of strained relations among the members of the family Knowing that he could not possibly get the facts otherwise he applied a combination of the association experiment with running associations For example the word water aroused the association corpse after four seconds There after the boy associated ship a drowned person I saw how a drowned person was taken into a boat Now tell all the words that occur to you said the clergyman Bathe swimming bathhouse bottom seaweed shark earth stone springboard air chain beam submarine boat screw no air drowned What occurs to you now? asked the clergyman I saw some moving pictures with two divers that found gold One cut the air tube of the other took the gold and went up The word diver brought up the association of the dead diver in the moving pictures We could see his pale face We once got a wax mask representing a dying king with eyes turned up Arno (his brother) put on the mask and wrapped a shroud around him He looked like a ghost I was frightened The dying diver reminds me of this wax figure (meaning his brother in the mask) Over and over again the boy produces series of associations ending up in some representations of his brother as dead as in prison as tortured as murdered by him self as crucified etc It was very evident that he hated his brother from the bottom of his soul This he did not realize in the least himself The information and the treatment came through this method of psychanalysis

The method of running association is based on certain laws of the association of ideas One of these we may state as follows The oftener an idea or an element of an idea has been in mind the more frequently it will appear in associations The brother Arno was constantly in little Max s mind, no matter what he started to think about the thought of Arno would sooner or later appear Another law is that the intenser an idea is or the more motion it arouses the more often it recurs A person will remember the time he made a fool of himself no matter how much he wishes to forgot it Start any one on memory associations and he will inevitably land over and over again on the chief topics in his mind and will involuntarily deliver his secrets over to you

The more the running association is freed from the control the better the information concerning the person s mind Seat yourself in quiet and let your mind wander in associations You will notice that at each step a dozen new things crowd in together Instinctively you pick out one and proceed For example, with the word lamp there appear at once to my mind in half formed condition a certain gas flame, a certain electric light a certain proverb etc , one of these I have to catch because I cannot think clearly of all of them at the same time I catch the certain electric lamp It is in a certain room this leads my thoughts in that direction If I had caught the gas flame, my thoughts would have gone otherwise"

From childhood up we have been trained to control our thoughts to proceed in an orderly fashion to speak only in a modest way, even to think in a modest way This control becomes automatic When we let the thoughts wander we automatically catch only those thoughts that fit our training In the presence of another person we are trained to speak only in a discreet manner even to think otherwise is not proper Automatically we catch only the discreet thoughts and suppress the others. In the doctor s office the conversation is freer but even here it usually requires some training before the patient can let him self think freely

Another method is that of assigning a topic concerning which all impromptu thoughts are to be noted down For example, the physician tells the patient to note down on the spot each thought that arises impromptu concerning himself (the physician) Thus a patient reports that in an entirely impromptu manner the thought occurred to him that the doctor was getting bald On another occasion he said he thought the doctor was getting stout, and so on An entire group of these observations revolved around the signs of advancing age This was in fact the great trouble of the patient He felt that he was getting old This line of psychanalysis lets a flood of light in upon the dark places of the human soul and heart

Another patient reports that the thought had occurred to him that the doctor was extremely considerate of the feelings of his patients that he was really rather bashful, and so on This simply reflected the patient s condition of bashfulness and overanxiety about how people felt toward him Still another patient thought that the doctor must make a great deal of money out of his practice that he dressed in expensive clothes etc Of course the inference was at once clear namely that the patient s thoughts centered around money I have never had an experience quite like one that Dr Jung related to me One of his patients a clergyman told him that the thought had occurred that Dr Jung was not strictly truthful that he was not quite honorable in dealing with his patients that he did not believe that he led a strictly moral life etc Before knowing the facts of the case Dr Jung replied It is *you* who are the liar *you* have not acted honorably with your parishioners *you* are doing something immoral The thoughts that arise impromptu like this are always reflections of the patient s own personality

Nor has this new method of psychanalysis produced results less remarkable in the interpretation of dreams It seems that the dream is in reality a clue to the mental and even the physical life of far greater importance than any scientist has ever suspected or been disposed to admit For the man who tells what he has dreamed the night before is revealing did he but know it the inmost secret of his whole life

Enlarging a Baltic Seaport.—A project for extensive engineering work for the purpose of enlarging the port of Dantzig was discussed at a recent meeting of municipal and commercial representatives of that city The matter bore upon increasing the size of the port at Neufahrwasser and the canal of the port would thus be enlarged considerably so as to reach a width of some 300 feet The outlay which is needed for this work is estimated at $500 000 to be borne two-thirds by the State and the remainder to be divided among the naval docks the municipality and the commercial interests of the city

SAVING HUMAN LIFE IN MINES.—[See Page 264.]

The Discovery of Kepler's Laws

An Epoch-making Astronomical Achievement

ALMOST exactly three centuries have passed since the discovery of the laws of planetary motion. In 1609 Kepler announced that the orbit of Mars is an ellipse having the sun in one of its foci. The simple and ingenious empirical process which led Kepler inevitably to the discovery of the true form of the orbit is not generally known. This process is described by Prof. Bigourdan of the Observatory of Paris in an article in *Revue des Sciences*, which may be summarized as follows:

I. THE FIRST LAW

In the year 1600 Kepler went to Prague to assist Tycho Brahé in the construction of his new Rudolphine tables of the planets. The two great astronomers soon fell into discord, for Tycho believed that the sun revolved about the earth, while Kepler adopted the Copernican theory of a central sun. Moreover, Tycho was haughty and arrogant and Kepler was ill paid and irritable. A complete rupture was averted by the sudden death of Tycho in 1601. Kepler succeeded Tycho as astronomer royal, and Tycho's accumulated treasure of observations was placed at his disposal. Kepler continued to occupy himself with the planets and particularly with the intractable planet Mars, asserting that the secret of planetary motion must be learned from Mars or remain forever unknown. In 1609, after nine years of patient research, he published his work, De Stella Martis, in which he proclaimed the elliptical form of the orbit of Mars.

For 2,000 years the Pythagorean theory of exactly circular planetary orbits had been admitted without argument, but the earth was not placed at the center of the circle. For example, those astronomers who believed that the sun S revolved about the earth T (Fig. 1) placed the center C of the solar orbit at a distance CT from the earth. This distance, called the eccentricity, accounted for the observed unequal motion in longitude of the sun, conceived as moving uniformly in its circular orbit. A planet was supposed to move in its circular orbit, not uniformly, but with uniform angular velocity about a *punctum aequantis* E, symmetrical with T with respect to the center C.

Kepler attempted in vain to represent the motion of Mars on this hypothesis. He succeeded in reproducing the longitudes observed by Tycho Brahé, but the latitudes were in error in some cases by as much as 9 minutes of arc.

Kepler then made trial of a theory of planets including the earth revolving about a fixed sun. This new hypothesis introduced a new difficulty, for if the observations are made from a moving earth it is necessary first of all to determine the earth's motion with accuracy. This problem, very similar to that of the determination of the orbit of Mars, was attacked by a method whose simplicity attests Kepler's genius.

In Fig. 2 let T, T, T represent three positions of the earth in the unknown orbit which it describes about the fixed sun S, and let M denote another fixed point whose heliocentric coördinates are known. From these coördinates the angles MST, MST, MST_3 can be deduced, while the angles MTS, MTS, MTS can be determined by observation. Hence all the angles of the triangles MST, MST, MST_3 can be determined, and as these triangles have a common side MS, the relative lengths of the radii vectors ST, ST, ST_3 can be found. By repeating this process for various positions of the earth the form of the earth's orbit can be determined.

The point M may be any one of the planets, if the planet's period of revolution is accurately known and its position in the heavens is observed at intervals exactly equal to multiples of this period; the planet represents a fixed point, so far as these observations are concerned.

The periodic times of the planets have been known pretty accurately since the days of Hipparchus. Kepler selected to represent the fixed point M the planet Mars, whose orbit was the ultimate object of his study. This enabled him to reverse the problem and calculate SM, the radius vector of Mars, after he had constructed his tables of the earth's motion.

Among Tycho Brahé's observations of Mars, which formed the basis of Kepler's work, there was little probability of finding even a few separated by exact multiples of the period of revolution, but it was only necessary that this condition should be satisfied approximately, as the observations could be reduced to the exact epochs required by the application of small corrections which could be calculated without sensible error.

Kepler formed his tables of the earth's motion on the theory of a circular orbit and a *punctum aequantis*. From these tables he could compute the earth's radius vector ST at any epoch and could thence deduce the radius vector of Mars SM. He then tried to represent the observed positions of Mars by means of a circular orbit about an eccentrically placed sun. Three values of the radius vector, together with the values of the heliocentric longitude for the same epochs, supplied data for computing the three elements of the orbit of Mars, the radius, the eccentricity and the position of the line of apsides.

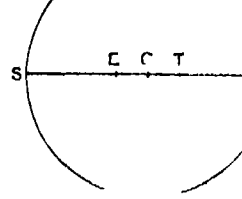

Fig. 1

These elements were already known approximately, and Kepler's results differed considerably from the known values. Furthermore, different groups of three positions gave different values of the elements. But Kepler was unwilling to abandon the old theory of a circular orbit without additional evidence.

From Tycho's observations and the old tables he determined the heliocentric longitudes of Mars at aphelion and perihelion. Then, by the empirical method indicated above, he calculated the values of the radius vector at the same epochs, i. e., the two segments of the line of apsides. Finally he assumed that the unknown orbit was symmetrically divided by that line. From these data he could calculate the radius vector at any epoch and compare it with the value obtained by the empirical method. He found

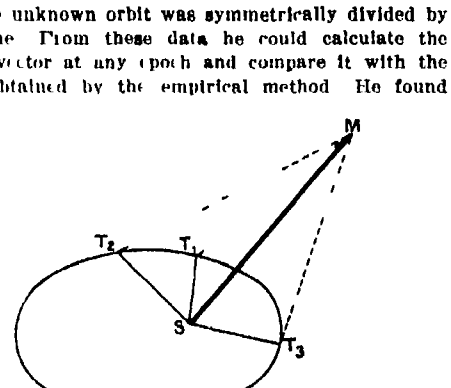

Fig. 2

that the value calculated on the theory of a circular orbit was always greater than the real or empirical value.

Kepler then definitely announced that the orbit was not circular. He at first rejected the ellipse in favor of the egg-shaped oval, but this curve likewise failed to stand the test which had eliminated the circle. At last, after long perplexity, in which he complained that his theory had gone up in smoke and that the problem would drive him mad, he found that the despised ellipse stood the test, and announced that the orbit of Mars is an ellipse having the sun in one of its foci. This is a particular case of Kepler's First

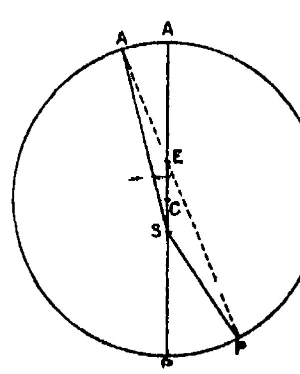

Fig. 3.

Law, which he subsequently extended to all of the planets.

II. KEPLER'S SECOND LAW

The law of the conservation of areas, which states that the radius vector of a planet describes equal areas in equal times, evidently applies to uniform motion in a circle. Kepler saw that this law also applies very approximately at and near the aphelion and perihelion of a planet moving in a circular orbit, with uniform velocity about a *punctum aequantis* E (Fig. 3) placed opposite the sun S, and equidistant with it from the center of the circle C. In the figure AA' and PP' represent arcs described, in equal short intervals of time, from the aphelion A and the perihelion P. A', E and P' lie in the same straight line by the hypothesis of uniform angular velocity about E. The areas described by the radius vector in the two equal intervals are ASA' and PSP'. Owing to the symmetrical position of E and S with respect to C, $AE = PS$ and $AS = PE$. Hence

$$\frac{ASA'}{PSP'} = \frac{\frac{1}{2}AS \times AA'}{\frac{1}{2}PS \times PP'} = \frac{AS}{PS} \times \frac{AE}{PE} = \frac{AS}{PS} \times \frac{PS}{AS} = 1$$

Having established this much, Kepler felt a moral certainty that the law of areas applied also to the ellipse, but he could not find a satisfactory demonstration of this fact until some years later.

Kepler's dedication of De Stella Martis to the Emperor Rudolph II, containing a poetical appeal for means to extend his researches to the other planets, is worth quoting in the following condensed form as an illustration of the writer's imagery and the spirit of the times:

I bring Your Majesty a noble prisoner, the fruit of a laborious and difficult war. It is not the first time he has been a captive, for long ago the terrible god of war was caught in Vulcan's net. Hitherto he has triumphed over all human devices. In vain have the astronomers employed every resource and put all their troops into the field. Mars, mocking their efforts, has shattered their engines and their hopes, retrenched himself in his impenetrable domain and concealed his movements from their spies. The valiant Captain Tycho Brahé has studied the enemy's mysterious movements almost nightly during twenty years and has bequeathed his observations to me. In the course of the war our camp has been desolated by death, pestilence and sedition. Many soldiers deserted and were replaced by raw recruits, and even the rations ran short.

At last the enemy sent his capitulation by the hand of his mother Nature. He gave his parole and Arithmetic and Geometry escorted him to our camp. He has since proved that his parole can be trusted, and he asks but one favor from Your Majesty. His father Jupiter, his grandfather Saturn, his brother Mercury and his sister Venus are still in the sky. He pines for their society and longs to see them also enjoying your hospitality. For this purpose the war must be prosecuted with vigor, but money is the sinews of war, wherefore I beseech Your Majesty for the funds required for the levy of fresh troops.

III. KEPLER'S THIRD LAW

The Third Law was not discovered until 1618, after twenty-two years of research and speculation. In the Mysterium Cosmographicum, published in 1596, Kepler writes:

"I propose to show that God, in creating the universe and arranging the spheres, had in view the five regular solids of geometry, and fixed by their dimensions the number, proportions and motions of the spheres. Take the sphere of the earth as a unit and circumscribe it with a regular dodecahedron. The sphere that contains this dodecahedron is the sphere of Mars."

The spheres of Mars and Jupiter, Kepler continues, are similarly related to a regular tetrahedron described about the former and within the latter, those of Jupiter and Saturn to a cube, those of Venus and the earth to an icosahedron, and those of Mercury and Venus to an octahedron. Kepler in this early work compares the distances of the planets from the sun derived from this geometrical system with the distances given by Copernicus, and finds that Jupiter alone presents a serious discrepancy, which he attributes to the inaccuracy of the value given by Copernicus. Kepler was satisfied with the result, although he could not then find a simple law connecting the distances of the planets.

He returns to the subject in the Harmonices Mundi, a work in five volumes, published in 1619, in which he discusses polygons, the five regular solids, astrology, politics, the faculties of the mind and other things. He revives the Pythagorean analogy between music and the harmony of spheres, and calls Saturn and Jupiter the bass voices, Mars the tenor, Venus the contralto and Mercury the soprano or falsetto of the celestial choir.

From this chaos of dreams emerges Kepler's Third Law, which is thus formulated:

"The proportion between the periodic times of two planets is exactly equal to the sesquialterate ratio of their mean distances from the sun." The sesquialterate ratio is the ratio of the 3-2 powers. In

other words, the squares of the periodic times are proportional to the cubes of the mean distances, as the Third Law is usually expressed. Contrary to his wont, Kepler does not give the history of this discovery, but the work terminates with the following famous passage:

"Eight months ago I saw the first ray of light; three months ago I saw the dawn; three days ago I saw the sun in his splendor. I give myself up to enthusiasm. I voluntarily defy mankind with the ingenious confession that I have stolen the golden vase of the Egyptians to make of it a tabernacle to my God far from the bounds of Egypt. If you pardon me I shall rejoice; if you reproach me I shall endure it. The die is cast. I have written my book. It will be read by the present generation or by posterity; it matters not. It can await its reader. Has not God waited six thousand years for a contemplator of his works?" He concludes with a prayer of thanksgiving to the Creator.

Thus were established Kepler's three laws of planetary motion which led Newton to the discovery of universal gravitation, the basis of modern astronomy.

Preparation of Pure Radium Salts*

The Process of Fractionation Employed

By Madame Curie

To effect the separation of pure radium chloride from the barium chloride with which it is associated I have subjected the mixed chlorides to a fractional crystallization first from pure water and then from water acidulated with hydrochloric acid. This process is based upon the fact that radium chloride is less soluble than barium chloride.

A saturated solution of the chlorides in pure distilled water at boiling temperature is prepared and is left to crystallize in a covered vessel. After cooling a deposit of fine crystals is found upon the bottom of the crystallizing vessel, and the supernatant solution can be readily poured off. If a sample of the mother liquor is evaporated to dryness and the residues tested it is found to be five times less active than the portion originally crystallized out. In this way the chlorides are separated into two portions A and B or which A is much more active than B. The operation is now repeated with each of these parts thus again obtaining from each a further crop of two parts. The less active portion obtained from A is then united with the more active portion obtained from B, these two portions having approximately the same activity. The result of this step is three fractions which are once more subjected to the operation described. The number of fractions thus prepared is not allowed to increase indefinitely for as the process goes on the activity of the soluble portion becomes less and less. When it has sunk to an insignificant value the particular portion is eliminated from the process. After a suitable number of fractionations the most difficultly soluble portion which is richest in radium is also withdrawn from the operation.

A fixed number of fractions is maintained. After a series of crystallization the saturated solution of one fraction is united with the crystals of the next following fraction. When however the most readily soluble fraction is discarded at the end of a series a new readily soluble fraction is prepared in the next series and the most active crop of crystals is taken out of the process. By systematically following out this scheme a very regular mechanism of fractionation is obtained, the number of fractions and the activity of each fraction remaining constant, each being about five times as active as the next lower in order. At the one end an almost inactive product is discarded and at the other end a chloride enriched in radium is collected. The total quantity of material diminishes continually and the several fractions become smaller and smaller as their activity increases. The work is begun with six fractions and the activity of the chloride discarded at the end is only one-tenth that of uranium.

The accompanying diagram represents the scheme of such a fractionation. Each point represents a crop of crystals from the portion indicated by the affixed numeral. The two arrows extending from a given point indicate the two products crystals and mother liquor resulting from each crystallization, e. g. to the left, crystal; to the right, mother liquor. Where two arrows converge to a point this indicates the union of the crystals separating from one portion with the solution from the immediately preceding portion. The outwardly directed arrows signify that the final product has been removed from the fractionating process.

When a large proportion of the inactive substance has been in this way eliminated, and the quantity of material has consequently been much reduced it is no longer worth while to separate out these portions at such low activity. The last members in the series are then discarded and are replaced from above by previously collected active chloride with the effect that a chloride richer in radium is precipitated than at first. This is continued until the crystal crops at the beginning of the series represent pure radium chloride. If the fractionation has been carried out perfectly, the amount of intermediate products left over will be very small.

When, in the course of the fractionation, the bulk of the individual fractions has been much reduced the separation by crystallization becomes less effective because the solutions cool off too rapidly and the volume of the mother liquor decanted off becomes too small. At this stage it is advantageous to add a definite amount of hydrochloric acid to the water used for dissolving, gradually increasing the amount of acid so added as the fractionation proceeds. This addition has the advantage that the volume of the solution is thereby increased owing to the fact that the chlorides are less soluble in dilute hydrochloric acid than in pure water. At the same time the fractionation becomes more thorough, the difference between the fractions separated from a given stock is increased. If the acid is added in considerable concentration a very excellent separation is obtained and the fractionations may be reduced to three or four. It is therefore a great advantage to begin with the addition of hydrochloric acid just as soon as the diminished amount of material permits this step to be taken without inconvenience.

The crystals which separate out from strongly acid solutions are long and needle-shaped and identical in appearance whether they be barium chloride or radium chloride. Both these are doubly refractive. The crystals of the barium chloride containing radium are colorless. If however the radium content reaches a certain limit the crystals assume after standing for several hours a yellow color ranging toward orange or sometimes a fine rose tint. This color disappears on dissolution. The crystals of pure radium chloride do not become colored in this way or at least not as rapidly so that the coloration appears to be dependent upon the simultaneous presence of radium and barium. The maximum coloration occurs when the amount of radium assumes a certain definite proportion and this furnishes a means of gaging the progress of the fractionation. So long as the most active fraction becomes colored we know that it still contains a considerable amount of barium. If it no longer becomes colored on standing while the fractions of lower order do, then the colorless portion is approximately pure radium chloride.

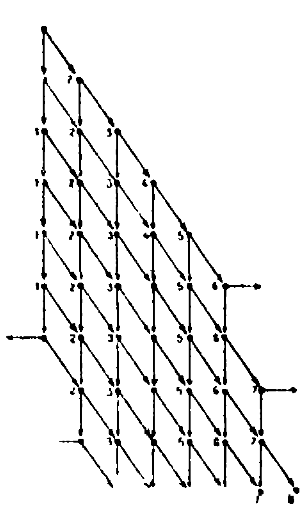

DIAGRAM INDICATING THE SCHEME OF SUCCESSIVE FRACTIONAL PRECIPITATIONS

I have sometimes observed crops of crystals which consisted partly of colorless crystals and partly of others which became colored upon standing. Perhaps they might have been separated by picking them out individually but this was not attempted.

Toward the end of the fractionation the successive fractions no longer display the same relative activity nor is the proportion of their activity as regular as at the beginning of the process; this however does not cause any serious disturbance in the progress of the fractionation.

In working up a few kilograms of the chlorides obtained from a ton or more of the residues used as raw materials, it is necessary to modify somewhat the mode of procedure. The first fractionation is in this case carried out at the factory, so that after eliminating ninety per cent of the barium salt a product enriched in radium can be delivered from the factory. This first fractionation requires comparatively large volumes of the saturated solutions and is carried out in cast iron kettles. In place of distilled water rain water or river water as poor in dissolved salts as possible is used from which all sulphates have been carefully precipitated by the addition of a small excess of barium chloride.

The separation of radium can also be carried out by the fractional precipitation with alcohol of an aqueous solution of the barium chloride containing radium. I used this method at first but subsequently abandoned it in favor of the one described above which assures greater uniformity. At times however I have made use of the precipitation by alcohol to purify radium chloride containing a small amount of barium chloride admixed with it. The latter remains dissolved in the slightly diluted alcohol and can be thus removed.

Giesel who has been occupied with the preparation of radioactive bodies since the publication of our first investigations recommends for the separation of barium and radium the fractional crystallization of the mixed bromides from an aqueous solution. I have found that this method is very advantageous especially at the beginning of the fractionation. This however is the case only if the amount of salts to be fractionated is not too large. If there are several kilograms to be treated the use of a corresponding amount of hydrobromic acid becomes objectionable partly on account of its high price and also because the cast iron kettles are more easily attacked by the bromides than by the chlorides. Nevertheless it is advantageous to convert into bromides the chlorides obtained from the first fractionation as carried out in the factory which are greatly reduced in bulk as compared with the original raw material. In this way a more rapid fractionation is secured so long as the quantity of material is not too greatly reduced. When however the amount of the salt is quite small working with the bromides is less satisfactory than with the chlorides owing to the fact that the former are on the one hand much more soluble and on the other hand much more subject to change than the latter. A solution of the bromide very rich in radium in water or dilute hydrobromic acid undergoes very rapid alteration with liberation of bromide. For this reason it is in my opinion advantageous to convert salts of high radium content into chlorides in preparing a pure and stable radium salt. In the dry state the chloride is more sharply defined and more stable than the bromide and does not undergo any appreciable spontaneous change.

Whatever process of fractionation is employed it is always useful to control the course of the process by measuring the activity of the product.

It should be emphasized that a radium compound which has been prepared in the solid form either by crystallizing or precipitating from a solution does not have a constant activity from the start. The activity increases for about one month to a limiting value which thereafter remains constant. The final activity is five or six times as great as the initial activity. These changes must be taken into account in measuring activity. The final activity is more clearly defined but in the course of chemical operations upon radium salts it is more practical to measure the initial activity of the solid product.

While the salt submitted to fractionation has of course always undergone a previous purification it is nevertheless often desirable to purify once more a salt of high radium content. The fractionation itself of course effects a certain purification inasmuch as traces of the salts which are very readily soluble in acidulated water (e. g. those of calcium, iron and magnesium, etc.) are eliminated. On the other hand however traces of lead chloride or bromide accumulate with the radium salt in the difficultly soluble portions. For this reason it is generally speaking necessary to treat the salts of very high radium content with hydrogen sulphide before proceeding to the final elimination of the barium.

International Standard Time

Its History and Its Recent Adoption in France

The French Senate recently passed a law which was passed by the Chamber of Deputies fourteen years ago and which will make the legal standard time in France 9 minutes and 21 seconds slower than Paris mean solar time which is the present French standard The reason for selecting this interval of 9 minutes and 21 seconds the reservations by which a complete and formal adoption of the meridian of Greenwich has been evaded and the advantages and disadvantages of the change are discussed in *La Revue des Sciences* by Prof Bigourdan of the Observatory of Paris Prof Bigourdan's article an abstract of which is here presented also contains an outline of the history of international standard time

Every place on the earth's surface has its own local time and the difference between the local times of any two places is proportional to the difference of their longitudes one hour corresponding to 15 degrees or 4 minutes to 1 degree of longitude When the stage-coach was the most rapid means of travel the difference in local time caused no great inconvenience but the development of the railway soon made it necessary to adopt a single standard of time for all the stations of a line or even of a country The local time of Paris was naturally selected as the standard of railway time throughout France but the local times of other places long continued in use for local purposes The difference between local and railway time varied according to the distance east or west of Paris Local time was 20 minutes faster than railway time at Nice on the eastern frontier and 27 minutes slower than railway time at Brest on the western frontier The local time gradually lost importance and the railway or Paris time gained until in 1891 the passage of the law which made Paris time the legal standard for all France and Algeria was scarcely noticed by the public The same practical conditions led to the enactment of similar laws in other countries each of which as a rule adopted the local time of its principal astronomical observatory

This simplification however produced remarkable diversities of time standards in some regions The Lake of Constance for example is bounded by five countries Switzerland Baden Wurtemberg, Bavaria and Austria—each of which had its separate national time standard The confusion thus created in railway and steamboat time tables and in the minds of travelers may be imagined In going from Paris to Constantinople a traveler was compelled to set his watch ten times

These inconveniences suggested the adoption of a single time standard for all countries but the impracticability of this idea is evident from the obvious fact that a single standard is inadequate for one country of great extent in longitude The United States for example covers five hours in longitude and the winter sun is rising on the Pacific coast when it is noon on the Atlantic coast The adoption of a single standard for the whole world would produce an intolerable displacement of traditional hours in most places and though the Japanese are ardent lovers of science and progress it is not to be supposed that they would consent to have the sun set at 9 o'clock in the morning It should be added, however that the advocates of a universal time stand ard limited its employment to railways steamship lines mails telegraph systems and similar uses

The question of a universal time standard is necessarily connected with that of an international prime meridian and the two questions were discussed together at the geographical congress which met in Venice in 1881 at the meeting of the International Geodetic Association in Rome in 1883 and elsewhere

Geographers have always felt the necessity of reckoning all longitudes from a single meridian but the location of this prime meridian is arbitrary and has varied greatly In the 17th century Richelieu selected the meridian of Ferro the most westerly of the Canary Islands and the most westerly land known to the ancients The meridian of Ferro was for a long time accepted almost universally as the prime meridian but as its longitude was not accurately known it was arbitrarily assumed, at the suggestion of the celebrated geographer Delisle to be 20 degrees west of Paris This assumption made the meridian of Paris the real prime meridian and in course of time each of the great nations adopted the meridian of its principal astronomical observatory as a prime meridian

When the return to a single prime meridian was discussed at the congresses of Venice and Rome it was agreed that this meridian must pass through an observatory of the first class situated in a region free from volcanic and other disturbances The choice was practically limited to the meridians of Greenwich and Paris

The latter had played a most important part in the 18th century in connection with the numerous expeditions sent out by the Paris Academy of Sciences for the determination of longitudes in Denmark Cayenne Senegambia the West Indies Siam China Cape Colony etc which resulted in the correction of errors amounting in some instances to 27 degrees In the expedition to Cayenne Richer made the memorable discovery of the shortening of the seconds pendulum in approaching the equator The exact measurements instituted by Picard and based on the meridian of Paris were extended from France to the Arctic circle, the equator and the Cape of Good Hope In short, geodesy continued for a century to be an exclusively French science

Subsequently the meridian of Greenwich gained importance chiefly in the determination of longitudes by the moon and nine tenths of the mariners of the world use English charts in which longitudes are reckoned from Greenwich The Rome congress of 1883 consequently decided in favor of Greenwich and this choice was confirmed by the international conference held in Washington a year later

The Canadian Institute had already proposed to divide the earth's surface into 24 sections each embracing 15 degrees of longitude and to employ in each section a time standard differing by one hour from those of the adjacent sections. This system was adopted in 1883 by the American railways, and has since been adopted for general use in America and Europe It is illustrated by the accompanying map. The prime meridian of Greenwich is represented by the doted line, marked 0 degrees. The hour section marked 0 at the bottom of the map is bounded by two meridians drawn 7½ degrees east and west of the prime meridian The hour section marked 1 extends 7½ degrees east and west of its central meridian (not drawn) which is 15 degrees east of Greenwich and so on Each country which has adopted the system uses as its time standard the time of the hour section to which its territory most nearly corresponds or if it extends over several hour sections employs several standards, determined by the same rule, for its various political divisions

This system possesses most of the merits and none of the defects of a single universal time standard, for local time never differs from standard time by much more than half an hour and the standard times of any two places or countries differ by a whole number of hours, the minutes and seconds being everywhere the same The figures at the bottom of the map mark the hour of each section when it is midnight at Greenwich (The numbers of the left hand half indicate afternoon hours and must be diminished by 12 to agree with the clocks used in most countries) Special names have been given to the most important hour sections as follows

Name	Section	Time
West European	0	12 P M.
Mid European	1	1 A M.
East European	2	2 A M
Pacific	16	4 P M.
Mountain	17	5 P M.
Central	18	6 P M
Eastern	19	7 P M
Intercolonial	20	8 P M

France is included almost entirely in the section of West European or Greenwich time which is 9 minutes and 21 seconds slower than Paris time

The difference between the longitudes of two places can be obtained either by linear measurement and triangulation or by determining the difference between their local mean times by astronomical observations The difference in longitude of the observatories of Paris and Greenwich has been repeatedly determined by each of these methods which often give discordant results In the present case in which the difference in time is the real object of search the results obtained by the second method are naturally adopted Accurate determinations of this kind have been possible only since the introduction of the electric telegraph The results obtained by various observers since 1854 are given below

		Min	Sec
1854	Donkin and Faye	9	20 51
1872	Coast Survey	9	20 97
1888	Lewis and Turner	9	20 85
1892	Hollis and Turner	9	20 79
1902	Dyson and Hollis	9	20 93
1902	Bigourdan and Lancelin	9	20 99

The value 9 minutes 21 seconds is sufficiently accurate for practical purposes

The law recently created contains only one article, which reads The legal time in France and Algeria is nine minutes and twenty one seconds slower than Paris mean time In this form the law was passed by the Chamber of Deputies in 1897 and by the Senate in 1911 In the original form of the bill introduced in the Chamber of Deputies in 1896 the meridian of Greenwich was explicitly adopted The change was made in, order to prevent sinister interpretations which might have killed the bill

The question of the meridian is left untouched by the new law which applies only to railways, mails and civil affairs in general The meridian of Paris remains the standard for the navy merchant marine astronomers and geographers and more than 3,000 official maps and 600 volumes of nautical instructions remain unchanged

The change brings unquestionable advantages in connecting French with foreign railway and telegraph schedules and meteorological bulletins and terminates the complete isolation of France in respect to time standards On the other hand, it presents the slight disadvantage of substituting for the meridian of Paris, which divides the country almost equally a meridian lying much farther westward But the difference between local and standard time will not be much greater at Nice than it was formerly at Brest.

The national *amour propre* has been wounded severely, especially as the meridian of Paris was the only one that could pretend to challenge the supremacy of Greenwich, but the French may console themselves with the thought that the new time is not English but international, and, furthermore, that it is ingeniously defined by the law as "nine minutes and twenty-one seconds slower than Paris mean time."

MAP OF THE WORLD DIVIDED INTO HOUR SECTIONS

The Air-brake as Related to Progress in Locomotion—IV*

The History of a Great Invention

By Walter V Turner, Chief Engineer, Westinghouse Air Brake Co, Pittsburg, Pa

Concluded from Supplement No 1842, page 246

STARTING AND STOPPING

THE problems of deceleration retardation and the flexible control of trains must receive more and more attention from a scientific and technical standpoint in order that to-day theory and practice may be combined to produce the best results in the shortest time This is necessary if the brake is to efficiently and satisfactorily meet the wonderfully changed conditions which have developed since the invention of the quick action automatic brake The high speeds and great weights of the present day requiring that advantage be taken of every opportunity offered to increase and flexibly control braking power

Starting and stopping of trains are complementary factors in the problem of making time between stations therefore it is evident that the best results can only be obtained where both factors are given due consideration Generally the starting factor is the only one fully considered or at least the one more fully provided for and this notwithstanding that better results can be obtained if both are considered and the more efficient brake system installed

In another sense the question of stopping is the most important as the safety of the service and the freedom of delays to a great degree depend upon it The measure of the value of the brake is two fold—(1) the ability to stop in the shortest possible distance when necessary and (2) to permit short smooth and accurate stops being made in regular operation Therefore both these factors should be considered when design is under way

Unfortunately the brake is usually looked upon as a safety device only and it is because of the prevalence of this idea that its installation and maintenance do not receive the consideration merited Considering the investment, there is no part of the railway equipment that will give greater material returns than the brake when properly installed operated and maintained If the brake could to some extent be separated from the idea or impression that it is a safety device only and proof advanced to show that it makes possible the hauling of heavier cars—in fact makes the heavy car possible—that it makes possible faster and more frequent service—as much or more than does the locomotive the block signal and the good roadbed—and that if given the consideration it should have it would increase the possibilities profits and value of all these things—its importance would be more fully appreciated and therefore at least the same consideration be given to its design and installation that is accorded to other parts of railway equipment A safety device the brake is *par excellence* but it has other reasons for its existence

Very few perhaps realize that the brake under a single car is much more powerful than the locomotive that pulls the train yet this will be apparent to any who examines the records of a dynamometer car stop the train The comparison is somewhat startling but it is only because the condition is one of those commonplaces which have been taken for granted so long that they are accepted as inherent rather than being given the degree of consideration which their significance warrants Fig 22 is an illustration of the facts stated taken from the records of a run during a series of tests at Absecon N J 1907 the train being composed of a locomotive and ten cars What it took the locomotive nearly six minutes and a distance of about three and a half miles to accomplish was overcome by the brakes in less than twenty seconds and within a distance of about one thousand feet The broken line represents what the stop might have been if no brakes had been used i e the train brought to rest by the resistance of the air and journal friction All the elements so strongly contrasted in Fig 22 are familiar in themselves but their reciprocal relationship is often overlooked The average passenger train of to day can be stopped from a speed of sixty miles per hour in about twenty seconds time To build a steam locomotive that would accelerate a train in the time and distance

alone attached to an engine the stops being made by brakes on the dynamometer car Few realize that it takes a locomotive perhaps five minutes perhaps ten minutes, and a distance of some miles—six or seven—to attain a speed of sixty miles per hour Imagine the condition of affairs which would exist if it took a brake that length of time and distance to that the brake stops it would be impossible for in order to have the necessary adhesion to the rails which permit of developing the required drawbar pull the steam locomotive would have to weigh approximately twice as much as the train itself which is of course prohibitive Electric locomotives however are no longer to be regarded with uncertainty or as mere experiments, and there is every reason to believe that the electric locomotive will be able to accelerate a train to a speed of sixty miles an hour in certainly not more than a minute and a half and probably not more than one minute's time That means that the brake is going to be even more important in the future than it has been in the past In proportion as we accelerate we must perforce be prepared to decelerate The ability to accelerate or even to run at high speeds must be measured by the ability to stop

As an example however of how little this is appreciated such a question as the following is often asked and a categorical answer apparently expected In what distance should a train be stopped from a speed of fifty miles per hour? Perfectly simple isn't it? Here we have one known factor from which we are expected apparently to derive all the other factors which are of equal importance and must be known before an answer of any value can be given to such a question A few of these factors are The light weights and loads of the vehicles composing the train the percentage of braking power used with engine and cars whether or not all wheels including truck and trailer (if any) of the locomotive were braked what type of brake equipment was used what pressures were carried whether the train was accelerating or decelerating on a curved or straight track on an ascending or descending grade or level the condition of the rail whether the brakes were applied in service or emergency or ordinary service and then emergency the piston travel on each vehicle the losses to friction of parts brake beam release springs, etc Wind resistance, quality and thickness

* Presented at the meeting of the Mechanical and Engineering Section.

of brake shoes and method of hanging them, for this affects materially the efficiency of the brake both as to absorbing power and lengthening the piston travel which reduces the pressure otherwise obtainable. Furthermore it should by no means be understood that the precise effect of each of these could be accurately calculated even though full information were at hand and a little thought will make it evident that each of the factors mentioned above may have a considerable influence on the length of the stop.

These things are merely mentioned to emphasize the great importance of the air brake and the necessity for considering carefully what principles govern its action. It does not make very much noise. It does not occupy so prominent a place in the papers as electricity, for instance, yet it has been much more of a factor in railroad development up to the present time than electricity.

Now from a comparison between the propelling and stopping mechanism of our steam railroads. The locomotive is much in evidence, being large and of powerful appearance and placed in the most conspicuous place in the train. The brake is outwardly a comparatively insignificant piece of apparatus installed on the different vehicles of the train, placed underneath the cars where it is hard to find and seldom observed by the traveler. The very fact that it is so distributed over the train is one reason for its power and efficiency. When we realize the forces handled by the two devices and the great difference in point of time in which their work is accomplished our respect for the brake will be stimulated since it *must* be capable of dissipating the energy stored by the locomotive in the train in but a fraction of the time required by the locomotive to do this if the safety of transportation is to be preserved.

FUNDAMENTAL PRINCIPLES IN BRAKE DESIGN

In the establishment of a logical basis of brake design applicable to the conditions under which brakes in general must operate and involving a determination of the essential elements of an elementary brake system for any given car the starting point must be the light weight of the car. Fortunately this can usually be determined in advance to any desired degree of accuracy. For convenience suppose the car to be fully equipped with a complete brake equipment and by an analysis of the factors involved in stopping the car determine how these factors may best be provided for in the design.

Assuming that the wheels do not skid the actual *braking force* acting on a car when the brakes are applied is the force of the friction between the brake shoes and the wheels tending to retard the rotation of the wheels and thus stop the car. The relation which this bears to the energy stored up in the moving car, provided the adhesion of the wheel to the rail is not exceeded, determines the effectiveness of the brake and the length and time of stop. The energy of the moving car consists of two parts—that of the car as a whole due to the velocity of translation and that of the revolving wheels due to their rotation and varies as the weight of the car and as the square of its velocity.

The latter may roughly be taken as 5 per cent of the energy of translation for 12-wheel cars and as 2 per cent of the energy of translation for 8-wheel cars. In ordinary calculations however this factor is usually neglected and properly so because for modern rolling stock the resistances other than as derived from the brakes, such as internal friction, air resistances, flange friction and so on has been shown by actual experiment to at least equal if not to exceed the inertia effect of the revolving parts. Consequently a greater error is made by considering the energy of rotation without at the same time taking into account the resistances to motion which exist due to other causes than the brake shoes (which it should be noted are usually indeterminate and subject to considerable variation) than to assume that these two opposing factors neutralize each other.

The frictional force between the brake shoes and wheels depends on the pressure acting on the shoes and the coefficient of friction between the shoes and the wheels. In making a stop therefore (it being assumed throughout that the wheels do not skid) the factors involved so far as retarding the rotation of the wheels is concerned are:

1. The total amount of brake-shoe pressure in pounds commonly called the "braking power."
2. Coefficient of friction between the shoes and the wheels by which the brake-shoe pressure must be multiplied in order to determine the actual retarding force.
3. The weight resting on the wheels.
4. The velocity of the car.
5. The rotative energy of the wheels.

Only one of these factors can be controlled even partially in service or fixed arbitrarily in designing the brake system, viz. the pressure on the brake shoes. Inasmuch as the wheels must not skid when the weight resting on the wheels is least—that is when the car is not loaded—the light weight of the car must be taken as the basis of calculation regarding brake-shoe pressure, except in the case of some form of empty and load brake. Since the "braking power" is by custom measured by a scale of percentages wherein 100 per cent represents a shoe pressure on each wheel equal to that wheel's pressure on the rail the problem is then to determine and insure the obtaining of the proper relation between the brake shoe pressure and the light weight of the car.

As pointed out above the factors involved such as frictional coefficient, speed, weights, etc. are so subject to variation in service that no theoretical conditions can determine the proper nominal percentage braking power (i. e. the ratio of brake-shoe pressure to light weight of car) which shall best meet average road conditions. This can be fixed only by experiment and experience and is subject to modifications as conditions change or become more thoroughly understood. For example many years experience has proven that 90 per cent braking power for passenger cars gives satisfactory braking effects with a reasonable margin against wheel sliding and sufficient power for service stops. This was determined by the results obtained on the lightest cars. So far as wheel sliding is concerned a 150,000 pound car braked at 95½ per cent has practically the same margin against wheel sliding as a 70,000 pound car braked at 90 per cent. But if the percentage of braking power is varied the uniformity of service braking effect other factors being the same is lost. *Therefore the percentage of braking power determined as a satisfactory maximum for the lightest cars* must be adhered to on all cars in order to bring about as nearly as possible the uniform results which are necessary for satisfactory service operation.

Having therefore chosen a certain percentage of braking power which should be obtained on all cars it is evident that what actually is obtained in any given instance depends on the total leverage ratio and the pressure per square inch on the brake piston. It will be apparent that all resistances between the brake piston and brake shoes such as release springs, reactions of hanger links, friction of rigging, etc. must necessarily be ignored until the essential factors in the design are determined upon.

The total leverage ratio is fixed within certain limits by purely mechanical consideration with regard to piston travel, shoe clearances, etc. and once the foundation brake rigging is designed remains always the same.

Hence in any given case the percentage of braking power actually obtained depends entirely on the pressure existing in the brake cylinder which varies in practice from zero to the maximum obtained when an emergency application is made.

In designing the brake system for a car therefore the leverage ratio and size of brake cylinder must be so proportioned as to give the required braking power in pounds with some arbitrarily chosen pressure in the brake cylinder. Evidently this braking power will be obtained in practice when the brake-cylinder pressure is that on which the design of the brake system was based. For any pressure lower or higher than this the braking power in pounds will be correspondingly lower or higher than the nominal. Furthermore the actual percentage of braking power (ratio of brake shoe pressure to weight on wheels) varies not only with the brake cylinder pressure but also with the condition of the car—whether loaded or empty.

From a consideration of these conditions it seems evident that it is practically impossible to provide for even an approximate uniformity of brake action on different cars in service by any method of design. The best that can be done is to establish and adhere strictly to the assumed standards upon which such designs are based.

1. The percentage of braking power in terms of the light weight of the car.
2. The brake-cylinder pressure upon which this percentage is based.

The former as has already been stated must be determined from experiment and experience. The latter must be chosen arbitrarily but it should have the same value for all brake calculations in order to insure a common base being universally used and understood. Fig. 23 graphically illustrates the relations existing between these two factors for different weights of cars and total leverage ratios. The question now is therefore: What brake-cylinder pressure should be used as a basis in designing the brake systems of all types and classes of cars?

With a given auxiliary reservoir charged to a standard pressure and with a given brake cylinder having standard piston travel a certain definite pressure of equalization is obtained which is constant so long as the other factors involved are kept constant.

When an emergency application is made, since a portion of the air in the brake pipe or other source of supply is used in addition to that in the auxiliary reservoir, the resulting brake-cylinder pressure is augmented in proportion, and a higher maximum pressure therefore obtained. Evidently its value must depend upon the relation which the supplementary brake-pipe volume bears to that of the auxiliary reservoir and brake cylinder combined. With equipments now in general use this ratio must necessarily decrease as the size of the car increases because the brake pipe volume remains practically constant for all sizes of cars while the brake-cylinder and auxiliary reservoir volumes increase as the size of the car increases. It then follows that where air from the brake pipe alone is used to augment the brake-cylinder pressure in emergency applications, the emergency pressure thus obtained must vary with the different combinations of auxiliary reservoir and brake cylinder necessary for different sizes of cars—the gain in pressure from this source over that obtained in full service equalization being greatest with the smallest sizes of auxiliary reservoirs and brake cylinders.

Hence in choosing a brake-cylinder pressure on which to base brake calculations that obtained in emergency which was satisfactory where the brake cylinders were of such size that a uniform pressure was obtained in both service and emergency, is now excluded at the outset—from the standpoint of uniformity—since in the nature of the case it is not uniform for all weights of cars. This is for the reason that brake cylinders may vary from 6 inches to 18 inches diameter with correspondingly varying pressures in emergency. And if the braking power desired is based on a brake-cylinder pressure higher than can actually be obtained then for lower cylinder pressures the brake is not so effective as it might be made were the braking power based on the pressure actually obtained. The smaller cars which do obtain this pressure give the calculated braking power in emergency but the heavier cars cannot, and there is a loss both in uniformity of emergency action and possible efficiency.

On the other hand for brake-pipe reductions less than sufficient to produce equalization the cylinder pressures obtained are uniform provided the other factors are uniform in value and the pressure at which the auxiliary reservoir and brake-cylinder equalize is supposed to be the same for all combinations of reservoirs and cylinders with the same initial pressure. To obtain this uniformity it is only necessary to properly proportion the reservoir volume to the brake-cylinder volume for some standard piston travel. We then have a pressure base which will be constant when the other factors involved have their proper or standard values. It would seem that this is the basis to which all braking power calculations should be referred for the reason that it is the nearest approach to a uniform and constant pressure obtainable under the wide range of conditions governing this choice. This adds to the standard enumerated in the preceding column the following:

3. This brake-cylinder pressure must be the equalized pressure on the auxiliary reservoir and brake cylinder.
4. A predetermined ratio between auxiliary reservoir volume and brake-cylinder volume to produce this equalization must be adhered to.

The fundamental steps in designing a brake system for any given car may now be outlined as follows:

Given the light weight of the car the proper braking power per cent has been established from results of experiment and experience and this enables the total brake shoe pressure to be calculated.

Mechanical considerations fix the total leverage ratio between certain limits, the maximum and minimum values of which enable a maximum and minimum total brake piston pressure to be calculated from the preceding.

This total brake piston pressure depends upon the size of cylinder and pressure per square inch used as a basis. The pressure basis to be used should be that agreed upon as a universal standard for such calculations as this and as has already been pointed out, uniformity requires that the *equalization pressure* (50 pounds per square inch) from the lowest standard brake pipe pressure carried should be the base chosen.

Having determined the unit pressure the size of cylinder can be chosen from the standard sizes manufactured to give the desired braking power with a total leverage within the maximum and minimum limits as defined above.

To obtain the desired 50 pounds equalization pressure from the standard 70 pounds brake-pipe pressure with a standard piston travel is simply a matter of correctly proportioning the auxiliary reservoir volume to that of the brake cylinder at the piston travel employed as standard.

We then have an auxiliary reservoir which, at 70 pounds initial pressure will equalize with its brake cylinder, when this has eight inches piston travel, at 50 pounds, and the brake-cylinder piston is of such an area that the total pressure thus obtained, when multiplied by the total leverage, will give a total braking

shoe pressure equal to the desired percentage of the light weight of the car

To be sure in an emergency application the braking power on all cars will be greater than that used in the design and the lighter the car the greater the variation between service and emergency braking powers But such non uniformity in actual service is bound to obtain and always has since an increase to 90 pounds brake-pipe pressure or a variation in piston travel produces similar results to say nothing of losses due to leakage resistances and variation in frictional coefficients The advantage gained however by the method of design outlined is therefore in the fixing of a uniform and actually obtainable brake-cylinder pressure which is necessary for service operations and is one of the most important factors in the calculation to be made

It may be said in passing that with the more recent types of brake equipments for passenger service using a supplementary reservoir volume in addition to that of a brake pipe to produce high emergency brake-cylinder pressure the size of supplementary reservoir used is calculated to give practically uniform brake cylinder pressures in emergency applications with *all* sizes of brake cylinders thus taking advantage of the principle of high pressures for emergency stops and at the same time conforming to the principles of uniformity laid down above it being a fundamental principle of modern brake design to keep the service equalization brake-cylinder pressure comparatively low for reasons fully explained elsewhere and use as high an emergency equalization pressure (as large a supplementary reservoir) as may be desirable

In the attempt to secure a high emergency brake cylinder pressure without the aid of the supplementary reservoirs referred to above the relationship between brake cylinder and auxiliary reservoir volumes existing in the *original* brake design was gradually lost the auxiliary reservoir volume being increased slightly from time to time as heavier cars requiring larger brake cylinders were equipped On the lighter equipment the variations thus introduced were relatively unimportant but in the case of heavy cars requiring the 16 inch and 18 inch cylinders it was impossible to increase the auxiliary reservoir volume sufficiently to obtain the desired emergency pressure without at the same time interfering to a marked degree with the proper operation of the equipment in service Consequently a compromise was made so as to obtain as high an emergency cylinder pressure as possible without increasing the service equalization pressure to an extent inconsistent with the proper normal functions of the brake

By the aid of a *supplementary reservoir volume* however reserved during service operation but available in emergency applications of the brake it is now possible to obtain the required increase in stopping power for emergencies and at the same time return to the original volume relationship the correctness of which has been established by long experience

These relationships are determined by the following principles which will be recognized at once as having been followed in even the earliest automatic brake designs

(A) For any given arrangement of leverage between the brake-cylinder piston and the brake shoes the braking power is directly proportionate to the gage pressure of air produced in the brake cylinder

(B) The limitation of the maximum allowable pressure of air in the brake pipe limits thereto the available pressure in the auxiliary reservoirs

(C) With this fixed maximum charge in the reservoir the highest pressure obtainable in the brake cylinder from this single source is that at which the air pressure equalizes between the two This (absolute) pressure therefore equals the product of the initial absolute pressure in and the volume of the auxiliary reservoir divided by the sum of the volumes of the auxiliary reservoir and of the brake cylinder (neglecting all clearance volume temperature effect etc) and the braking power is as the corresponding gage pressure

(D) This pressure of equalization should be limited because its height determines the range of those differences between final auxiliary reservoir pressure and initial brake-pipe pressure which range affords the control of "braking power applied

(E) That while low pressure of equalization limits "full service" pressure yet small range precludes nicety of control, especially as from the range there must be deducted such initial differences of pressure as are necessary to overcome the inertia and friction of the triple valve parts.

(F) That to afford heightened brake-cylinder pressure for use in emergency another quantity of air is necessary, and if this be, as in all past practice that contained in the brake pipe, the resulting absolute pressure will be equal theoretically to the maximum absolute brake-pipe pressure multiplied by the volume of the auxiliary reservoir plus the amount of air, in cubic inch pounds obtained from the brake pipe this sum then divided by the volume of the auxiliary reservoir plus that of the brake cylinder so that the measure of the resulting braking pressure is the gage pressure corresponding to this resulting (absolute) pressure

Now it is the interdependence and reactive results of these simple and recognized principles in their combinations together with a corresponding proportioning of leverage between the brake-cylinder piston and the brake shoes that determine the relative efficiency of a brake design

From (F) it is seen that if other parts be enlarged the volume of the brake pipe which is practically the same on all cars becomes relatively small and the emergency pressure sought is so insufficient that in the equipments for heavy rolling stock resort has been had to enlarged auxiliary reservoirs with a corresponding heightening of the full service pressure (C) and a resulting lessening of the range of control (D)

Again when (C) is heightened while (D) is lowered the results of the lighter brake pipe reductions cause magnified effects in the service braking so that when it is realized that such range as is possible is lessened by the lack of sensitiveness of the triple valve (F) there is likelihood of roughness of service stops

Such being the case it is apparent

1 That there is a ratio of volume of auxiliary reservoir to that of brake cylinder that should not be exceeded

2 That such service pressures as result in the brake cylinder should be made sufficient by a corresponding proportioning of the leverage

3 That the volume of each cars part of the brake pipe should be supplemented by proper means so as to afford the required braking pressure in emergency

Starting therefore with a brake cylinder of the size *dictated* by the vehicle to be equipped as already explained and by a proportioning of the leverage which shall accord with the service required and assuming that—

C equals volume of brake cylinder in cubic inches

P equals service equalization pressure in absolute units

R equals volume of auxiliary reservoir in cubic inches

a equals absolute initial pressure in the auxiliary reservoir

r equals permissible range of brake pipe reductions

it follows first from the above definitions that

$$r = a - P$$

and from (C) above neglecting clearance volumes

$$\frac{a \times R}{R + C} = P$$

from which

$$R = \frac{P}{a - P} \times C$$

$$= \frac{P}{r} \times C$$

which may be expressed in the following law

The proper auxiliary reservoir volume according to the principles laid down above is equal to the volume of the brake cylinder determined upon multiplied by the ratio of the service equalization pressure fixed upon as standard to the permissible range of brake pipe reductions

Assuming as in current practice that *P* equals 50 pounds per square inch (gage) and *a* equals 70 pounds per square inch (gage) then we have

$$r = a - P = 20 \text{ pounds}$$

and

$$R = \frac{P}{r} \times C$$

$$= \frac{65}{20} \times C$$

$$= 3\tfrac{1}{4} \times C$$

That is the volume of the auxiliary reservoir should be three and a quarter times the volume of the brake cylinder It is plain however that the effect of the clearance volumes leakages temperature and other adverse influence will be such that to obtain the desired results in actual service a somewhat higher auxiliary reservoir volume must be used than that found by the above calculations For example with the standard 8 inch equipment an auxiliary reservoir volume of 1 620 cubic inches is used which is about three and one-half times the brake-cylinder volume

In determining the proper size of supplementary reservoir (*F*) to be used, a similar reasoning may be used In addition to the symbols already defined let

S volume of supplementary reservoir in cubic inches

E absolute emergency equalization pressure

Assuming for the purposes of calculation that the emergency pressure is the result of the equalization of the brake cylinder auxiliary reservoir and supplementary reservoir volume it follows that

$$\frac{a\,(R + S)}{R + S + C} = E$$

whence by proper substitution and reduction is derived

$$S = \frac{a\,(E - P)}{r\,(a - E)} \times C$$

While the above expression is interesting as showing the simple relation which exists between the various volumes involved in the typical equipment as we have assumed it it must be clearly understood first that all the additional air supply in emergency is supposed to come from the supplementary reservoir having taken no account of that vented from the brake pipe and second that in any actual installation similar to that discussed the equalization is dependent upon the movement of certain valves actuated by spring and air pressures in combination the resultant effect of which is such that in the actual working equipment the state of affairs is by no means as simple as has been assumed for the typical equipment Instead of equalization taking place between all the volumes concerned simultaneously there are time limitations imposed on the rate of flow from the various sources of air supply to the brake cylinder so as to derive the maximum possible benefit from the compressed air stored in each There is also a material modification of these calculated results due to the processes not being truly isothermal as assumed and so on Proper allowance being made for these limitations a formula might be derived in the same manner as above to completely *cover the more complicated conditions but as only* the principles involved are now being considered it is unnecessary to go further into details particularly as these are accurately determined by experiment

In the above analysis as is necessarily the case with all theoretical considerations relative to mechanical apparatus of this character certain assumptions were made to furnish a basis from which to start Hence it should always be remembered that the formula derived must be interpreted for any given case in the light of the modification of these primary assumptions which the nature of the installation or the character of the apparatus used may involve With this understanding the above reasoning affords a logical and sound theoretical basis not only for determining the correct proportions of new types of equipment but also establishes a criterion by means of which the shortcomings of incorrectly designed installations may be discovered

BRAKES FOR ELECTRIC TRACTION SERVICE

It would hardly be proper to conclude without mentioning the fact that the electric traction service has required even more specialized apparatus than that already mentioned in connection with steam road service on account of the great variety of conditions under which electric cars operate from the single city street car up to the eight and ten-car subway and elevated trains to say nothing of the electric locomotive and multiple unit train service on electric division or steam railroads It can easily be appreciated that these phases of the subject are of even greater magnitude and require a greater variety of apparatus and complexity of detail than in the case of steam railroad service Consequently no more can be said at this time than to simply state the fact that the multiplicity of requirements has been anticipated and provided for to the extent that the high standard of efficiency already outlined has been maintained with out any compromise or failure to meet the requirements of the service In one particular at least the highest type of brakes for electric service namely the Electro Pneumatic System affords superior stopping power and service efficiency since its electric transmission of quick action insures simultaneously and almost instantaneously maximum braking power on all cars in the train while for service braking it possesses the maximum flexibility of control possible only in an electrically actuated brake system This brake therefore possesses superior features which are particularly noteworthy whether they are considered from the standpoint of the time saved the increased traffic made possible or the safety insured At the present time this type of equipment appears to be the acme of the braking art, but as past experience has always shown the same time which brings about changes in operating conditions is also sure to develop new and more efficient means for meeting new requirements

Saving Human Life in Mines

The Work of the United States Bureau of Mines

A LIFE-SAVING service for the rescue of miners in time of disaster is the first important step taken by the United States Bureau of Mines in its effort to reduce the appalling loss of life in American coal mines

Six specially constructed cars fully manned by a corps of miners trained in rescue work and equipped with the latest rescue apparatus and first aid to the injured appliances have been located in the midst of the great coal districts in different sections of the country These cars are ready at a moment's notice to proceed to the scene of a disaster where the rescue corps in co-operation with the state mining officials do everything possible to save entombed miners

During the year 1909 there were 2 412 miners killed in the coal mines and 7 979 injured In the coal and metal mines it is estimated that 3 000 men were killed and 10 000 were injured in 1909 For every 1 000 men employed from three to five men are killed each year in the mines of the United States In foreign countries from one to two are killed in each 1 000 employed In those European countries where the deaths are least per 1 000 men employed rescue apparatus has been in use for some time and it is with the hope that European conditions can be approached that rescue apparatus is being introduced here

The saving of human life is the emergency feature of a general campaign of educational work among the miners who are not only taught the use of rescue apparatus but also the proper way to care for an injured miner Lectures on different phases of the mining problem looking toward greater safety are given by the mining engineer attached to the car The mine rescue cars go to the miner in his own town or camp so there is little excuse for the miner not benefiting himself Each car has a specified territory and it is expected that every community of any importance will be visited In addition to a mining engineer, a surgeon of the American Red Cross accompanies each car The lectures delivered touch upon the use of explosives, electrical equipment, fire prevention sanitation and first aid to the injured surgical treatment When a suitable meeting place cannot be secured the lectures are given in the cars The itineraries are so planned that the cars remain long enough at each place for the miners to go through the training in rescue work which is in charge of the foreman of the car a practical miner

THE OXYGEN HELMET

NUMBER

The United States of America.

BUREAU OF MINES

DEPARTMENT OF THE INTERIOR

Certificate of Mine Rescue Training

This is to certify that ______ of ______

has been trained in the use of MINE RESCUE APPARATUS at the Government Mine Rescue Station at ______ during which training he performed hard labor within a gallery filled with noxious and irrespirable gases and gave evidence of being qualified to care for and use such apparatus within mines

Trained under the direction of *Approved*

Washington, D. C. ______ 191__

CERTIFICATE ISSUED BY THE UNITED STATES BUREAU OF MINES

The cars contain eight small oxygen helmets a supply of oxygen in tanks one dozen safety lamps one field telephone with 2 000 feet of wire resuscitating outfits and a small outfit for use in demonstration and actual practice of equipment relating to first aid to the injured in connection with mine accidents

One end of the cars is fitted up as an air tight room to be used in training men in the use of the small oxygen helmet This room is filled with noxious fumes and the miners wearing the helmets remain inside for two hours in an atmosphere that would kill without the helmets These are the helmets that permit one to enter a mine immediately following an explosion while it is still filled with poisonous gases, and breathe artificially

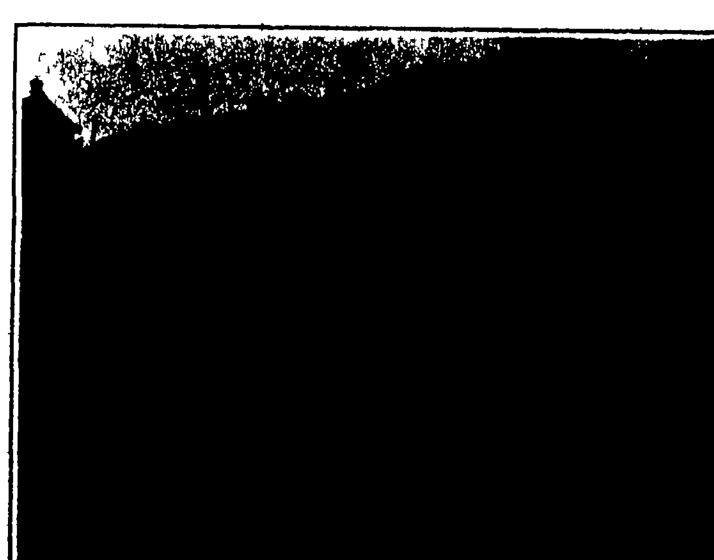
The absence of the helmets at great catastrophes in the United States has it is believed resulted in greater loss of life than necessary Frequently miners who have not suffered physical injury by an explosion have been entombed in the mine to die solely from the inhalation of the poisonous gases Had it been possible to reach these men within a few hours their lives might have been saved.

Every effort is made to encourage the miners to form rescue corps at the mines where they are employed and to have the operators equip them with the rescue apparatus As a result of the educational work along this line numerous coal operators throughout the country have purchased mine rescue equipment. For instance according to the annual report of the State Inspector of Coal Mines of Washington eleven companies have purchased thirty-one pieces of the Draeger rescue apparatus during the past year

The bureau has already trained more than five hundred men in rescue work and first aid to the injured It expects to train upward of three thousand men a year Each man taking the training receives a certificate The certificates are highly prized by the men and are usually framed and exhibited with great pride A large percentage of those who have taken the training have announced their intention of again taking it at the expiration of six months or a year They are all thoroughly trained in the use of the oxygen helmet and practically promise to be volunteers at any accident that occurs in their territory If the rescue car is near it will pick up these men on its way to the disaster Perhaps as a result of the rescue work of the bureau nearly one hundred coal companies have equipped themselves with complete rescue stations whereas in the past they not only had no trained rescuers, but had no apparatus to enter a mine

Past experience has been that in every big mine disaster a great many of the volunteer rescuers themselves have been killed At one mine disaster with seventy men killed fifty rescuers were among the number In the famous Cherry Mine disaster twelve men who went down as rescuers were brought up

THE IMPROVISED AMBULANCE CAR



A HOSPITAL CAR FOR MINE USE

SAVING HUMAN LIFE IN MINES

...ed on the cage. The death of rescuers has swelled the deaths of men killed in the mines. Since the Bureau of Mines has been established only two helmeted men or rescuers have been killed in mines.

There has never been any question as to the bravery of the miners in time of disaster. The only trouble has been the recklessness displayed. The miners have never hesitated to rush into danger in order to save a fellow worker and that is the reason so many have been killed. A very large percentage of the rescuers have met death owing to lack of proper equipment. For example, recently in a Pennsylvania mine some trouble was experienced and the superintendent and half a dozen of the best men went down to ascertain what the trouble was. They got in and were overcome but one of the number managed to telephone to the top. Several helmeted men went in and rescued them. If it had not been for the use of the helmet in this instance the men would have been killed. In a recent mine disaster in Ohio where a large number of fatalities resulted two men having been overcome lay along the floor of the working and had been passed by the rescuing parties for nearly twenty hours. One of the engineers of the bureau noticing them felt under the arm pits and found a slight warmth. The pulmotor was used and the men resuscitated. To-day these men are alive and working, whereas if it had not been for the application of the pulmotor they would have expired within a short time.

Eagle Hunting in China

A Lucrative Oriental Sport

Every year according to an old custom in the second quarter of the September or October moon the inhabitants of the Chinese province of Shantung go to Mongolia to hunt the eagles which abound in that region strewn with many bodies of animals and even of men. The huntsmen march in troops along the roads carrying on their shoulders long poles from which are suspended their baggage and provisions and on which are perched tame eagles to be used as decoys. Commandant Laribe encountering such a procession obtained the photographs which are here reproduced from *L'Illustration* from which we also take the details given below.

The hunters make use of a large net laid flat on the ground and baited with small dried fishes in the midst of which is placed the tame eagle. The decoy naturally begins to devour the bait and thus invites his wild cousins to follow his example. When the birds have alighted and are feeding the hunter from his hiding place two or three hundred yards distant quickly closes the net by means of a system of cords and thus captures the eagles.

Eagle hunting is very lucrative; the feathers are used in the manufacture of fans and are sold at a high price even in China.

There are three sorts: Kie-pei, black with white centers; Che-ma, white spotted with black; Tou-tsing, half white and half black. Several eagles are required to make a fan for only a small part of the plumage can be utilized. Hence these fans are very costly. A fan made of Kie-pei feathers may cost as much as fifty taels or about thirty dollars. A fan of Che-ma feathers is worth thirty taels. Fans made of the feathers which do not belong to any of the three sorts named are worth only a few taels. This information was obtained from a native of Kalgan on the Mongolian frontier. It is therefore probably correct.

Up-to-Date Pearl Diving

One by one industries of various kinds about which for centuries there has clung the atmosphere of romance are losing their glamor by reason of the advancement of practical science. For instance pearl diving. The era of naked divers exposed to peril from sharks has passed away; modern progress equips the pearler with a suit of India rubber, copper breastplate with leaden weights back and front, helmet, glass panelled and with telephonic attachments, air pipes, life lines and a submarine search light. Thus furnished forth the pearl diver may spend six or eight hours at the bottom of the sea, whereas in other times three minutes made a record.

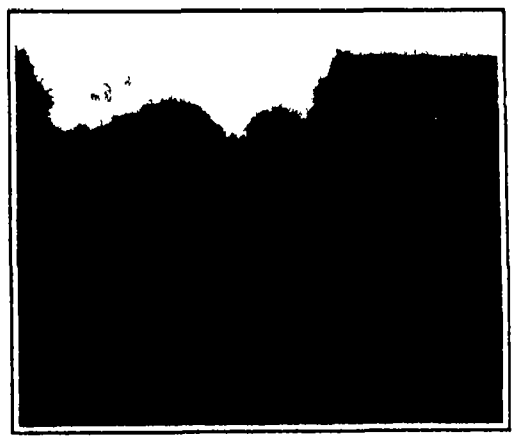
Although pearls are found in nearly all molluscs and even in univalves like the Australian haliotis, a kind of barnacle, true pearls are produced only by the pearl oyster or mother of pearl shell. The latter is really the diver's bread and butter. The shells are nearly as large as a dinner plate and weigh two pounds when cleaned. They fetch from $500 to $750 a ton.

The ancient fisheries were chiefly in the Indian Ocean and Persian Gulf but nowadays the best pearls come from Ceylon and from Australian waters, especially Torres Straits. Pearl fishing in Ceylon is a government monopoly. In March the fleet starts for the pearling grounds, each vessel with twenty or thirty divers and their assistants. But the headquarters of pearling are to be found in the desolate country extending from Exmouth Gulf to King Sound in Western Australia.

Chinese and Malays as well as tribes of native blacks are there to-day, but the old nude divers, the reign of terror and piracy where a large haul was made these and similar conditions have passed away, giving place to fleets of luggers carrying modern diving outfits and representatives of capitalists in the person of the master pearlers. Here is 600 miles of coast line, with perhaps 3,000 hardy adventurers engaged in the pearl trade.

There are some thousands of Japanese, Manilamen, Malays and men of other races acting chiefly as crews for the vessels. The vessels are schooner rigged and from seven to fourteen tons burden. Each carries a master diver and a crew of four, one of whom is the diver's assistant and works the air pumps.

The shells are found on ledges about ninety feet



TAME EAGLES USED AS DECOYS

down in the sea but they are far more plentiful at greater depths. Fortune awaits the inventor of a diving apparatus that will enable the pearler to work in comfort a hundred fathoms down.

A good day's work is anything more than 200 pairs of shells. The business is absolutely speculative. One diver may gather ton after ton of shells without securing anything of greater value than a few seed pearls while another may take a fortune out of a day's gathering.

The most famous pearl discovered in Australia of late years is known as the Southern Cross. It consists of a cluster of nine pearls in the shape of a cross. This freak of nature was picked up at low water on the Lacipede Island by a beach comber who after burying it for some time for superstitious reasons sold it for $50. It afterward brought $50 000.

The worst enemy the Australian pearl divers have are the storms that annually visit the coast. As to sharks, they rarely attack a diver in modern dress and he can always frighten them off by letting a few air bubbles out of his dress. Other enemies are the sea snakes, the smaller octopi, the stringray and the blowfish.

After a day's take of shell has been conveyed ashore the shell opener begins work at once. The pay of the men is $30 a month plus ten per cent on the value of the pearls found. Some idea of the magnitude of the industry may be obtained on learning that in one year five hundred and twenty luggers paid an annual five-dollar license to engage in the trade and that they took many thousands of tons of pearl shell, while as to the pearls themselves the customs duties in the pearl town of Broome exceeded $5 000 a month.

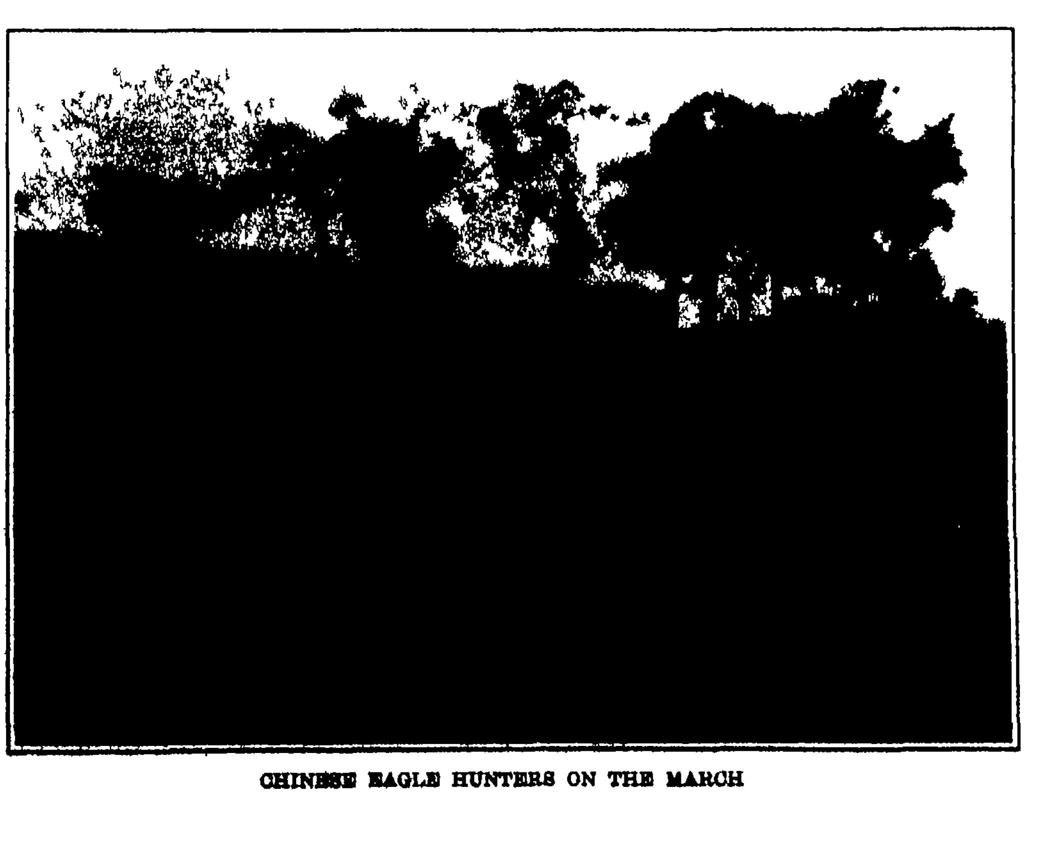
The treasury authorities of Western Australia estimate that they receive at least $100 000 a year in dues from the pearlers. Hardly a month passes without the discovery of pearls having a market value of from $5 000 to $15 000 each. A beautiful pink pear-shaped specimen weighing two hundred and six grains was found last season and sold for $80 000.

Before setting, pearls are classified according to size on a setting board and the delicate work of drilling a valuable specimen is invariably done by an old fashioned hand apparatus. Moreover no matter how valuable a set of pearls may be they are invariably strung on fine silk thread.

Inland pearl fishing forms no mean industry in this country. Although pearls have been gathered from the fresh water mussels of our country as far back as the time of the aborigines, yet the hunt for them did not become systematic and general until shortly after the middle of the last century. Since then nearly every stream east of the Rockies has been prospected in the search for these valuable parasites of the pearl mussel.

One of the finest pearls ever secured in the fresh waters of the United States was found in Notch Brook near Paterson, New Jersey, in 1857. It weighed ninety-three grains. Subsequently it became known as the Queen pearl and was sold for $2 500 to the Empress Eugenie. Owing to the great increase in the value of pearls in recent years it is now worth more than five times that amount.

Shortly after the year mentioned what was probably the largest pearl ever found in these waters was taken in the same brook. In shape it was round and weighed over four hundred grains, but unfortunately



CHINESE EAGLE HUNTERS ON THE MARCH

the pearl was ruined by the crude method of boiling them employed to open the shells

During the pearl excitement near Waynesville Ohio in 1876 a few extraordinarily good pearls were found One button shaped on the back weighing thirty eight grains was the gem of the collection In the early eighties a sky blue pearl which was found in Caney Fork Tennessee was sold for $950 and subsequently brought $3 300 in London

During the summer of 1889 a quantity of magnificently colored pearls were found in creeks and rivers of Wisconsin One of these pearls sold for over $ 00 and some among them were equal to any ever found for beauty and coloring

The year 1897 saw the pearling craze break out in Arkansas A deep pink pearl of forty grains weight was found in the mud of one stream by a woman while a farmer's boy obtained a pink pearl of thirty one grains in Black River and sold it for $35 the purchaser disposing of it in St. Louis a little later for $500

In 1898 a fisherman searched the head waters of the Mystic River in Connecticut and after a few week's work gathered a number of pearls one of which he sold for $500 and two for $400 each

The best price ever received by a finder for an American fresh water pearl was $10 000 for one from Tennessee Two others from the same State brought $650 and $1 000 each A Wisconsin pearl sold for $8 000 dollars while two Florida pearls of sixty-eight and fifty eight grain brought $850 and $600 respectively

A year or so ago there was offered for sale by a gem dealer of New York a perfect pearl white and rounded weighing sixty-eight grains which he valued at $15 000 This pearl was found near the Wisconsin bank of the Mississippi River, and was sold by the finder who evidently had not the slightest idea of its value, for seventy-five cents. Another pearl, found about the same time, was recently offered for sale in New York for $5 000 The latter is a pink pear-shaped pearl and weighs ninety nine grains

A few years ago a fisherman became so agitated on finding a pearl the size of a pigeon's egg in a mussel that he dropped it into the water and it was never recovered

Many odd-shaped pearls are found One was found in this country that strikingly resembled the bust of Michelangelo In a few instances small fishes crabs, and insects which entered the shell have been imprisoned and covered eventually with nacre thus making pearls of them at the same time retaining the animal's shape

Charles Darwin*

The Justification of the Darwinian Theory

By August Weismann

Forty-six years ago when I delivered my inaugural address as a professor of this university I took as my subject The Justification of the Darwinian Theory It is a great pleasure to me to be able to lecture again on the same subject on the hundredth anniversary of the birth of Darwin

This time however I need not speak of justifying the theory for in the interval it has conquered the whole world Yet there remains much that may be said much indeed that ought to be said at the present time In my former lecture I compared the theory of descent or evolution to the Copernican Cosmogony in its importance for the progress of human knowledge and there were many who thought the comparison extravagant But it needs no apology now that the idea of evolution has been thoroughly elaborated and has become the basis of the science of life

You know that Darwin was not the only one and was not even the first to whom the idea of evolution occurred It had arisen in several great minds half a century earlier and it may therefore be thought an injustice to give as we now do almost all the credit of this fruitful discovery to Darwin alone

But history is a severe and inexorable judge She awards the palm not to him in whose mind an idea first arises but to him who so establishes it that it takes a permanent place in scientific thought for it is only then that it becomes fruitful of and an instrument for human progress The credit for thus establishing the theory of evolution is shared with Charles Darwin only by his contemporary Alfred Russel Wallace of whom we shall have to speak later

Nevertheless a reflection of the discoverer's glory falls upon those who about the end of the eighteenth and the beginning of the nineteenth century were able to attain to the conception of evolution notwithstanding the incomparably smaller number of facts known to them As one of these pioneers we must not omit to mention our own poet Goethe though he rather threw out premonitory hints of a theory of evolution than actually taught it Alle Gestalten sind ähnlich doch keine gleichet der andere und so deutet der Chor auf ein geheimes Gesetz

The secret law was the law of descent and the first to define this idea and to formulate it clearly as a theory was as is well known also a Darwin Charles Darwin's grandfather Erasmus, who set it forth in his book Zoonomia in 1796 A few years later Treviranus a botanist of Bremen published a book of similar purport and he was followed in 1809 by the Frenchman Lamarck and the German Lorenz Oken

All these disputed the venerable Mosaic mythus of creation which had till then been accepted as a scientific document and all of them sought to show that the constancy of species throughout the ages was only an appearance due as Lamarck in particular pointed out to the shortness of human life

But Cuvier the greatest zoologist of that time a pupil of the Stuttgart Karlsschule would have none of his idea and held fast to the conception of species created once for all seeing in it the only possible explanation of the enormous diversity of animal and plant forms

And there was much to be said for this attitude at that time when the knowledge of facts was not nearly comprehensive enough to afford a secure and scientific basis for the theory of descent Lamarck alone had attempted to indicate the forces from which in his opinion, the transmutation of species could have resulted

It was not however solely because the basis of fact was insufficient that the theory of the evolution of organic nature did not gain ground at that time it was even more because such foundation as there was for it was not adhered to All sorts of vague speculations were indulged in and these contributed less and less to the support of the theory the more far reaching they became Many champions of the Naturphilosophie of the time especially Oken and Schelling promulgated mere hypotheses as truths forsaking the realm of fact almost entirely they attempted to construct the whole world with a free hand so to speak and lost themselves more and more in worthless phantasy

This naturally brought the theory of evolution and with it Naturphilosophie into disrepute especially with the true naturalists those who patiently observe and collect new facts The theory lost all credence and sank so low in the general estimation that it came to be regarded as hardly fitting for a naturalist to occupy himself with philosophical conceptions

This was the state of matters onward from 1830 the year in which the final battle between the theory of evolution and the old theory of creation was fought out by Geoffroy St Hilaire and Cuvier in the Paris Academy Cuvier triumphed and thus it came about that an idea so important as that of evolution sank into oblivion again after its emergence and was expunged from the pages of science so completely that it seemed as if it were for ever buried beyond hope of resurrection

Scientific men now turned with eagerness toward special problems in all the domains of life and the following period may well be characterized as that of purely detailed investigation

Great progress was made during this period entirely new branches of science were founded and a wealth of unexpected facts was discovered The development of individual organisms of which little had previously been known began to be reavealed in all its marvelous diversity first, the development of the chick in the egg then of the frog then of insects and worms then of spiders crustaceans starfishes and all the classes and orders of mollusks as well as of backboned animals from the lowest fish up to man himself Within this period of purely detailed investigation there falls also the discovery in animals and plants of that smallest microscopically visible building stone of the living body the cell and this discovery paved the way for the full development of the newly founded science of tissues histology

In botany the chief progress in this period was in regard to the reproduction and development of the lower plants or cryptogams and the discovery of alternation of generations a mode of reproduction that had previously been known in several groups of the animal kingdom in polyps and medusæ in various worms and later in insects and crustaceans

At the same time it was found that the proposition which had hitherto been accepted as a matter of course that an egg can only develop after it has been fertilized is not universally valid, for there is a development without previous fertilization—parthenogenesis or virgin birth

Thus in the period between the Napoleonic wars and 1859 an ever increasing mass of new facts was accumulated and among these there were so many of an unexpected nature that further effort was constantly being put forth to elucidate detailed processes in every domain This was desirable and imporant—was indeed, indispensable to a deeper knowledge of organic nature. But in the endeavor to investigate details naturalists forgot to inquire into the deeper causes and correlations, which might have enabled them to build up out of the wealth of details a more general conception of life So great was the reaction from the unfortunate speculations of the so-called Naturphilosophie, that there was a tendency to shrink even from taking a comprehensive survey of isolated facts which might lead to the induction of general principles.

How deep was the oblivion into which the philosophical conceptions of the beginning of the century had sunk by the middle of it may be gathered from the fact that in my own student days in the fifties I never heard a theory of descent referred to and I found no mention of it in any book to which I had access One of the most famous of my teachers the gifted anatomist J Henle had written as a motto under his picture There is a virtue of renunciation not in the domain of morality alone but in that of intellect as well This sentence was entirely obscure to me as a student, because I knew nothing of the intellectual excesses of the Naturphilosophie and I only understood later after the revival of interest in general problems that this insistence upon the virtue of intellectual renunciation was intended as a counter active to the over speculations of that period

This was one-sided but it was a necessary reaction from the one-sidedness in the opposite direction which had preceded it

The next swing of the pendulum was brought about by Charles Darwin in 1859 with his book on "The Origin of Species

Let us now consider the development of this remarkable man and note the steps by which he attained to his life work Charles Darwin was born on the 12th of February 1809 the same year in which Lamarck published his Philosophie Zoologique" But he had not sucked in the doctrines of that evolutionist or of his own grandfather Erasmus Darwin with his mother's milk His youth fell within the period of the reaction from philosophical speculation, and he grew up wholly in the old ideas of the creation of species and their immutability His birthplace was the little town of Shrewsbury near the borders of Wales where his father was a highly respected physician well to do even according to English standards

If we think of Charles Darwin's later achievements we are apt to suppose that the bent toward natural science must have been apparent in him at a very early age but this was not the case at least not to a degree sufficient to attract the attention of those about him It is easy now of course, to say that the pronounced liking for ranging about wood and field and collecting quite unscientifically plants, beetles, and minerals, foreshadowed the future naturalist Even as a boy Darwin was an enthusiastic sportsman and an excellent shot, and the first snipe he brought down excited him so much that he was hardly able to reload[1] But he must have been not merely a sportsman but an eager observer especially of birds, for at that time he wondered "in his simplicity" that every gentleman was not an ornithologist, so much was he attracted by what he observed of the habits of birds.

The school which he began to attend at Shrewsbury in his ninth year was probably very similar to our earlier gymnasia. Darwin himself maintained that nothing could have been worse for his intellectual development than this purely classical school, in which

* An address delivered at the University of Freiburg on the occasion of the Centenary of Darwin Reprinted from *The Contemporary Review*

[1] I can say the same of myself for, although in my boyhood I did not shoot birds, I had a passion for butterfly hunting. When I saw the rare *Limenitis populi* resting on the ground in front of me for the first time, I became so excited that I could not at first throw my net, and when I did throw it, though my aim was usually very accurate, I struck the butterfly obliquely over the wing with the iron ring of the net. The traces of this awkward aim are visible on the wing to this day.

nothing was taught, in addition to the ancient languages, except a little ancient history and geography

Darwin had no talent for languages and no pleasure in them So he remained a very mediocre scholar and his father therefore removed him from school in his sixteenth year, and sent him to the University of Edinburgh to study medicine

The condition of the English universities at that time must have left much to be desired for Darwin characterises the majority of the lectures as terribly dull, and the time spent in attending them as lost Moreover, anatomy disgusted him and the tedium of the geological lectures repelled him so that he vowed never again to open a book on geology a resolution which happily he did not adhere to

In his student days as in his school time he roamed about in the open air sometimes shooting sometimes riding sometimes making long expeditions afoot But even then he was not a conscious observer of nature not a naturalist but rather a lover of the beauty of nature and a collector of all sorts of natural objects though he collected still as he had done at school rather from the collecting impulse frequently characteristic of youth than from any real scientific interest If he had had that interest his chief passion would not have been the shooting of birds. His friends even found him one day making a knot in a string attached to his buttonhole for every bird he succeeded in bringing down! Thus he must have been mainly a sportsman a hunting fanatic whose chief desire was to bring down as many birds as possible in a day However this devotion to sport must have stood him in good stead later especially on his great journey for through it he not only acquired the technique of shooting but he sharpened his naturally acute powers of observation

He remained two years in Edinburgh and then entered the University of Cambridge His father who had observed his disinclination for medicine proposed that he should study theology and Darwin knew himself so little that he was quite willing to agree to the proposal He examined himself very conscientiously to see whether he was able to subscribe to the dogmas of the Anglican Church and he came to the conclusion that he could accept as truth every word that the Bible contained This was certainly remarkable and proves that the Zoonomia of his grandfather Erasmus and the doctrines of Lamarck as far as he was acquainted with them had not taken very deep root

So he proceeded to study theology But he did it much in the same way as he had studied medicine in Edinburgh he listened only to what pleased him and that can not have been very much for here too he complained of the dullness of official lectures Nevertheless at the end of three years he passed his examination quite creditably and received the degree of B A

Of the greatest advantage to him in Cambridge was his intercourse with two distinguished teachers of the university and this intercourse probably guided him imperceptibly toward the real work of his life One of these teachers was Prof Henslow a theologian who afterwards accepted a living but who had a comprehensive knowledge not only of entomology but of chemistry botany mineralogy and geology By Henslow Darwin was introduced to the professor of geology Sedgwick and he too interested himself greatly in the young man taking him with him on his longer geological excursions and thus giving him a most valuable introduction to the science This proved of the greatest use to Darwin on his travels and probably enabled him to make his numerous geological observations

Other older men also admitted Darwin to their friendship so that it is obvious that there must have been something about him even then which distinguished him from others of his age His interests now began to widen, he came under the educative influence of art and studied the picture gallery in Cambridge and later the National Gallery in London He gained the entrance to a musical circle and derived great pleasure from music though curiously enough as he tells us he was almost destitute of ear and could not even whistle God Save the King correctly He was thus one of those rare persons who are exceedingly sensitive to the emotional effect of music and yet possess little or nothing of its physical basis the sense of tone

In addition to all this Darwin retained his passion for beetles and collected with such ardor that twenty years later he recognized at sight small rare species he had found under bark or moss at that time His powers of observation had thus been awakened although as yet they were employed mainly to minister to his zeal for collecting But collecting is not a mere amusement for the young naturalist it is a necessary discipline in surveying a definite range of forms and it can not well be replaced by anything else One who has never collected and thus never made himself thoroughly acquainted with a limited circle of forms will find it difficult to fill up the gap in his attainments in later life

In vacation time toward the autumn of each year Darwin turned again with enthusiasm to sport either at his home in Shrewsbury or on his uncle Wedgewood's large estate of Maer He did not lose a possible day from this amusement for as he says in his autobiography I should have thought myself mad to give up the first days of partridge shooting for geology or any other science Thus notwithstanding his interest in geology and beetle collecting in pictures and music the old passion for the chase was still the dominant one one pleasure crowded upon another and the whole made his life a joyous symphony so that he could say of that period The three years which I spent at Cambridge were the most joyful in my happy life But in the midst of all the joyousness of life he was undergoing an inward preparation for the seriousness of it We can gather from his own account of that time that the strongest impulse toward the study of natural science came from reading two works which aroused his interest, Humboldt's Personal Narrative and Herschel's Introduction to the Study of Natural Philosophy Darwin says of these No other book influenced me so much as these two He used to copy long passages from Humboldt about Teneriffe and read them aloud to Henslow He was very anxious to go to Teneriffe and even made inquiries in London about a ship to take him there when an event happened which overthrew that project but at the same time opened up the way to a naturalist's career—the only one really suited to him—in a much more satisfactory manner He received a proposal to make a voyage round the world

It must appear to us singular that a young man who had just finished his university course and had done no scientific work of any kind should be invited to accompany as a naturalist a naval vessel which was being sent round the world by the government for the purpose of making nautical observations It proves that Darwin's older friends must have had very high expectations in regard to his future

Capt Fitzroy of the English navy was looking for a young man who would go with him as naturalist on a voluntary footing on his voyage in the Beagle

Darwin himself was at once eager to accept but his father objected very decidedly seeing no reasonable object in spending five years ranging over the globe But he concluded his letter with the sentence If you can find any man of common sense who advises you to go I will give my consent

The necessary adviser was found in his uncle Wedgewood who as soon as he heard of the matter immediately drove the 40 miles from Maer to Shrewsbury and persuaded the elder Darwin that he must allow his son to go

Thus it happened that Darwin made the journey which he speaks of later as the most important event of my life as it undoubtedly was It was only later that he learned that even then his going was not a certainty for Capt Fitzroy after seeing him was in doubt as to whether he should accept him for a reason not easy to guess because of the shape of his nose! Fitzroy was an enthusiastic disciple of Lavater whose doctrine of physiognomy was then widespread He believed that the shape of Darwin's nose proclaimed a lack of energy and he was doubtful about taking anyone deficient in that quality on such a journey Happily Darwin's friends were able to reassure Fitzroy on this point and he must often enough afterward have had opportunity to convince himself of Darwin's energy

Thus it was apparently by mere chance that Darwin got the opportunity to develop actually into the great naturalist we now know that he must have been potentially But I do not believe that this is a correct judgment His inward impulse would certainly have forced a way after he had been led to perceive through Humboldt and Herschel what the way for him was to be And even at that time no serious obstacle would be likely to stand in the path of a young Englishman of fortune who wished to explore foreign lands and seas But undoubtedly this manner of traveling for five years through the seas and countries of the different zones was particularly advantageous

And Darwin used his opportunities to the full On board ship he studied the best books especially Lyell's Principles of Geology but he also collected certain kinds of natural objects and investigated all that came in his way keeping a detailed journal of everything that struck him as worthy of note in what he observed Thus he became a well informed and many sided naturalist But he valued much more highly than any other result of the voyage the habits of energetic industry and concentrated attention to whatever he had in hand that he then acquired And thus he became the great naturalist for which nature had designed him

Darwin published his journal later it fills a closely printed volume of 500 pages Like all his books it is characterized by a simplicity and straightforwardness of expression there is absolutely no striving after sensational effect but an innate enthusiasm and truth pervades it and I have always found it most enjoyable reading Other people must have found it so too for by 1884 16 000 copies of the English edition had been sold I cannot here give even a brief account of the voyage of the Beagle I can only say that its work lay chiefly on the southern coast line of America and the journey included the east coast of Bahia to Tierra del Fuego and the inhospitable Falkland Islands and the western coast to Ecuador and Peru

This occupied several years and thus the young explorer had a chance to make himself thoroughly acquainted with a great part of the South American continent for while the ship lay at anchor taking soundings in some bay or other Darwin ranged over the country on horseback in a boat or on foot In Brazil on the plains of the La Plata River and in Patagonia he made excursions into the interior which lasted for weeks and he was thus able to see and investigate everything that interested him

(To be continued)

Bienaimé's Proposed Ascension

M MAURICE BIENAIMÉ is to make an interesting balloon ascension from Paris especially for meteorological and other scientific observations Without wishing to break the record which was made by the German aeronauts Suring and Berson in 1901 at 10,800 meters (35,433 feet) altitude, he expects with a much smaller balloon of 1,600 cubic meters (56 502 cubic feet) of the usual touring size, to go higher than the 8,558 meters altitude (28 077 feet) reached by Balsan and Godard in 1900 Seeing that the aeroplane has not been used as yet for exploring the upper atmosphere to any extent, this must be done by sounding balloons of small size or by regular balloons mounted by an aeronaut Such observations are more difficult to make than may be thought, seeing that the air pressure becomes much less and is only one-half of the ordinary when we rise to 15 000 feet This causes bleeding from the nose and ears and like disorders, while the rarefied air becomes difficult and even impossible to breathe. Intense cold is another point and it may reach 40 deg below zero C added to which is the altitude sickness so that the aeronaut is likely to become paralyzed or in a lethargic state and this may even cause death However by using the proper precautions M Bienaimé expects to make his ascension a success The scientific commission of the French Aeronautic Club has laid out a programme for this occasion The radio-activity of the atmosphere and the solar heat are to be observed

As the air is always more or less a conductor of electricity and its conductivity varies with the altitude it is of interest to measure this at different heights The value depends on the number of electrified particles or ions in a given amount of air Experiments made on mountains are not of much value as the electric charge follows the reliefs of the ground From a practical standpoint the study of the distribution of these particles in the atmosphere is important in meteorology, seeing that it is now admitted that this is the cause of rainfall Besides electric charges in the upper air allow of explaining the variations of terrestrial magnetism Such variations are often very considerable and cause disturbances which may interfere with telegraphs or telephones as is well known It is found that magnetic disturbances always coincide with the appearance of the aurora borealis Apparatus will be carried on board for making observations in this field For other work there will be used various kinds of instruments such as a sphymograph for registering arterial tension and a Mathieu instrument for measuring muscular force at different altitudes Registering instruments of the Richard type will serve to make records of the temperature of the air and the moisture Other recording devices will take the highest altitude which is reached and make other measurements M Albert Senouque will have this work in charge and he is well known for his researches in terrestrial magnetism during the Charcot expedition to the Antarctic regions having also made researches at the Mont Blanc observatory.

Reclamation of the Southern Louisiana Wet Prairie Lands—I*

By A D Morehouse, Office Engineer, Drainage Investigations*

INTRODUCTION

In the conquest of the country the heavily timbered areas of the East have been subdued the vast prairie lands of the Middle West have been settled the riches of the west coast have yielded of their stores the waterless regions of the Great American Desert have been turned into verdure under the magic of irrigation and dry farming has brought into productiveness turies by that river and its tributaries and deposited here by every recurring flood they form now the most fertile agricultural lands of the State equaled by few and surpassed by none in the world in productive capacity as described by Dr Hilgard in writing of this region

FORMATION OF THE LANDS

Recent borings to a depth of 3 170 feet in the was deposited in the more slowly moving waters away from the main currents of the streams This point, as well as the fact that the natural drainage is away from the river is well brought out by the following from A Preliminary Report Upon the Bluff and Mississippi Alluvial Lands of Louisiana by W W Clendenin[1] written a few years since

'With every flood the river now overflows its flood

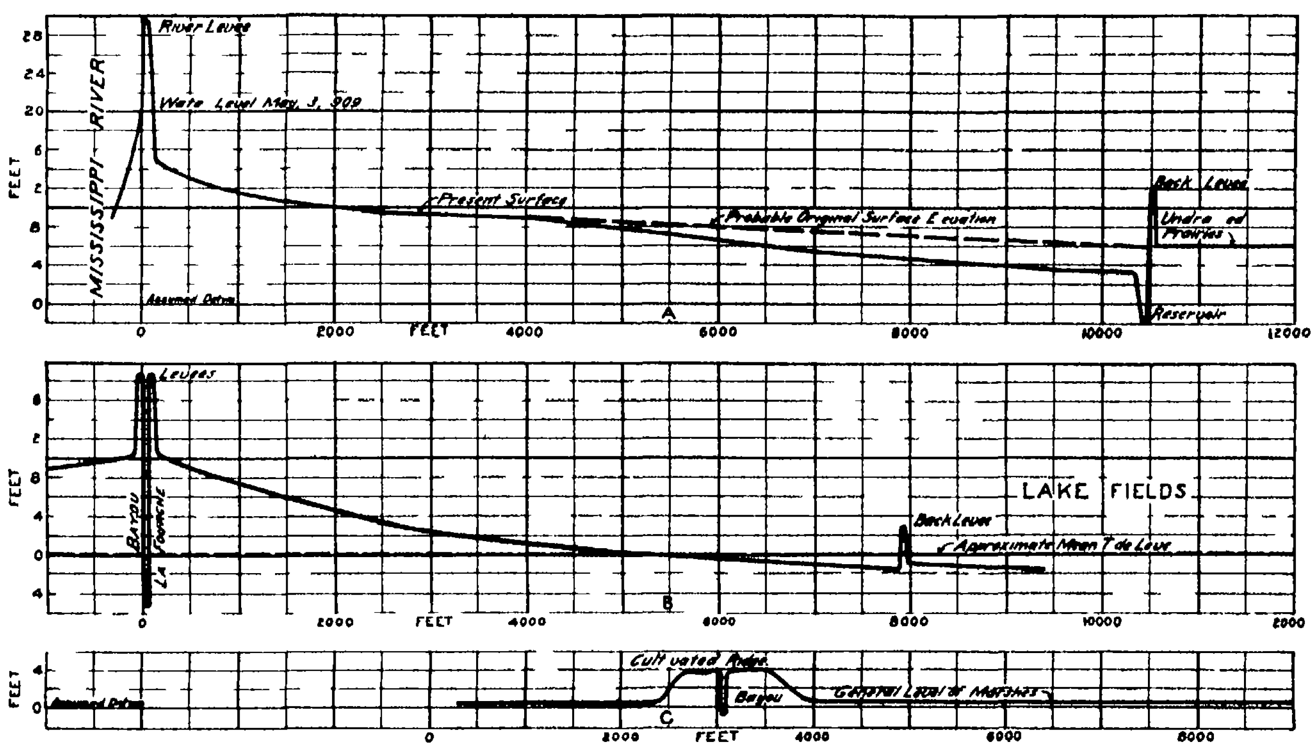


Fig 1 TYPICAL EXAMPLES OF LOUISIANA MARSH LAND FORMATION

A profile through Willswood plantation B section through Smithport plantation C formation caused by small bayou near Lockport

immense sections of land once considered worthless However throughout the space of the several centuries which have witnessed this wonderful development one of the richest sections of the country's great domain has lain unused and unproductive first clothed in the mystery cast upon it by its Spanish ownership and later since its acquisition by the United States associated in the minds of men with visions of pestilential swamps deemed worthy only of neglect owing to the supposed difficulties of its reclamation and never thought to be a region whose wonderful agricultural possibilities would test the credulity of men

Within the last few years all this has changed and the alluvial prairie lands of southern Louisiana are coming into their own Formed by the richest soils of the whole Mississippi Valley brought down for cen

vicinity of Houma have failed to penetrate this layer of sediment and at a depth of 2 400 feet pieces of fairly preserved wood have been encountered Owing to the fact that the soil is water laid material nothing coarser than river sand is encountered except the overlying layer of humus formed by the decaying vegetation A typical section of these lands would show a layer of humus or muck 2 or 3 feet thick overlying a grayish or drab clay subsoil composed of very fine particles which when saturated form a tough impervious mass Layers of sand of varying thickness are encountered in this clay subsoil and occasionally no clay stratum intervenes between the humus and sand The surface soil is from a few inches to 5 feet or more in thickness

NATURAL LEVEES

The embankments or natural levees along all the bayous and streams with which this region abounds and those along the Mississippi are formed by the constant overflows They are composed of coarser sand than the clay subsoil of the prairies as this latter

plain and deposits much of the sediment from its headwaters As with a slight increase in velocity the transporting power is vastly increased so with a slight checking of velocity as occurs over the flood plain outside of the channel deposit takes place As the greatest decrease in velocity takes place near the channel there the heaviest and coarsest sediment is deposited and in greatest quantity The river banks are thus built higher by each flood and a system of natural levees is produced There is thus a marked difference in the front lands and the back lands along the river The former are higher and coarser textured than the latter and therefore much more easily cultivated and drained

Drainage from the very channel margin is away from the river and unless forced by the topography of the land will not reach the river proper but unite with some outlet of the river produced during some extraordinary flood period and kept open by the escape of water during ordinary periodic flood stages As the feeders of the river are called tributaries these

* This article is based on reports to the chief of drainage investigations by A M Shaw C E New Orleans, La, and of W B Gregory M E Tulane University of their investigations made during 1909 and also upon data furnished by C W Okey assistant drainage engineer who continued the work of this Office during 1910 in Southern Louisiana All quotations not otherwise credited are from the foregoing mentioned reports the portions referring to pumping equipment being by Professor Gregory and the rest by Mr Shaw

For a discussion of these soils see U S Dept Agr Field Operations of the Bureau of Soils 1903 p 430

Fig 2 —WILLSWOOD PLANTATION ST CHARLES PARISH LA SHOWING PUMPING PLANT AND MAIN RESERVOIR, WITH LEVEE ON RIGHT BANK

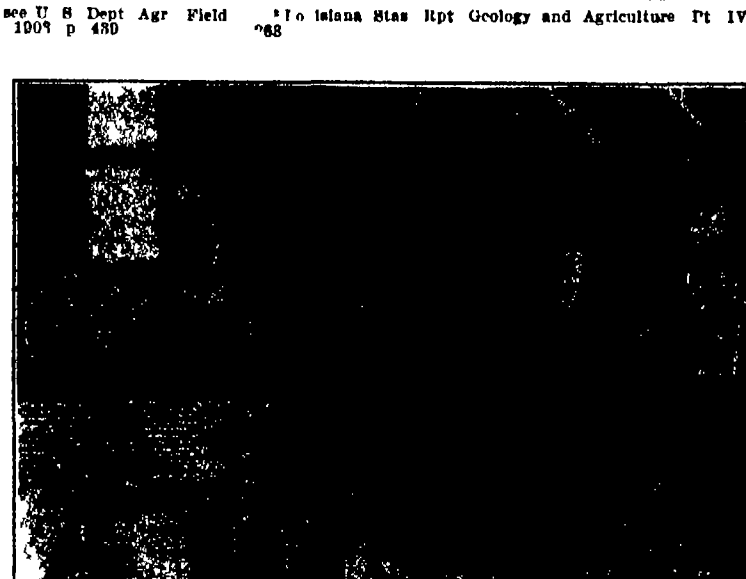

Fig 3 —INTERIOR VIEW OF PUMPING PLANT, WILLSWOOD PLANTATION, ST CHARLES PARISH, LA., SHOWING ARRANGEMENT OF MACHINERY

outlets have not inaptly been styled distributaries

The water in breaking over the banks and spreading over the marshes in sheets was gradually lessened in velocity thus gradually dropping its load of sand and silt and causing a delicate gradation of soil texture to the finest river silt far out in the marshes These natural levees and those that have been constructed and the improved methods of closing crevasses in the levees have reduced the danger from general overflows to a minimum, and whereas this has prevented much damage which would be caused by the cutting out of new channels and the destruction of much valuable property it has also checked the building up of the lowlands and their natural conversion from marshes to well-drained fields Thus it is that nature has forced upon man the necessity of exercising his ingenuity and labor in wresting these productive lands from their water ridden state even as centuries ago the brave and industrious Hollanders wrested their empire from the sea

Many of the streams and bayous now isolated have served in times past as mouths of the Mississippi or as overflow outlets in times of flood and they have been instrumental in the distribution of the rich silt laden waters and in the gradual advance of the coast line

"Even before the construction of the artificial levee system there was no raising of the general level of the marshes during periods of normal flow and probably little sedimentation of the river bed excepting at its mouth the most of the material which was carried in suspension to the lower portion of the river being carried out and deposited in the Gulf As the river rose however the waters constantly sought additional outlets through the various bayous of the delta country At times of extreme high water there was a general breaking over the banks of the river and its outlets It is probable that the most of the building up of the lands above sea level has been done at such times

The fact of the silt bearing capacity of water being directly dependent upon the velocity is clearly demonstrated by observing the natural embankments formed by streams of various sizes In the case of smaller streams when the water overflows its force is soon spent and the silt is quickly deposited near the stream forming narrow ridges with steep side slopes while those formed by large streams are broad with slight slopes Three typical examples showing this difference and the manner in which the land surface has been raised on the marshes are given in Fig 1 A B and C

The sections were taken as follows

A—From the right bank of the Mississippi River across the Willswood plantation about ten miles above New Orleans This section is about two miles long and a part of the lands crossed has been under cultivation for a great many years while those farthest from the river were reclaimed only twelve or fifteen years ago

The lowering of the surface of the cultivated and drained fields due to the shrinkage of humus soils is here well illustrated There are many examples of highlands having been built up for much greater distances from the river than this but as such accretions are indirect on account of being formed by a number of small bayous or temporarily contracted areas of overflow which assisted in maintaining the velocity these have not been considered as being typical

B—The right bank of Bayou La Fourche at Lockport extending back through the village of Lockport and the lands of the Smithport Planting Company to Lake Fields. Until 1903 Bayou La Fourche served as an overflow outlet for the Mississippi River the opening at Donaldsonville not having been permanently closed until that year

C—This is a very small bayou running through the lands of Dr I D Fay about four miles west of Lockport The abrupt rise of the ridge from the surrounding marshes is especially noticeable and is characteristic of smaller bayous

Important exceptions to the foregoing general statement as to the relation between the size of bayous and the ridges built by them are frequently found

From the foregoing discussion it is seen that these lands may not in general be drained through gravity outlets in the ordinary way but that it is necessary to surround them by levees or embankments and then by the construction of an interior drainage system

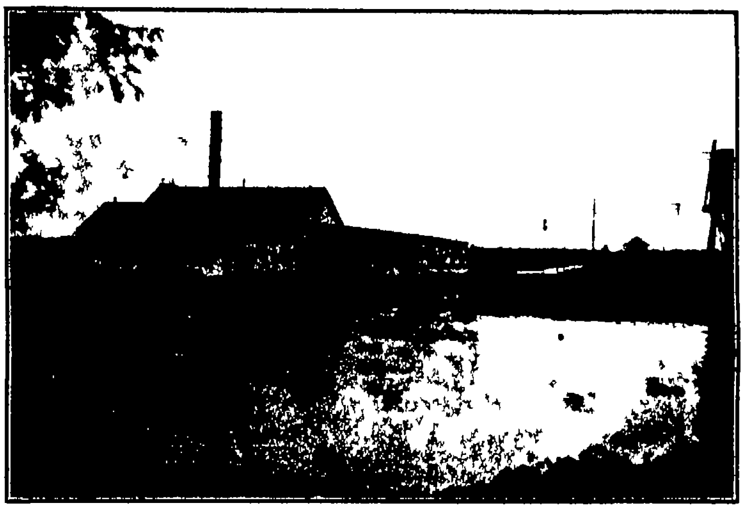

FIG 6—MODERN PUMPING PLANT AT LA BRANCH ST CHARLES PARISH LA SHOWING OUTLET CANAL AND DISCHARGE FROM PUMPS

Prominent among those are the Bayou l'Ourse in the southeastern part of La Fourche Parish and the Wax and Little Wax Bayous in St Mary Parish Bayou l'Ourse is an insignificant stream occupying the center of a long and important ridge It is probable that at one time this bayou served as an outlet for the La Fourche or possibly of some predecessor of the latter bayou draining in a more easterly direction through Bayou Blue Lake Fields and Long Lake Wax and Little Wax Bayous are streams of

FIG 7—OUTLET CANAL ON A LARGE SUGAR PLANTATION IN SOUTHERN LOUISIANA SHOWING IT COMPLETELY FILLED WITH WATER HYACINTHS

erosion rather than of sedimentation and have been formed wholly or in part by the action of storms and the tidal flow which is quite strong along this portion of the coast. As a result the bayous are bordered by the marsh or by very low ridges Both streams are from ten to fifty feet in depth and 100 to 200 feet in width

of ditches lead the drainage water to some convenient point from which it is pumped over the embankment into the adjacent stream or bayou

PURPOSE OF INVESTIGATIONS

The development of these lands is now progressing with such rapidity that the United States Department of Agriculture through drainage investigations of the Office of Experiment Stations decided in the spring of 1909 to make a study of the conditions entering into the reclamation of these most valuable lands

The engineers making the investigation were charged to determine the volume of water or percentage of the rainfall which it is necessary to pump from the fields in order to secure adequate drainage of these soils the area of the field surface served by ditches and the depth width and arrangement of the ditches and the levees required in a drainage system the influence of bad physical condition of ditches upon the efficiency of the system the distance from the ground surface at which the water table should be maintained the difference in the level of the water in the ditches while the pumps were in operation the percentage of saturation or the quantity of water which the soil should contain when in the best condition for growing crops

Accordingly four reclaimed tracts of land were chosen in the vicinity of New Orleans which were regarded as having good ditch systems coupled with ample pumping capacities and as practically no information was extant as to the relation of rainfall to the resulting run off from these lands rain gages were established on each tract and continous rainfall records kept in order to compare them with the pumping records for the same period

The following gives a brief description of the tracts in question including their pumping machinery equipment and also describes a new tract District No 3 which is being reclaimed

DESCRIPTION OF EXPERIMENTAL TRACTS

Willswood Plantation 2400 Acres

The plantation fronts on the Mississippi about ten miles above New Orleans and is crossed by the Southern Pacific Railway The tract was enlarged twelve years ago necessitating the digging of new canals and the replacing of the old wheel pump by an up to date pumping plant Sugar cane is grown principally but some corn and cowpeas are also raised

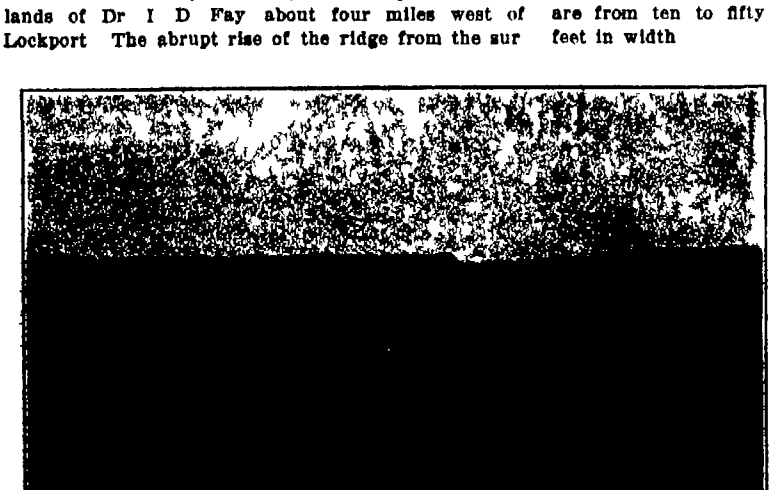

FIG. 4.—TYPICAL WET PRAIRIE SCENE, SHOWING WILD GRASSES. DISTRICT NO 2, NEAR RACELAND, LA FOURCHE PARISH, LA.

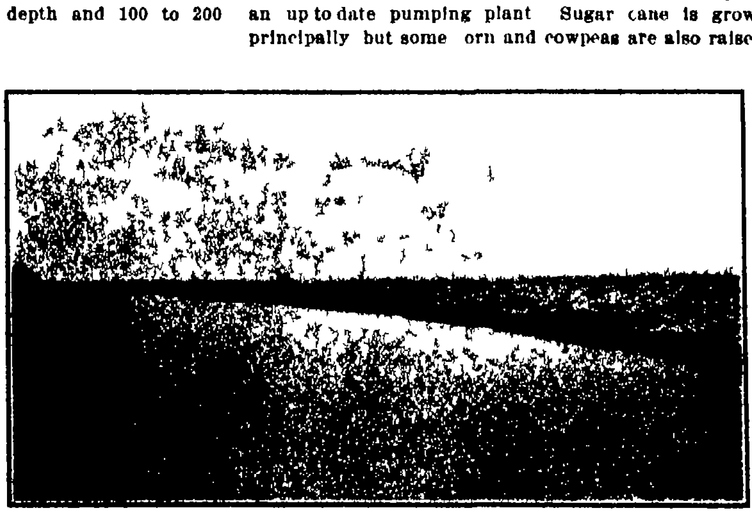

FIG 5—DISTRICT NO. 2, NEAR RACELAND, LA FOURCHE PARISH LA AFTER RECLAMATION, SHOWING BAYOU FALSE, USED AS AN OUTLET FOR THESE LANDS, WITH LEVEE ON RIGHT BANK

cultivation having taken place for a number of years. Steam for the three following pumping units is furnished by two water-tube boilers and one return tubular boiler, crude oil for fuel and a feed-water heater being used.

(1) One 40,000 gallons per minute maximum capacity rotary chamber wheel pump, rope driven from a 16 by 24 automatic non-condensing engine.

(2) One 42-inch by 16-inch Menge pump, connected by a rope drive and a bevel gear to a 16 by 24 automatic non-condensing engine.

(3) One centrifugal pump with 36-inch diameter discharge pipe, direct connected to a double vertical engine.

Pumps 1 and 2 discharge into open flumes at an average head on pump of about ten feet, which is about five feet greater than is necessary. Pump 3 has a siphon on the discharge pipe, but the end is not always submerged.

The pumping plant, with the main reservoir leading to it, is illustrated in Fig. 2, while Fig. 3 gives an interior view of the pumping plant. The direct-connected centrifugal pump appears in the background.

Smithport Planting Company Tract—647 Acres.

This tract, adjoining the village of Lockport, La Fourche Parish, has been recently reclaimed, a large portion of it from Fields Lake. Although it is all drained by well-made lateral ditches placed 200 feet apart, but a small part was put under cultivation previous to 1909. The tract is well shaped and one well adapted to a regular layout of ditches. In this respect it has the advantage of either of the other two plantations.

The pumping plant consists of two Menge pumps with impellers of 32 inches by 12 inches and 24 inches by 8 inches, running respectively at 230 and 330 revolutions per minute. Each pump is rope driven by a slide-valve non-condensing engine, while steam is supplied by a 100 horse-power return tubular boiler, no feed-water heater being used.

District No. 2—940 Acres.

Located five miles west of the village of Raceland, La Fourche Parish, this plantation is as yet only partly under cultivation and the system of ditches is not complete. On account of a very thick top layer of humus of only partly decayed vegetation, good drainage is secured with lateral drains spaced several hundred feet apart instead of at distances as shown on the map (Fig. 1).

Two 42-inch by 12-inch Menge pumps are used, one belt driven and the other rope driven by two 12 by 16 slide-valve non-condensing engines. Two 60 horse-power locomotive-type boilers furnish the steam.

Fig. 4, a typical marsh scene, shows the wild grasses common to this section. It is a view of a portion of District No. 2 before reclamation. Fig. 5 gives a view of the same district after reclamation, showing the levee as constructed, and also Bayou False, which serves as an outlet for these lands as well as for the new tract adjoining them, which is described later.

Fig. 6 is an excellent view of a modern Menge pumping installation at La Branch, La. It is very similar to that installed for District No. 2 near Raceland.

New Orleans Land Company Tract—1,380 Acres.

Although inside the city limits of New Orleans, this tract has but recently been inclosed by protection levees. Originally heavily timbered with cypress and gum, there are still many of the small trees standing, and thus far only a few main canals have been dug. These canals vary in width from fourteen to forty feet, and interior lateral ditches will be constructed later. Drainage is secured by gravity into the city sewer system, and thus this tract differs from the other three in requiring no pumping installation.

District No. 3—2,400 Acres.

This is a new project lying between Raceland and Lake Fields in La Fourche Parish, and it embraces the latest practices as to ditch arrangement and modern pumping equipment. The soil is typical turf land and the surface elevation is 3 to 6 feet above mean tide. The reservoir canals are 40 feet wide and 6 to 8 feet deep, and the collecting ditches have a bottom width of 2½ to 3 feet and a depth of 4 feet. The laterals are spaced 210 feet apart and are made 3 feet deep, with bottom widths of 1½ to 2 feet. The pumping equipment consists of two 30-inch Lawrence centrifugal pumps discharging under water, so that the lift varies between 2½ and 5 feet, according to the stage of water in Bayou False, which takes the discharge. Direct-connected to the pumps are two 100 horse-power vertical engines, steam being supplied by two locomotive-type boilers.

MEASUREMENTS OF RAINFALL AND RUN-OFF.

The calculations of run-off were made from the logs kept at the various pumping plants, each pump having previously been rated. Most of the discharge flumes are rectangular in section and open at the top, permitting the use of weirs for making measurements of the water pumped. These measurements were simplified by the fact that each pumping unit was equipped with a separate discharge flume. Pumps discharging through pipes were rated by means of a Pitot tube.

The run-off from the New Orleans Land Company tract was obtained by means of weir measurements. A 4-foot weir is placed in the main ditch and discharges into a flume, which in turn empties into the drainage canal leading to city drainage station No. 7. The weir and flume are covered by a small tent house, in which is located a recording gage or water register. The cross section of the canal is large back of the weir, insuring complete contraction, so that the measurements are unusually accurate and the Francis weir formula applies. Two rain gages are now located on different sides of the tract and the mean of the records is used in calculations of rainfall.

Records were kept continuously from June 1st, 1909, to January 1st, 1910, with the exception of those of the New Orleans Land Company tract. These latter started June 16th, but were interrupted on September 20th, 1909, by a breaking of the city levees and the consequent shutting down of the city's pumping plants, due to the severest hurricane known to this section, sweeping in from the Gulf of Mexico. Backwater from Lake Pontchartrain and the accumulation of the city drainage water prevented normal conditions from being established till October 9th, when the records were continued.

As the investigations cover such a short period of time, care must be exercised in making deductions from the results. The records are still being continued, however, so that more reliable conclusions can be made at some later time.

During August the pumps in District No. 2 were operated on ten days, although the actual amount of run-off was small. This was due to the fact that it was desired to maintain a certain stage of water to insure the successful operation of a hydraulic dredge which was engaged in clearing and deepening the reservoir canal.

The data which have been collected would indicate that a much greater run-off may be expected from the better ditched and fully cultivated lands than from those that are more nearly in a natural state. While this may be true, it is probable that a long series of uninterrupted records will show a less striking variation. The records on the New Orleans Land Company tract did not begin until the effects of a 5-inch rainfall of the first part of June had passed, and they were suspended during and after the severe storm of September 20th, thus not including the heaviest storms of the season, with the exception of that of December, when the rainfall was heavy and mostly fell in a few hours' time, thus giving the largest percentage of run-off of any recorded. The decreased evaporation of December no doubt also increased the run-off."

Owing to the fact that at times of extreme high water a few acres are drained by gravity on the Willswood plantation, it is probable that the run-off records for that tract show a slightly less quantity than they should.

The fact is well known that very heavy storms cause a larger percentage of run-off than smaller ones, but for storms of all magnitudes there is a variation in the ratio of run-off to rainfall, due to the varying conditions of the soil and to its character and state of moisture, the duration of the storm, amount of evaporation and seepage, slope of ditches and fields, and arrangement and capacity of reservoirs, manner of pumping, and probably to other causes not yet determined.

Excepting as affected for short periods by rains and by pumping, the height of water in the reservoir canals represents fairly accurately the height of ground water of the lower lands. This is notably true of the Willswood tract, where the lowlands are porous and allow a quick adjustment of water level following a change in level in the canals. As an indication of the effect of evaporation, including the transpiration of the vegetation, the record for the month of July is especially interesting. The month was begun with the soil well moistened by showers late in June, yet with a precipitation of 1.17 inches from July 1st to 19th there was a rise of only 2½ inches in the reservoir, while from July 5th to 19th, with a precipitation of 0.99 inch, there was an actual lowering of the water level in the canal.

A few records of pumping operations are available, but the lack of essential details makes them of little value for the purpose of the calculation of run-off. An approximate idea can be gained, however, as to the amount of pumping necessary in order to maintain the water table at the proper height for profitable cultivation. A daily pumping record of the Willswood plantation for 1907 and 1908 has been compiled by Mr. Shaw from the diary of the engineer in charge of the pumping plant. Comparing the two years, it is found that during 1907 it took 14.8 hours pumping for each inch of the 66.32 inches of rainfall, whereas in 1908 the pumps ran 12.9 hours per inch for the 51.06 inches of rainfall in that year. This on its face would seem to indicate that the uneven distribution of the rainfall throughout the year, as well as the fact that one part of the plantation may receive a very heavy precipitation during certain storms while only a small shower may affect the rest of the land, has but slight effect on the general yearly average, and that year by year the ratio of the necessary pumping to the rainfall will be fairly constant.

The mean annual rainfall at New Orleans amounts to 57 inches. There is a slight increase in precipitation in the extreme southeastern part of the State, while it drops off to about 50 inches at Cameron, which is in the western part near the Gulf coast. At Shreveport, about 200 miles from the Gulf of Mexico, the average precipitation is 46 inches.

(To be continued.)

The Mercadier System of Multiplex Telegraphy

The new Mercadier system of multiplex telegraphy showed very good results in tests which were made between Paris and Lyons not long since. Only one wire was used, with a ground return. It will be remembered that several transmitters are used at once, each producing a wave of a certain pitch, so that all the waves are sent at once over the wire and are selected at the far end by vibrating diaphragm selectors, each tuned for only one pitch. Signals are sent by an ordinary Morse key for each transmitter. Professor Mercadier adapts it specially to rapid printing telegraphs, Baudot, Hughes or Wheatstone or Morse registers, such as are used in Europe. In the Paris-Lyons experiments there was used a quadruple Baudot printing telegraph working on direct current. In addition to this there was connected the Mercadier apparatus applied to six Hughes printing telegraphs. Wave currents were used here on the wire, but the Mercadier relays translated these into direct current signals with local batteries, so that the printing telegraphs could be thus operated. In this way the quadruplex Baudot printers worked with direct current on the live wire, while the same wire carried six kinds of vibratory current, each sending its own message to one of the six Hughes printers. This greatly increases the capacity of the wire. The new apparatus is designed so that it is very simple and is easily worked.

French Studies of Insecticides

We already had occasion to mention some researches made in France upon applying insecticides to plants, and it is shown that special attention must be given so as to have a liquid which will wet the surfaces, such as insects, etc., properly in order to be effective. For use upon leaves of plants this is also true, as the proper wetting increases the adherence and it thus favors the penetration of active matter, such as copper salts, into the leaves. For insoluble substances, such as arsenate of lead or copper, capillary attraction gives a closer adherence, and this is more durable. More recently M. G. Gastine shows that the wetting can be obtained not only with soaps, but also with the saponines, which are better than alkaline soaps, as they are not decomposed or precipitated by certain bodies, so that they can be used where soluble soaps cannot be employed. Numerous plants contain saponines, such as Quillaya, Saponaria, Nielle and others. An alcohol solution of Quillaya has been used for making emulsions of medicinal substances like resins or balms. But there is an Algerian fruit which contains a large amount of saponine, and this is the Sapindus, a tree cultivated for a long time past. The fleshy part of the fruit has over 50 per cent of a saponine which is very soluble in water and alcohol. Insecticide liquids can be made of it which give a very good adherence, also emulsions can be made without needing alcohol, and these are very stable. The author prepared specially different emulsions of tar oils or crude petroleum. These oils are officially prescribed in Italy for use in destroying an insect of the small cochineal kind which is of Japanese origin and is very dangerous (Diaspis pentagona). It attacks fruit trees of different kinds, and also flowering plants. In winter there are applied 7 per cent emulsions of tar oils or crude oil, so as to act on the adult female insect, which is well protected and hard to penetrate. The young insects are easily killed by 2 per cent emulsions. However, in spite of the fact that salt solution is

used so as to bring the density near that of the oil and flour is added to flavor the emulsion such products are unstable, and if not well shaken the oil separates out quickly The oil, however will destroy the buds of the plants. Soaps will gave stable emulsions but it was found in Italy that these could not be used as the soaps lessen the poisonous action of the oils The author made good emulsions with Quillaya and Saponaria, etc but the Algerian fruit is especially good A small quantity of the powder will emulsify a large amount of tar oil and the emulsion is so fine that it passes through filter paper Under the microscope it resembles milk Copper salts can be added to tar oil and crude oil emulsions and this is excellent for use against the above insects and also Aphides as well as parasite growths Water 10 liters sopindus powder 20 grammes neutral acetate of copper 100 grammes

Eugenics and Genetics*

"Good Breeding" and Its Significance

By G Clarke Nuttall

The terms are new—the problems they stand for are as old as Cain and Abel And yet it is well that the nomenclature should be of to-day for these terms represent the points of attack at which we of the present with the latest weapons of modernity are attempting to storm the hitherto impregnable strongholds of the mysterious heritage of the children of men

From the beginning of time such questions as to why the son is like and yet unlike the father why and how it comes about he may have say his father s hair with his mother s eyes and the character and personality of a great uncle or yet more puzzling why in a family marked by a strong unity of characterization one child may be strikingly dissimilar to all the rest have forced themselves with bewildering fascination upon all who have stood aside to consider for a moment our common humanity while the deeper problems of the inheritance of moral traits and defects and within what limits moving among hereditary influences free will can act are points that have pressed upon the thinkers of mankind with an almost unbearable burden Hence this present generation with its mind set on keen scientific inquiry was necessarily bound to approach this illimitable field of research into which explorers have as yet pierced so short a distance and it is interesting to note the two chief roads by which it is setting out in its quest the one road being known as the Eugenic and the other as the Genetic

Now Eugenics (literally good breeding)—a term already familiar enough among a small and select school of thought but practically unknown to the commonality at large—is defined as the study of agencies under social control that may improve or impair the racial qualities of the future generations either physically or mentally It is the science which deals with all the influences that tend to improve the inborn qualities of a race and its aim is to influence by every possible means the useful the sane in the fullest connotation of both mental and physical health—in a word the *best* classes in the community—to contribute more than their proportion to the next generation and, incidentally of course to discourage in every way the degenerate the unfit from perpetuating their weaknesses Obviously then there is in Eugenics in addition to the ordinary study of the well worn problems of heredity a large ethical element and it is this element this definite appeal to the common conscience to bring moral laws into a sphere hitherto singularly outside of them that stamps this science with the impress of to-day It is this feature that is the special product of our time and we owe its inception to the genius of that veteran student of human problems—Francis Galton

Genetics on the other hand contains no element of ethics *per se* within it for it is purely an inquiry into the physiology of heredity and variation It examines the ultimate physical elements of life it records processes, it seeks to discover and tabulate the laws that govern them Good bad and indifferent stocks are all alike in its eyes, for all afford suitable material for research to the student of this science Genetics merely cares how things *as they are* happen it carries no ideal other than the acquisition of knowledge before it Therefore while the aim of Eugenics is the realization of an ideal in the future the aim of Genetics is pure knowledge of facts in the present. Genetics, therefore, is the handmaid of Eugenics, for the Eugenist will take the facts that Genetics provides and use them in the furtherance of his aims Curiously enough while Eugenics is the child of a living scientist, the source of inspiration of recent Genetics is a dead monk—the Abbot Mendel of Brun He, working in his monastery garden fifty years ago, was dead and forgotten for twenty years before his writings were found but then so instinct with vitality were they that they had only to be placed in suitable soil for a veritable tree of knowledge, a new science to spring from the tiny grain he had planted so unobtrusively many years before

Both Eugenics and Genetics exhibit phases of novelty hitherto undreamt of and react one upon the other Genetics has presented startlingly new conclusions before us, and has brought into discussion facts that had become practically axiomatic in their acceptance while Eugenics has placed in the moral sphere considerations that have hitherto been received as nature and therefore not to be questioned Let us then pass in review some of these phases

Now it is absolutely amazing how callous the social conscience of the ordinary person has become upon the moral issues raised by Eugenics Even the most flagrant transgressions are condoned The following anecdote is but a sample of general experience The present writer had occasion to visit at times a small house where the door was always opened by a little household drudge of the poorest description A dwarf of poor mentality her lack of intelligence had a peculiar weirdness given it by an appalling squint One day she was missing and an inquiry after Eliza elicited the surprising information that she was married An expression of dismay was met by the retort from her acquiescent mistress That it really did not matter for he was no better than she He proved to be a weak minded youth who could just earn a scanty wage of 10s a week by blowing a church organ By this time indignation was boiling over and a forcible remark on the iniquity of the mistress allowing such a marriage was met by the offended retort that It couldn t in no way be wrong for they were married in church And that was the last word What more could one say? Not only are such marriages sanctioned by our common morality but they have actually the blessing of God called down upon them by His appointed minister! And yet there is not one decent minded person who if he will but stop and think it over does not turn in disgust from the very idea of such a marriage

It is to meet cases like this—better and worse—and many similar problems that the Eugenist is setting himself to work for he has been converted to the fact that the law of inheritance is as inevitable as the law of gravity and moreover that psychical characters are inherited just as surely as physical A notable work in driving this fact home has been done of late by Karl Pearson who examined a large number of children from the point of view of both physical and psychical characteristics Thus on one side they were scrutinized as to their heritage for health eye color curliness of hair cephalic index head length head breadth etc and on the other side for vivacity assertiveness introspection popularity conscientiousness and the general conclusion arrived at was that both physical and psychical characters in man are inherited (within broad limits) *in the same manner and with the same intensity* Again with regard to insanity and pathological defects generally the same rule holds good—they are inherited in precisely the same manner as are the physical and psychical characters

Now since we are shown to inherit our parents conscientiousness shyness and ability even as we inherit their stature forearm and span the Eugenist goes a step further and points out that when we come to the bedrock of things all moral health like physical health all goodness probity capacity and the like together with eyes and hair and stature are an inheritance— Bred not created A question of breeding not pedagogics Of course if the germs are there to begin with they can be quickened by religion encouraged by environment and directed by all the wonderful resources of education moreover the will is free to stimulate or stifle as the man desires but nevertheless the main contention is that no amount of moral effort no excellence in teaching, will evolve what is not there—"The creature is not made but born

Since qualities (or no-qualities-at all) of the intellect come under the same ruling the Eugenist challenges some of the latest of our philanthropic movements For instance the efforts now being made to deal with the slightly deficient—both morally and mentally—the attempt to screw them up to the normal and keep them there—heart breaking work for all engaged upon it—is work which, it is pointed out is not only useless but positively harmful In the past the weak and unfit were allowed to go to the wall, trampled out of existence, the lunatic treated as a criminal and the survival of the fittest was the only law Then came a revulsion against the cruelty and unreason of it all a higher ethical standard was set the law of kindness asserted itself and the weak the unfit the insane were protected but the movement went too far—it o'erleaps itself and falls on the other side for it began to form classes under specially trained teachers with the express object of dragging up the feeble people so that they could enter on better terms in the race of life and but alas! never truly compete for from the outset they are foredoomed to ultimate failure and the course has been strewn with the ill starred wreckage NO the Eugenist insists that the weak and defective are not to be dealt with in such a way that for the few best years of their lives when their capacities are at their highest they may be able to lag along not too remotely behind the average folk and thus earn a pittance and meanwhile incidentally leave a legacy of equally unhealthy equally deficient children to the nation These classes this philanthropy is socially unsound and immoral if that is what it does

Pity and help the weak but remember that it is a national evil when any charitable or social institution allows the indefinite multiplication of the unfit in mind and body says Major Leonard Darwin Instead the Eugenist urges these efforts should simply aim at separating out of the vast number of school children those who are distinctly below the normal in intelligence distinctly lacking in moral sense and after careful consideration over a period of time place those judged undesirable on one side saying The strain from these poor children shall never vitiate the stream of our national life the degeneracy the pollution they exhibit shall as far as they are concerned die with them They shall not be treated as if they were responsible for their deficiencies their lives shall be made happy but they shall run under definite discipline and within definite bounds they shall have as it were the freedom of a large and pleasant garden which is however shut off from the outer world by an impregnable fence In several parts of the country the Eugenic spirit is providing little homes upon these lines In one recently visited by the writer there were about a dozen girls all of whom were defective and yet not one of whom was bad enough for an asylum In an ordinary way such a girl would have lived at home supported or half starved as the case might be the drudge of the house the butt of those around a trouble to relatives a misery to herself with the almost inevitable result of eventually landing in the maternity ward of the workhouse and mother child brought into the world to carry on the heritage of misery sin and defectiveness But here in Sunnyside they were in a happy home with simple tasks and games cheerful pictures and the simplest but brightest surroundings all directed by a firm but kindly matron—prisoners indeed in one sense but prisoners with no sense of bondage no desire for freedom And the State is the gainer for the lopping off of a diseased limb from the community the poison flow is checked

It is confidently asserted that feeble mindedness could be practically stamped out in two generations if the State rigorously determined to check the perennial flow of the strain of the unfit into our national life The cost of establishing homes for the feeble minded throughout the country is often demurred to but granted that it is great would it not pay a hundredfold in the end? And indeed it is rather a rearrangement than an increase of expenditure that is needed for practically all these cases come upon the Poor Rates in the long run when parents or relatives die They cannot support themselves and there is in addition the double heritage from those years of freedom of children to follow their parents for on an average each degenerate has one child as degenerate as himself or herself and others in whom the taint is latent but liable to appear in a succeeding generation The taint of degeneracy in our population is now alarmingly great and threatens to increase indefinitely under our present policy of encouraging the unfit So that the Eugenic Education Society lately formed to call attention to this most

* Reproduced from Fortnightly Review

pressing question is in the forefront of reform movements of the day in attempting to meet that great need as set plainly forth in the report of the Physical Deterioration Committee, when in 1904 it stated The committee are impressed with the conviction that some general educative impulse is in request which shall bring home to the community at large the gravity of the issue i e physical deterioration and the extent to which it is within individual effort to promote and make effective the conclusions of expert opinion

One thing is certain the ordinary man and woman of to day is in a fools paradise with regard to this question They contentedly pass it by as not concerning them at all as not quite nice for their consideration And yet at this moment our country is at a most critical time It is an open secret that the intellectually strong the best of our national life are not adding their full quota to posterity they hang back from the responsibility they shrink from the pressure of adjusting ways and means For the last forty years says a student of the subject the intellectual classes of the nation enervated by wealth or by love of pleasure or following an erroneous standard of life have ceased to give us a due proportion of the men we want to carry on the ever growing work of our empire to battle in the fore-ranks of the ever intensified struggle of nations On the other hand the degenerates the feeble the hangers-on of the strong fostered by false sentiment are adding more than their due share thus intensifying the discrepancy and— The ultimate result is in no doubt We have two groups in the community one parasitic to the other The latter thinks of to-morrow and is childless the former takes no thought and multiplies It can only end as the case so often ends the parasite will kill its host and so ends the tale for both alike

If then Eugenics the influencing of the hereditary forces that are molding our national life is to-day of such primary importance all knowledge which can help in this great work is of no less importance as has already been pointed out and Genetics is far and away its most serviceable handmaid In a sense Genetics represents the material side of the question It attempts to show precisely *how* powers and faculties are transmitted what cells are engaged what physical elements carry the inheritable properties from generation to generation

Already Mendelism—and Genetics to day is largely Mendelian in its lines of work—has brought some striking facts to our knowledge For instance it has absolutely revolutionized our idea of what is known as pure bred Now in pre Mendelian days our conception of a pure-bred individual was one who was descended from a long line of ancestors all of whom were of the same type and as a consequence of which the individual in question more or less nearly approached it But now we know that purity of type in no way essentially depends upon continued selection In certain cases a pure bred individual may result from parents both of whom are cross bred which is a paradox and moreover that the descendants of these individuals will be absolutely pure bred henceforward for all time as long as no new element is introduced later How this can happen must be sought for in that wonderful discovery of the segregation of gametes which is Mendel s priceless legacy to the world It is not the place in this short paper to go into the technicalities of Mendelian hypothesis but the underlying idea may be roughly summarized as follows

Each individual is made up of a large number of distinct characters contributed from two sources i e from its two parents in respect to any of which he may have received two similar portions or two dis similar portions one from each parent. But one or other of the parents may be lacking in some of the characters in which case he will receive a character from one parent and nothing corresponding to it from the other either like or unlike Further to use an Irishism any particular character may be absent in both parents and therefore necessarily represented in the offspring also by its absence Now the offspring will be pure bred for any character if it receives it alike from both parents or does not receive it at all it will be cross-bred if it receives it unlike from both parents or receives it only from one parent and not from the other If neither parent possesses a certain factor at all then none of the offspring will have it if both parents have it then all the children will have it if one parent has it and the other has not then on an average half the family will have it and half be without it

A second most important fact that Mendelism has lately pointed out is that it is in the *second* generation from the parent the grandchildren so to speak —in which we must look for the possibilities that may result from cross breeding There all types possible from that particular cross will be found It has been ignorance of this law that has been chiefly responsible in the past for the disappointments of breeders of both animals and plants

Again all sorts of interesting side-lights are being thrown upon our knowledge of biology, such as, for instance that in the flowers of certain stocks the pollen—the male element—is all of one type, while the egg cells—the female element—carry either the quality of doubleness or that of singleness Then too in the question of the nature of sex the interesting suggestion is now put forward that the quality of femaleness is a definite Mendelian factor following ordinary Mendelian rules, while maleness is a condition due to the absence of this quality

Although so far Genetic conclusions have been principally based upon research confined to the realms of plants and the lower animals owing to the difficulty of treating human subjects and the length of time observation required in their cases yet sundry successful excursions have been made into human affairs and the descent of certain abnormalities and defects has been brought under law Of the law of transmission of normal qualities little is yet proved or in fact attempted Eye coloration is one quality however that has recently been successfully dealt with Here it has been shown that parents whose eyes are without any brown pigment at all i e blue or gray eyes can only hand on to their children blue or gray eyes while those parents who have any brown pigment in their eyes may hand on to their children both brown eyes and eyes without it namely, blue or gray But even if progress has not yet gone far at any rate sufficient has been done to show that man can control his heritage far more effectually than he dared once to suppose

The Eugenists and the Mendelians do not in these early days always see eye to eye in their statistics or in the whole of their policy Thus Prof Bateson, one of the leading Mendelians of the day believes that while the elimination of the hopelessly unfit is a reasonable and prudent policy for society to adopt any attempt to distinguish certain strains as superior and to give special encouragement to them would probably fail to accomplish the object proposed and must certainly be unsafe and referring to some of the Eugenic ideas already set forth earlier in this article he continues Their proposals are directed in the belief that society is more likely to accept a positive plan for the encouragement of the fit than negative interference for the restraint of the unfit Genetic science gives no clear sanction to these proposals Still he joins issue with them in that Some serious physical and mental defects almost certainly also some morbid diatheses and some of the forms of vice and criminality could be eradicated if society so determined And that Genetic science must certainly lead to new conceptions of justice

But in the present embryo state of both Eugenics and Genetics unanimity is not to be expected and definite dogma is impossible and indeed undesirable But the upshot of the whole matter at the present time is that Genetics is working—and apparently along successful lines—to bring law and order into the inchoate mass of the facts of heredity while Eugenics is striving to lead man to use his conscience as well as his intellect in dealing with his knowledge

A Great German Barrage

THERE is being built in Germany a great barrage which forms a storage lake of very extended area in order to supply the new Rhine-Weser canal especially the section of the canal leading from the Ems to the Weser stream However as the canal takes a large supply from the Weser and it is desired not to interfere with navigation on the stream on that account an extra supply is needed so as to come into use to bring up the level of the Weser during low water stage and give the needed flow for the canal A great barrage is to be erected across the valley of the Eder so as to store up the water due to the winter freshets of this latter stream It is known as the Waldeck Barrage and the artificial lake thus formed will drain off a basin of over 14 000 square kilometers (5 405 square miles) The lake will extend for about fifteen miles above the barrage Three villages will disappear and will be submerged under the lake Its surface will be 1 200 hectares (2 965 acres) and it will contain no less than 202 000 000 cubic meters (264 195 800 cubic yards) The retaining wall is to be 48 6 meters above foundations and is built of stone On the upstream side there will be a protecting sole of reinforced concrete in order to prevent leakage of water under the dam The concrete work will go down below bed rock and thus cover over the junction of the dam with the rock bottom. On the same side there will be applied a three-foot clay flooring over the surface of the valley for a distance of 100 feet. The total volume of the masonry work is 300 000 cubic meters (392,370 cubic yards), and the cost of the work is estimated at $5,500,000 at a low estimate.

Engineering Notes

It is planned to use about 76,000 horse-power in two large hydraulic plants which are to be erected in the South of Switzerland, not far from the Italian frontier This will rank among the large power plant enterprises in Europe It will be remembered that the great Brusio hydraulic plant is located in this region A Swiss company is planning the work and it is proposed to use the Landwasser and Albula streams with the turbine stations erected at Filisur and Bergun

Separation of Oil from Condenser Water by Electrolysis.—The condenser water of steam engines always contains more or less lubricating oil, which is too valuable to be thrown away This oil can be recovered by the Davis-Perret process in which the very stable emulsion which the oil forms with the water is electrolyzed with iron electrodes, after the addition of sodium carbonate In these conditions a basic iron salt is formed which envelops and precipitates the oil globules which are then removed by filtration Ellis finds that the addition of colloidal oxide of iron to the condenser water produces the same result The Davis-Perret separator is useful for clarifying all liquids which are turbid owing to the presence of colloidal or emulsified substances

Farm Engines—The agricultural commission of the French Automobile Club holds a concourse every six years and gives prizes to cultivators who make the best use of gasoline motors for farm work It is especially desired to encourage small plants which are mounted by the farmer himself and show an ingenious use of the motors M Yvonnet Thovareck received the first prize for a very well designed plant where a 1½ horse-power motor can drive no less than nine farm devices such as straw cutter root cutter crusher grindstone circular saw well pump besides various dairy machines. All these are in the same building and are belted to different countershafts This gives him $600 yearly saving M Thiebaut uses a second hand tricycle motor for a thresher and other devices For plants of this kind the commission awarded six teen medals or cash prizes

The Art of Felling Chimneys—An interesting method of felling lofty chimneys is practised in England The originator of this method a Manchester man is credited with having felled without accident more than 100 chimneys which for one reason or another had become useless Some of these were from 200 to 250 feet in height The method consists in removing the stones or brick near the foot of the chimney and substituting an underpinning of wood which is afterward set on fire About two thirds of the area of the base is removed up to a height of 5 or 6 feet so that most of the weight rests upon the underpinning Experience has shown that when the work is properly done the chimney leans slightly toward the side where the underpinning is inserted and when a slight crack appears in the masonry on the opposite side the time has come for the fire to be applied As the chimney falls it partially telescopes in consequence of the shock produced by dropping into the void left by the burned timbers

Explorations in Chaldea

COMMANDANT CROS has been exploring the site of the ancient city of Sirpourla in Chaldea, and found remains of buildings and various objects which go back before the founding of Babylon The part which he uncovered consists of different kinds of constructions which were of practical usefulness such as granaries and like storehouses Water from wells was brought to various places by culverts built of brick and went into a number of basins for industrial use A somewhat unusual find among the storehouses was a large collection of dried fish these being of large size The skeletons of the fish and their scales are still to be seen On the spot were found many stamped baked clay tablets and among these were storehouse accounts which showed that the fish like many other products represented tribute paid to the King's treasury by various tribes these being under the control of the Queen s intendant

An Artificial Method of Forcing Basket Willows

Basket willow growers can not always find a good market for steam peeled rods and are therefore obliged to peel them in sap To do so requires con siderable work during the spring months when other work on the farm is plentiful and labor is scarce If a grower has a large willow plantation and wishes to peel his rods in sap he is obliged to employ an un usually large force and pay them higher wages than they could get elsewhere, in order to complete the work by the first of June Or he may erect a forcing house hire fewer men pay less wages commence to peel about the first of January which will give him plenty of time to complete the job before the other work on the farm begins

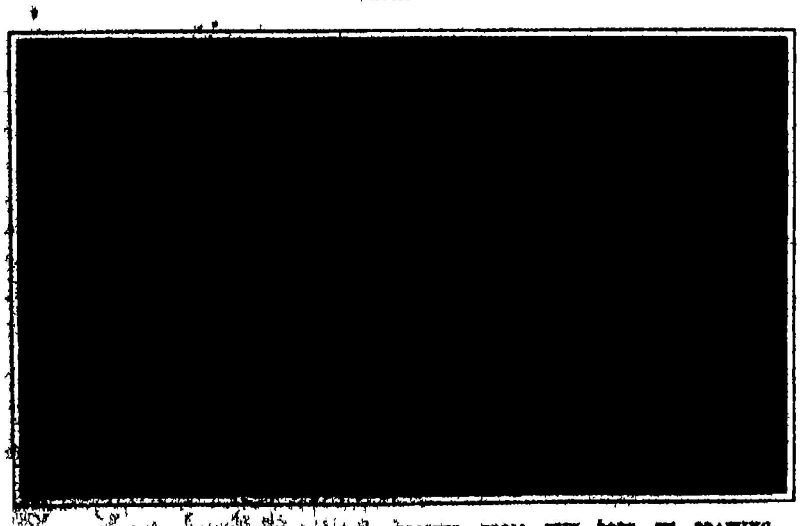
Messrs Lohrig & Odenwald of Balti more Maryland erected a building in which their willow rods are forced to sprout during the winter months at a time when they are peeled in sap The main buildings are located at Laurel Maryland where the firm owns a 60 acre plantation The largest building is about 100 feet long 40 feet wide and 2 stories high The location of the plant is excellent being close to the station of the Pennsylvania Rail road where the peeled rods can be placed on board the cars and shipped to their basket and furniture factories in Baltimore The owners who have been experimenting for nearly eight years have finally demonstrated that this method of treating basket wil low rods is an entire success They are able to har vest and to peel their entire crop by the end of March which is the time when other willow growers com mence to cut their rods The operation has been actively going on with about 40 hands since the first of January "We have the only plant of its kind in America and save a good deal of time and money Mr Lohrig said One of the greatest advantages of this artificial method over that of the natural method of preparing the rods for peeling is the fact that the work can be done during the winter months when labor is cheap and plentiful

Ordinarily willows are harvested in March tied in bundles about a foot in diameter and set butt end down in running water about 4 or 6 inches deep They are left in this position until the sap commences to flow when they are ready for peeling This usually lasts from April 15th to about the first of June In stead however of having only a n onth or six weeks at most in which to do this work Mr Lohrig has over five mon hs t me To erect a suitable b ilding and to equip it for work s exj ensive but the farmer who has 10 a es or more of willows would find t profital le to] t p a for ing l ouse The l d g sh ld be so con str ted that e e y square foot may be tilize l t he best ad antage Tl e best res lts an be a ta n d only if the conditions with n he p ant are as favorable as t ose d ring the bes growing on l i s o ts de f e h ng of first nporta s l e maxi nun amount of gh a l l eat fr l e su and se o d tl]] r f r g be l or p wl l l sl o l nsist f l l fer l e s il abo t n l es dee nde lai l with a] e able on te floor The so l n s l e kept tl or ghl} sat rated with wa er The pit m st l e supplie l w h water at one end wi a run off at the other so that the soil annot turn so r or he water bec me stagnant

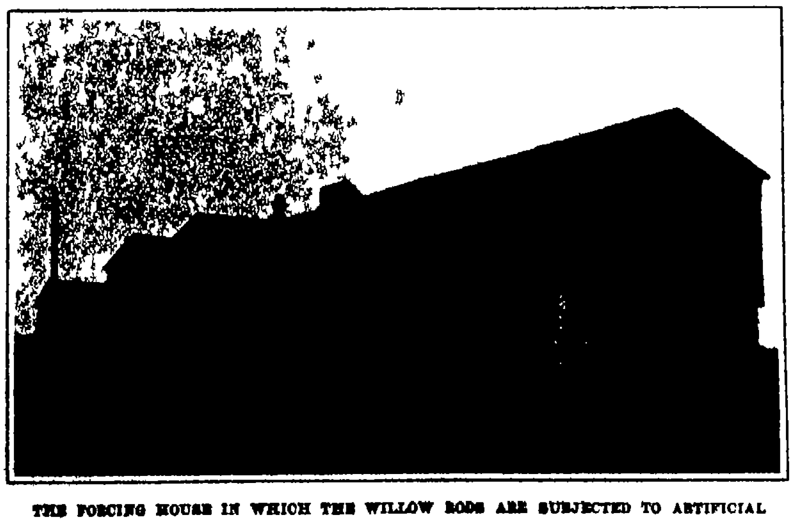
WILLOW RODS BUNDLED AND READY TO BE PLACED INTO THE PIT TO SPROUT

A PORTION OF THE PLANTATION SHOWIN THE FOR NG HOUSE N THE BACKGROUND

PEELED RODS IN THE DRYING ROOM



PEELING ROOM, WHERE THE BARK IS REMOVED FROM THE RODS BY DRAWING THEM BETWEEN TWO STEEL PRONGS



THE FORCING HOUSE IN WHICH THE WILLOW RODS ARE SUBJECTED TO ARTIFICIAL HEAT CAUSING THEM TO SPROUT AFTER WHICH THE BARK IS REMOVED

AN ARTIFICIAL METHOD OF FORCING BASKET WILLOWS

The forcing room in the building here illustrated faces south with a view to derive as much light and heat from the sun as possible and to protect it against the cold north winds To the north of the forcing room is the peeling room and to the west the boiler room The drying room is immediately above the boiler room A building of this kind is kept as low as possible for the purpose of saving in heat The peeling room however is as high or higher than any ordinary working room In Germany the forcing houses are provided with glass roofs which are considered a great improvement over the kind here shown A glass roof slightly slanting would undoubtedly add to the success of the plant especially if provisions were made to cover it with a poor conductor of heat during the coldest nights of the season to prevent chilling the sensitive young shoots The specifications for a building of this kind are determined by the amount of willows to be treated as well as by the local conditions and conveniences at hand The steam required to heat the plant may be drawn from the exhaust pipes of breweries, creameries or grist mills and under such conditions the building and equipment would naturally take on a shape and arrangement according to conditions

An attempt will be made here to give a few facts helpful in planning a forcing house and equipping it properly The forcing room is the most important one and the size of the other rooms is dependent upon this one Since the basket willow plant by nature requires at least six weeks of rest, it is useless to place the rods into the forcing room before December 15th, and it is better not to do so until after the first of January One must not count on more than four months to accomplish this, for the willows commence to sprout in the open as early as April, when there will be no need of subjecting them any longer to artificial heat.

One bundle of willows a foot in diameter requires a square foot of standing room and must remain in this position for at least two weeks before the rods are ready for peeling Two bundles can be forced each month on one square foot, and during four months from the first of January to the end of April it will be possible to sprout eight bundles. It is best to select only the short and medium grade rods to be treated in this way because the long rods sprout much quicker in the open and labor can be secured more readily during the spring for peeling long rods than for the short ones The small rods require more care in peeling so as not to split them and there is more time during the winter to take caution in this respect than during the busy season in spring Less room is also required for peeling the short rods than for the longer ones which may be peeled in the open during the spring months

One bundle of short and middle sized rods weigh approximately 33 pounds and during four months it will be possible to sprout about 264 pounds of green rods which will yield about 66 pounds of dried sap peeled willows. About 75 per cent of the original weight is lost in peeling and drying. In one day of 10 hours a man can peel about 100 pounds of green rods, which amount to about 25 pounds of peeled rods after they are thoroughly dried. At this rate it will take one man 24 days to prepare 600 pounds for market. In 120 working days—the length of the peeling season—he can peel 3,000 pounds, which, in the form of green rods would require a space of 45 square feet in the forcing room. Three thousand pounds of dry peeled rods is an average yield one can expect from an acre of willows Since one acre requires 45 square feet in the forcing room a 10-acre plantation calls for a pit 9 by 50 feet, or 450 square feet.

The space required by one man in the peeling room is about 40 square feet, which has been found to be the best under all practical conditions. If one wishes to save in space required for peeling he can do so by having a night force at work, when only half the space is needed. The boiler room must be large enough for a boiler with a 150-gallon capacity and the necessary room around the boiler for the storage of coal and wood A room 10 by 14 feet will be large enough for a boiler of the above named capacity The drying room must be about 6 feet wide 10 feet long, and about 7 feet high to dry the rods of a 10-acre plantation This room must have a rack 6 feet wide, 10 feet long and 7 feet high which will be large enough to hold all the willows 10 or 15 men can peel in a day

Charles Darwin—II*

The Justification of the Darwinian Theory

By August Weismann

Continued from Supplement No 1843, page 267

In all his descriptions of what he saw his keen appreciation of the beauty and grandeur of nature are manifest Thus he writes from Bahia on the first day of his arrival in South America The day has passed delightfully Delight itself however is a weak term to express the feelings of a naturalist who for the first time has wandered by himself in a Brazilian forest The elegance of the grasses the novelty of the parasitical plants the beauty of the flowers the glossy green of the foliage but above all the general luxuriance of the vegetation filled me with admiration A most paradoxical mixture of sound and silence pervades the shady parts of the wood The noise from the insects is so loud that it may be heard even in a vessel anchored several hundred yards from the shore yet within the recesses of the forest a universal silence appears to reign To a person fond of natural history such a day as this brings with it a deeper pleasure than he can ever hope to experience again (p 4 1884 ed)

Not less delightful are his descriptions of the monotonous and almost endless plains of Patagonia and the La Plata River over which accompanied by Gaucho Indians he rode for many days or his account of the wild mountain scenery of Tierra del Fuego with its gloomy evergreen woods broken into by deep inlets and bays in which whales disported themselves and its mountains whose dark cloud laden summits are swept by the most violent storms A different picture is called up by Darwin s description of his ascent from the Vale of Paradise (Valparaiso) up the Cordilleras to a height of 13 000 feet and the view from there down upon the coast region and the Pacific Ocean far beneath him And how many other passages might be cited'

He cared however not only for what was beautiful but for what was most interesting from a scientific point of view Thus he discovered in a pass in the Cordilleras a stratum of fossil shells a proof that this place was at one time a part of the sea floor and that therefore it had been raised in the course of ages more than 13 000 feet

His journal contains a wealth of observations about plants and animals as well as about man and many detailed accounts of the geological structure of the countries visited We see how well his Cambridge studies and the excursions he made there had prepared him for this work

I cannot enter into any details of his observations but I must at lease mention those which deal with the facts that led him gradually to change his previous views in regard to the nature and origin of species

When he first began his explorations in South America he was as he expressly says still completely under the influence of the dogma of the creation of species once for all and their immutability and he regarded it as unassailable But very soon he was struck by certain facts which seemed to him difficult to reconcile with this dogma and these increased in number in the course of his journey, till finaly they led him to the conviction that the old position was untenable and that the organic world had not been created immutable but had slowly evolved

I select two of these phenomena first the occurrence of the fossil remains of gigantic mammals in the diluvial strata of the great plains of La Plata and Patagonia Darwin found a gigantic armadillo (*Dasypus gigas*) and he was led to ask how it happened that small armadillos now live in South America whereas they do not occur either living or fossil anywhere else in the world The answer was easy if it was possible to assume that the present day species were descended from the diluvial forms or from other smaller still undiscovered forms from the same period But he was especially impressed by the fauna and flora of the Galapagos Islands which lie under the equator 590 nautical miles to the west of the South American coast.

On these isolated and comparatively barren volcanic islands there live many animals which could not fail to arrest the attention of the naturalist—land birds which are like those of the neighboring continent, and those of purely American type yet are not identical but closely related species Most of them are so-called endemic species that is species which occur in no other part of the world This was striking enough but the matter proved even more remarkable on closer investigation for several of the fifteen islands of which the archipelago consists possess species of the same genus peculiar to themselves—mocking thrushes for instance which are represented in the other islands by similar but not identical species

What inference is possible from these facts except that, at some earlier period bird migrants from the neighboring continent had landed on these volcanic islands and in the course of thousands of years had varied that is to say had become distinct species on each island?

These and other phenomena aroused in Darwin's mind the idea of evolution, and he resolved to devote his attention to this problem after he returned home for he was persuaded that he could attain to certainty in regard to it by patiently collecting facts Thus he set himself the task of his life It may be well to inquire here whether or to what extent, Darwin had taken over the idea of evolution from his predecessors at the beginning of the century, and especially from his grandfather, Erasmus. It is certain that at sixteen he had read the "Zoonomia," and that he admired it He relates in his autobiography that, during his student days in Edinburgh Dr Grant, afterward a professor at University College, London, spoke to him in the course of a walk in the most enthusiastic manner of Lamarck and his views on evolution Darwin listened to these views with interest, but was in no way impressed or convinced by them The same is true of the 'Zoonomia, and when he re-read it fifteen years later he was disappointed in it 'the proportion of speculation being so large to the facts given (p 38)

Thus Darwin was quite familiar with the views of his grandfather and of Lamarck, but it was not these that incited him to follow in the same paths, it was rather his own observations of nature that led him to abandon his old opinions and it was only after long years of investigation study and doubt that he gained sufficient certainty to venture on giving his ideas to the world

I must refrain from saying more about this journey which was so fruitful for Darwin himself and for science the two groups of facts of which I have spoken were undoubtedly decisive in their effect on his conception of nature. In December, 1836 with a wealth of great impressions and rich experiences in all the domains of natural science his mind concentrated on the new idea of evolution, Darwin returned to his fatherland after an absence of five years

Two years after his return he married bought the estate of Down, in the county of Kent, and retired there to spend the whole of the rest of his life in constant work but also in constant fellowship and personal touch with the most prominent naturalists of the day, who were readily accessible in London. He gradually came to have correspondence also with many naturalists in other countries.

His "chief pleasure and constant occupation" was his work, which sometimes even enabled him to forget the daily discomfort due to his health, which had been bad ever since his voyage. From the very beginning of the voyage he had suffered from severe and persistent seasickness, and his constitution had apparently suffered lasting injury for in his autobiography he often speaks of being unable to work because of illness, and sometimes of having lost days and weeks, and one one occasion two whole years, from this cause.

In dealing with his work it is impossible for me to speak of all the important volumes he published in the course of his life. The first were the results of his voyage, various geological observations, and a new theory of the origin of coral islands.

Up till that time it had been believed that the so-called atolls, or lagoon reefs, had been simply built up by the coral polyps from the ocean floor until they finally reached the surface, where they formed flat

* An address delivered at the University of Freiburg on the occasion of he Centenary of Darwin Reprinted from *The Contemporary Review*

islands. Darwin recognized that the process could not be quite so simple, because the polyps cannot live at great depths. He therefore assumed that a secular subsidence of the ocean floor must have played a part and this hypothesis not only explains in the most beautiful way the details of the structure of an atoll but it has been brilliantly corroborated by later investigations, especially by borings on one of the islands, and the theory is now a permanent possession of science. After the completion of this volume he worked for eight years at the rich material he had brought from the coast of Chile of that remarkable group of sedentary crustaceans the Cirripedes usually known as barnacles and acorn shells. Two thick volumes on this subject appeared in 1851 and later two other quarto volumes on fossil species of the same group. Even here in this apparently dry and purely systematic province the true spirit of the investigator revealed itself for he did not neglect what was unintelligible to him and therefore inconvenient for his theory but devoted the most persistent attention to obscure points until he had found a solution of the difficulty. Thus he discovered that within the group there are species which like all Cirripedes are hermaphrodite but which possess in addition small degenerate-looking males of different structure attached as parasites to the hermaphrodite animals. It is however only in our own day that it has become possible to understand the deeper significance of this important discovery.

In addition to these special pieces of work Darwin collected with untiring energy facts which had any bearing on the theory of transmutation having begun in 1837 just after his return to England a large collecting notebook in which he entered all the facts referring to the variability of animals and plants in particular of those which are under the care of man. By means of printed lists of questions of conversations with expert breeders of animals and plants and of wide reading in books and journals he sought to lay the foundation of fact which he required in order to attain to clearness in regard to the supposed transformation of organisms.

He was very soon led to the conviction that the essential factor in the artificial modification of an animal or plant form was selection for breeding. But how could such selection take place in free nature? For a long time he was unable to find the answer to this question until chance made him acquainted with the work of the economist Malthus on Population and the ideas developed in this book suggested to him the solution of the problem. Malthus showed that the human population multiplied much more rapidly than the means of subsistence could increase and that therefore catastrophes must occur from time to time to diminish the excessive number of human beings. Darwin said to himself that in the rest of nature among other forms of life also an enormous number of individuals must perish since all that were born could not survive and since the greater part of a species furnishes food for some other species. Thus the ceaseless struggle for existence became clear to him and suggested the question whether it was merely a matter of chance which of the many born should survive and which should perish. He concluded that the answer to this question was evidently that favorable variations would have more prospect of survival than unfavorable and thus he discovered the principle of natural selection—that the principle at once so simple and so powerful which alone enables us to understand the transmutation of organisms in adaptation to the conditions of their life. But it was a long time before Darwin ventured to publish this luminous idea. For his own satisfaction he wrote a rather short sketch of it in 1842 and in 1844 he expanded this to 230 pages but it was not till the fifties that, urged by his friends Lyell and Hooker, he resolved to give his ideas to the world. Even then he might have delayed publication but that in the meantime the same idea had occurred to Alfred Wallace in Ternate in the Malay Archipelago and had been communicated by him first to Darwin and then through Darwin to Lyell and Hooker. Then followed the memorable meeting of the Linnean Society London in July 1858 at which two papers were read one written by Darwin the other by Wallace both setting forth the same far reaching idea of evolution based upon the principle of selection a beautiful example of the unenvying magnanimity of two great discoverers.

This private communication to a scientific society made no great stir. But the publication in the end of 1859 of Darwin's book The Origin of Species by Means of Natural Selection attracted great attention. A new edition was called for on January 2 1860 and during the twenty two years between that time and 1882 the year of Darwin's death one English edition followed another and more than 24 000 copies were printed. During the same period one German edition succeeded another and it is doubtful whether any other scientific book attained to such a circulation.

Yet the book is simple and straightforward never sensational in style but advancing quietly and concretely from one position to another each supported by a mass of carefully sifted facts. Every possible objection is duly considered and the decision is never anticipated but all the arguments on both sides are carefully and impartially discussed in a manner that is apt to seem to the impatient reader almost too conscientious and cautious.

To readers who were acquainted with the scientific results of the time who were aware of the numerous important facts that had been discovered but missed the unifying idea which should gather them all together into a harmonious picture of life the book came as a revelation. I myself was at the time in the stage of metamorphosis from a physician to a zoologist and as far as philosophical views of nature were concerned I was a blank sheet of paper a *tabula rasa*. I read the book first in 1861 at a single sitting and with ever growing enthusiasm. When I had finished it I stood firm on the basis of the evolution theory and I have never seen reason to forsake it.

This must have been the case with many. You know that the generation at the beginning of the century satiated with speculation threw itself wholly into detailed research and its whole endeavor was to acquire new facts. Darwin furnished the unifying idea for these. It was evolution. Almost the whole younger generation of naturalists ranged themselves at once on his side the older generation gradually followed first zoologists then botanists even my excellent friend Anton de Bary was only converted to the new views in 1880 and from that time onward there was little further opposition even on the part of the botanist.

Although Darwin's book was straightforward and simple its effect was nothing less than revolutionary. It upset the old deep-rooted doctrine of creation just as completely as Erasmus Darwin Lamarck and Oken had desired. The book raised a conflagration like lightning in a full barn. This was soon so widespread that people read only against or for Darwin especially in Germany but later also in England. At first the opponents had the upper hand the church regarded the new doctrine as dangerous to religion because the old Mosaic mythus of creation could no longer be regarded as the basis of belief and many of the older naturalists did not care to give up their inherited opinions without a struggle and therefore strove to depreciate the new theory either by serious argument or by satire and ridicule. The first to publish a work for Darwin was the German naturalist Fritz Müller (1864) in Brazil. His book contained the first important deduction from the Darwinian theory. It went further than Darwin himself and contained the germ of what Ernst Haeckel called in his suggestive Generelle Morphologie (1866) the fundamental biogenetic law. I myself was probably the third champion of Darwin's views when in 1867 I delivered my academic inaugural address on The Justification of the Darwinian Theory.

At that period almost every special study in the domain of embryology and comparative anatomy revealed fresh facts which were only intelligible on the assumption that the theory of descent was valid much was now observed that had formerly been overlooked simply because it was not understood and much of the work done in the period of detailed investigation had to be done over again because the points that were now most important had previously been disregarded. In this no reproach is implied to the many excellent observers of that period. No one can possibly observe everything that takes place for instance in the development of an animal each notes only what seems to him to have some significance whether he is able to interpret it or not. We do not work with our eyes alone we must think at the same time.

But I need not dwell longer on the manner in which the Darwinian theory gained over the scientific workers of all countries and penetrated deeply even among the laity. We have all had some personal experience of it for the triumph of the theory of evolution has not long been won. A few words may be necessary as to why it was won so easily and so completely.

This was due in part to the enormous and increasing mass of facts in support of it but mainly to Darwin's discovery of a principle capable of explaining transformations in so far at least as these are adaptations the principle of selection. Lamarck too had thought out a principle of explanation—the use or disuse of parts—but it was obviously insufficient to explain evolution as a *whole* since it could only apply to actively functional organs.

The discovery of the principle of selection is the greatest achievement of Charles Darwin and his contemporary Alfred Wallace and it alone in my opinion at least affords a secure basis for the theory of evolution. It reveals to us how the apparently impossible becomes possible how what is adapted to its purpose can have arisen without the intervention of a directing power.

(To be continued.)

Geology and Our National Resources

In his recent presidential address before the New York Academy of Sciences Prof J A Kemp took up the discussion of some of the problems which arise in connection with the ultimate limitations of our supply in raw materials derived from the earth's crust. The consideration of a number of special aspects of the situation was introduced by some reflections of a general character. Prof Kemp says:

The problems of the production of the metals and non metalliferous substances as we know them to-day are of quite recent growth. High explosives efficient engines and pumps steam shovels and the like are all not so old as many men who are still living. They have so greatly reduced costs that practically a new world has opened to the miner. Not only on the surface or near it has he been able to work but the depths have become accessible and where the value of the ore justified the effort no floods of water have sufficed to keep him out.

"These successes, coupled with ever-expanding markets have until recently directed attention almost wholly toward discovery and production. But the last ten years have brought a further change. We are now less concerned about new discoveries than about the maintenance of old ones. We are not altogether intent on production, but are much given to forecasting and husbanding. From being solely an aid to the miner, the active worker the producer geology has become the colleague and helper of the economist, the statistician and the philosopher.

"Like all other changes in fundamental points of view this one has not come with absolute suddenness. As far back as 1879 certain geologists and engineers began to raise and discuss the question of the duration of the Pennsylvania anthracite. In 1894 the late Richard P Rothwell long the able editor of the *Engineering and Mining Journal* gave these coal fields a future of 70 to 100 years. Thus for over thirty years the question of their death has been a very live one. Even earlier the future of the coal fields of Great Britain came up for discussion. A parliamentary commission was appointed in 1866 and reported upon the question in 1871. For forty years anxiety has prevailed regarding the continued production of our petroleum wells and naturally so. The very means of production of this useful source of heat and light starts a train of thought along the lines of its permanence.

"Some ten years ago the question of our reserves in iron ore began to excite interest. Mr Andrew Carnegie gave most forcible expression to the feeling of alarm in his rectorial address in 1902 at the University of St Andrews Scotland. Mr Carnegie was known from one end of the world to the other as one of our greatest ironmasters and his words made a profound impression. In his address he assigned us only enough first-class ore to last for sixty or seventy years and only enough of the inferior grades for thirty years thereafter. We all trembled for some years with the prospect of seeing our greatest industry in the production of metal disappearing within a century. Many thoughtful people began to wonder what would become of us with its extinction."

At this time when the movement for the preservation of our national resources is the order of the day it is interesting thus to call to mind the past history of the rise and origin of the modern policy.

M Pierre Lesage of Paris states that he is able to show whether certain seeds are able to grow or not by placing *them in potash solution*. The seeds which are defective and are not good for planting are found to give a yellow color to the solution. At present he confined his experiments to one kind of seed the lepidium sativum using old seeds collected in 1888 to 1893 and comparing them with fresh seeds from 1909. He finds in general that the seeds which have lost their growing power will color the potash solution yellow owing to the diffusion of a substance which he has not examined as yet. They do not produce this color in pure water however. As to the time which is needed to give the yellow color this is shorter than what is needed for grains of the same kind to sprout. For instance using the old seeds from 1893 they showed a color in the solution in about four hours while fresh seeds from 1909 took twenty hours to show a sprouting in the same conditions. Thus the process allows of gaining considerable time in observing the seeds. The present experiments are only in the first stages but it will be seen that should we be able to find out at once whether certain seeds or grains are able to grow or not by a simple experiment, the result will be of great practical value. Other kinds of solutions will no doubt be found which can be used for testing seeds or grains in this way.

Reclamation of the Southern Louisiana Wet Prairie Lands—II*

By A D Morehouse, Office Engineer, Drainage Investigations

Concluded from Supplement No. 1843 page 270

METHODS OF RECLAMATION

Early Methods

SOME years ago systematic efforts looking toward the reclamation of these fertile marsh lands began and it is interesting to note that as early as 1883 84 1 300 acres were reclaimed by one company During the great flood of 1884 however the levees were broken and further work ceased for the time Later Mr J B Watkins reclaimed a large area in south western Louisiana and in Tide Marshes of the United States he gives the following description of his methods

O r plan of reclamation is to build dikes along the g lf rivers lakes and bayo s of sufficient height and strength to prevent overflow of each in the event of floods from rain and storm tides and in this we will be assisted by the natural levees found in many places along these waters We cut parallel to each other and one half mile apart canals 18 feet wide and 6 fe t 1] A right angles with these at intervals of 2½ miles we cut larger canals, thus forming the land into oblong blocks one-half mile by 2½ miles each containing 800 acres Across these blocks at proper intervals we cut lateral ditches 30 inches deep by 8 inches wide at the bottom flared to 30 inches wide at the top

The canals are cut the levees formed and the dikes are to a considerable extent built by the use of power f l floating steam dredges Smaller ditches are cut by ditchers propelled by steam power passing through l it once at the rate of 1½ miles per hour

At proper localities we erect automatic flood gates by means of which we control the stage of water in the canals and the necessary volume of water is regulated to some extent by the ebb and flow of the tide This is supplemented by the use of powerful wind pumps and when the natural elements will not accomplish the work we readily move upon the canals to the spot our ditching plowing and cultivating engines and attach them to pumps Thus arranged with control of the water these blocks of land are in condition for the most successful rice culture

In the rice and sugar belt in the southern part of the State the land ranges from 2 to 8 feet or more above mean gulf level and the swamps bayous bays and rivers with which the section is interspersed furnish the outlet system by which the drainage water may be carried to the gulf In a majority of cases it is necessary to levee a part or all of a plantation in order to protect it from the overflows in times of flood and also in regions near the gulf coast to protect it from backwater and high tides especially at times when the prevailing southeast winds are blowing At such times the waters along inland streams the ast n ay be raised as much as from 3 to 5 f fron l is a so In this connection might be lo d the fact that on the Matthews plantation in La l our he Parish it was considered that usually the p[illegible] s had to operate only after a rainfall of 4 inches or more in twenty four hours but when the southern wi s made high tides in the bayou they were started f r as small as a 2 inch rainfall

FIG 9—SAME VIEW AS FIG 8 BUT SHOWING RESERVOIR CANAL OF DRAINAGE DISTRICT DAMMED ACROSS AND PUMPING PLANT BEING ERECTED

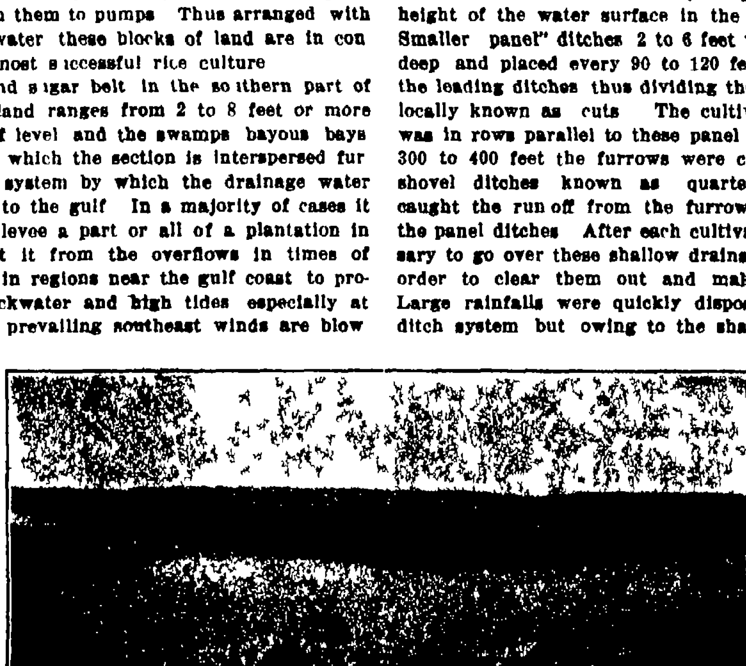


FIG 8 CONSTRUCTED CANAL SERVING AS OUTLET FOR TWO DISTRICTS AND AFFORDING GOOD TRANSPORTATION FACILITIES

Until very recent years the ditch systems for the reclamation of sugar lands were nearly identical Often it seemed that the chief effort was simply to rid the land of the rainfall without much regard as to whether or not the drainage of the soil was secured. As most of the plantations ran from the bayous or streams back into the swamp there was usually at least a slight fall away from the streams and a series of parallel leading ditches from 6 to 10 feet wide and 2 to 4 feet deep spaced from 800 to 1 200 feet apart ran the length of the plantation These were intersected at right angles usually by ditches of similar size at distances of 800 to 1 200 feet apart These latter ditches were laid with no fall so that the water would flow either way dependent upon the height of the water surface in the leading ditches Smaller panel" ditches 2 to 6 feet wide 1½ to 3 feet deep and placed every 90 to 120 feet, ran parallel to the leading ditches thus dividing the land into blocks locally known as cuts The cultivation of the crop was in rows parallel to these panel ditches and every 300 to 400 feet the furrows were crossed by shallow shovel ditches known as quarter drains which caught the run off from the furrows and led it into the panel ditches After each cultivation it was necessary to go over these shallow drains with a shovel in order to clear them out and make them effective Large rainfalls were quickly disposed of by such a ditch system but owing to the shallow depth of the ditches the drainage of the soil was not as effective as under more modern systems, and from 10 to 20 per cent of the cultivable area was taken up by the ditches besides the inconvenience caused by the smallness of the plats to be cultivated The cost of such a ditch system not including levees or pumping equipment would amount to over $2 000 for 80 acres or an average of over $25 per acre

PRESENT METHODS.

It is apparent from the experiences of the past that in the reclamation of small areas of land the cost might often be prohibitive, but as the size of the plantation increases the cost per acre rapidly diminishes and probably approaches a minimum price when the plat of ground amounts to eight sections (5,120 acres) of land or more. Under ordinary circumstances however it would be difficult to find such a tract of land lying in regular shape and available for reclamation hence there are few single projects thus far which have attained this size although the impetus recently received in the matter of reclamation of these lands indicates that the undertakings will become larger and larger The various main elements which enter into these projects are the levee system seepage outlet canal system interior ditch system and lastly the pumping plant

Levees and Seepage

Sometimes the natural embankment or high ground adjacent to the bayou or river makes a levee unnecessary along the stream side of the plantation but ordinarily the other three sides need such protection wholly or in part the height of the levees depending in large measure upon the proximity to the gulf and upon the elevation of the land surface respective to the high water in times of flood Ordinarily the levees do not require such careful construction as those along streams subject to frequent and prolonged floods where the water often stands against the embankement for long periods nor is it always so necessary to clean the entire levee site as in this latter case It is always well however to remove all coarse vegetable matter and a plowing up of the site is very desirable in order to insure a good bond. The general specifications for levee construction and maintenance have been given in a previous publication of this Office A muck ditch 2 or 3 feet in width and about 2 feet in depth and approximately on the center line of the proposed levee should be constructed in order to insure against excessive seepage Such seepage is liable to be the minimum in the fine close-textured silt soil back in the marshes In the case of the Gheens plantation La Fourche Paris two parallel muck ditches spaced 25 feet apart are used under the levee

Shrinkage of the levee should also be taken into account and experience would indicate that levees in these soils built by means of shovels or wheelbarrows shrink about one-fifth of their gross height, while those constructed by wheel scrapers shrink one-eighth in height. Where an excavating machine is used in dry material the shrinkage is approximately one-sixth and where excavated material is wet it is probably not more than one-tenth In the latter case the spoil generally being from a greater depth and being well compacted during the construction usually insures less seepage than where hand work is performed and where the levee is constructed from the looser coarser material nearer the surface. In order to prevent excessive seepage it is preferable in constructing the levees to excavate the canals on the outside leaving a sufficiently wide berm to prevent the spoil from sloughing back into the ditches. Unless care is exercised this is especially liable to occur in the soft prairie lands. The levees require for the first few years frequent additions in order to keep them to the required height, unless when first constructed, shrinkage has been allowed for In order to maintain them with as little care as possible, it is well to have them sodded to Bermuda or some native grass which not only prevents them from washing but also prevents the growth of weeds, brush, and other vegetation that

---

* This article is based on reports to the chief of drainage investigations by A M Shaw, E New Orleans, La., and Prof W B Gregory M E Tulane University, of their investigations made during 1909 and also upon data furnished by C W Okey, assistant drainage engineer, who continued the work of this Office during 1910 in Southern Louisiana. All quotations not otherwise credited are from the foregoing mentioned reports, the portions referring to pumping equipment being by Professor Gregory and the rest by Mr Shaw

would furnish shelter to the many borrowing animals which, ordinarily, occasion much annoyance and also damage to the levees. The sudden rise of outside waters often endangers levees on account of the increased seepage at such times which is probably often due rather to the more porous nature of the soil above the ordinary water level than to the increased head. Such floods, however develop all weak spots caused by muskrat holes and the like When a failure occurs from this cause the outer end of the break should be immediately closed by a few shovelfuls of clay planks, or sacks of earth and a trench then dug across the levee The tunnel made by the animal can then be filled with puddled clay and the damage thus remedied.

Canal Systems

Where a plantation does not adjoin a bayou or other good outlet it is often necessary to construct outfall canals for some distance often through heavy timber which of course greatly increases the cost of the reclamation work and calls for the co-operation of a number of land owners in order to make the plan feasible These outfall canals as well as those surrounding the levees furnish good means of transportation by boat and often the flow of water from the drainage plant will be sufficient to keep them scoured out so that they require little attention Such transportation routes connecting as they do with a series of lakes bayous and streams place the various plantations in a comparatively independent attitude so even though not furnished with convenient rail road facilities they are still within easy and convenient reach of good markets Fig 8 shows such a canal const uct d as ai utlet for two I ali age dis tricts The small canal shown for us th reservoir of one of these districts and as shown by Fig 9 it has been cut off from the o itfall canal by an earth dam and the pumping plants as appears is it process of erection Along the banks of these canals willows and cottonwoods brush and weeds often grow b t as they are above water level they do not as a rule offer much interference to the flow of the stream Another growth however that causes a great an o int of annoyance and in some cases pra tically stops the flow of the water in the ditches is the water hyaci th which is known locally as a lily It is practically impossible to navigate throigh these obstructions when once well established except by the use of stern wheel power boats These plants introduced from abroad have rapidly spread through many of the southern streams so that means for checking their growth or eradicating them entirely are eagerly sought Fig 7 shows a canal filled with these water hyacinths which have grown to about 18 inches above the water surface The view shows the main discharge canal of a large plantation, and it can readily be understood how its efficiency is impaired by this pest The following description of the plant is taken from a report by F F Shafer drainage engineer

"The plant when young has a bulbous stem but as this grows upward the enlargement disappears, apparently being absorbed by the stem which is cylindrical and hollow The plant multiplies rapidly by sending out shoots or suckers from the base of the bulb the shoots and roots seeming to start from the same place. The latter grow in feather-shaped tufts, presenting a large surface to the water They are tender and break off readily but if not disturbed grow downward 4 or 5 feet In the latter part of May a flowering stem appears which bears a spike of odorless flowers, pale lavender in color resembling the ordinary cultivated hyacinth The stems reach a diameter of one-half to three-fourths of an inch and in this vicinity frequently extend 3 feet above the water surface Crowding does not seem to hinder the growth of the plant and since it floats upon the surface of the water wind tide, and currents tend to produce closely packed masses When a ditch becomes filled with these plants the floating stems and roots offer a very serious obstruction to the flow of water Two or three years of undisturbed growth in a ditch will greatly reduce its usefulness as a drainage channel Booms are placed at the outlets of the drainage canals to prevent the plants from floating into the ditches I it it is difficult to prevent these booms being left open by people passing through in boats

The attempt has been made to use poisonous chemicals for the eradication of these plants this not only proved more or less ineffective but the expense was far too great On the Matthews plantation before mentioned an attachment in the shape of a gridiron some 7 by 8 feet in size was fastened to the dredge dipper and the plants dipped p and d imped on the banks in a similar maner to the operation of a dipper The plants when exposed to the hot sun soon die The cost of removal by this method amo nts to about 0 4 cent per square yard for the area cleaned On other plantations during the rainy periods the laborers use pitchforks to remove the water hyacinths from the ditches If is often necessary to repeat the operation once or twice a m nth Tl e cost in th s ase is practically the same as by tl e use of the n a chine In localities close to the gulf where salt wate prevails the plants do not thrive

Interior Ditch Systen s

Although somewhat dependent upon the size and shape of the area inclosed within the levees the pres et t general scheme of drainage is more or less the same throughout this region This system usually in cludes a main reservoir canal or canals upon which at some convenient place a pumping plant is installed Leading into these reservoirs are collecting ditches of somewhat smaller size and at right angles to these latter are lateral ditches which are still smaller and which usually feed into the collecting ditches as on the Willswood plantation In certain cases as in the Smithport plantation the collecting ditches are practically dispensed with and the lateral ditches dis charge directly into the reservoirs In addition to the laterals shallow shovel ditches corresponding to the old quarter drains" are maintained at right angles to the furrows and thus collect the water rapidly from the fields and discharge it into the ditch system These latter are made new each year and they vary in arrangement and size to meet the individual requirements

Although subject to variation the main reservoir canals range in width from 30 to 60 feet and usually have a depth of from 5 to 8 feet The deeper the canal the greater storage capacity it possesses and the better outlet it furnishes for the collecting ditches or laterals as the case may be and it is also less liable to water-growth obstructions As shown in the following table, the reservoirs of the three plantations under investigation have varying capacities equivalent to a rainfall on the tributary lands of from 0 1 inch to 0 4 inch It would seem preferable to construct reservoirs having even greater capacity than the larger amount mentioned as by so doing the size of the pumping plant can be decreased This table from Mr Shaw s report besides showing the reservoir capacity also gives the length of the various ditches and area occupied by them and gives as well, the normal capacity of the pumping plant in inches of water depth per twenty four hours It will be noticed that the ditch systems of these three plantations only occupy from 3 to 6 per cent of the area which is a decided decrease from the 10 and 20 per cent nder the old ditching system as previously mentioned

F G 10 —OPEN TRACTION DITCHER USED FOR DIGGING LATERAL DITCHES N WET PRAIR F ANDS SOIL S DEP S TED AT ONE SIDE OF DITCH LEAVING GOOD BERM

Th arrangement of th colle ting dit hes largely depen is up the shape of the fields and tl e nat ral opography of the land and also upon the method and kind of c ltivation th t is desired The endeavor is to arrange them l owever so that they may get the water from the fields into the reservoir canals as promptly as possible They vary from 4 to 10 feet in width and are us ally maintained at a depth of fro 4 to 5 feet

Ordinarily the lateral ditches in heavy soils are placed 100 feet apart and are dug so ne 3 feet deep with bottom width of about 2 feet and a top width of about 4 feet Formerly these laterals were lug en tirely by hand but a litcher machine has been developed which now ligs them with great rapidity as well as economy A view of this machine may be seen in Fig 10 All the larger ditches are constructed usually by floating dipper dredges having 1 or 1½ yard dippers and the present contract price is abo it 7 cents per cubic yard

Thus far drain tile has not been extensively used in this locality as the nature of the soil and the slopes found are likely to introduce difficulties which will have to be overcome before underdrainage is uni versally adopted It is probable that in the coarser looser soils near the bayous and streams tile would be more effective than in the more impervio s silt farther out in the swamps If it can be s iccessf lly introduced so as to supersede in part the se of the smaller dit hes a gain in land area and in convenience of cultivation and in the effective draining and aeration of the soil would be the result By proper care in protecting the joints it is improbable that silting of the tile would give much trouble

As a general thing the water table of the plantations in southern Louisiana is carried at from 1½ to 3 feet beneath the surface and it is well known that the greater depth is preferable as besides furnishing a greater depth for the roots of the growing crop it also furnishes greater reservoir capacity in the soil to provide against excessive rainfall It likewise makes possible a smaller pumping equipment By keeping the pumps running during the winter season when necessary the water table is kept as low as possible aeration of the soil takes place and the soil is thus put in good physical condition

Pumping Plants

Some plantations are so situated that fairly satisfactory drainage can be secured by the installation of outlet gates through the levees either automatic or hand regulated These drain the system of reservoirs and ditches in times of sufficiently low water but when the water outside the levees is higher than the outlet of course the gates must be closed and the reservoirs depended upon to hold all the interior drainage water A great majority however of the plantations which are reclaimed require the installation of a pumping plant in order to make the drainage system effective at all times and make the leveed area independent with the possible exception of seepage of everything except the rainfall These pumping equipments vary greatly according to individual opinions and means but each particular location should be studied carefully in connection with all its surrounding conditions in order to choose an installation whose first cost will be warranted by the benefits received and also one the operating expense of which will be reasonable A balance should also be struck between the economical reservoir capacity and the size of the pumping plant

In years past a machine that has been greatly in favor especially upon the sugar plantations is the drainage wheel This is made of any desired capacity and may vary in diameter up to perhaps 40 feet, with a width of from 5 to 7 feet By proper gearing usually a double reduction the speed can be regulated to suit the case but usually a peripheral velocity of 3 to 4 feet per second is maintained It is probable that a speed of 5 feet is desirable for revolving at a greater velocity the water is liable to be carried over while with a slower one a portion of the water may flow back into the pit. These wheels are placed at the end of the main ditch, and when not in operation the flood gate in the levee is closed When the circumference of the wheel fits closely in a smooth pit with the lift not exceeding one-third the diameter of the wheel and when running at the proper speed such a wheel will handle a large quantity of water at a small cost Although they have been made ordinarily by the individual plantation owners and the actual expense of the material and labor of the wheel itself is not excessive still the large foundations required make them probably more expensive than some of the more modern installations

Another machine sometimes used is the rotary or chamber wheel pump One objection to this form is that for the larger sizes the construction necessitates that the water be lifted about 10 feet and in case the necessary lift is less than this there is lost work They are also somewhat expensive and are limited to their normal rated capacities

The centrifugal pump is especially adapted to varying lifts for by the use of a discharge pipe whose end is submerged in the out fall canal or bayou a siphon effect is produced so that the actual head against which the pump is working is simply the difference in elevation between the waters in the reservoir and in the outlet canal These pumps on account of the varying speed at which they can be operated have discharges for short periods of time far in excess of their rated capacities which is especially desirable in cases of excessive rainfalls of short duration The ordinary type of centrifugal pump made principally of cast iron is somewhat used and can be installed with either vertical or horizontal shafts In the latter case it can be direct-connected with the steam engine

There is a special form of centrifugal pump particularly adapted to low lifts that has been in use for a number of years and is doing most satisfactory work on a great many plantations including three of the experimental tracts It consists of a wide submerged impeller wheel on a vertical shaft driven by belt or rope from the engine The water rises through the large wooden body of the pump flowing away through a wide discharge trough Except the impeller shaft bearings and pulley the entire machine is of wood. This pump is of large capacity and is perhaps especially adapted to lifts up to 10 feet, although it is claimed that by the use of two or more wheels, set one above the other, water can be pumped against a head of 40 feet The discharge trough or platform can be placed at any height required, If it is set at high water mark however there would always be some waste of power when the water in the bayou or out-fall canal is less than this height

As the necessary water lift in the plantations of this section varies from 3 to 10 feet, it is a matter of economy that the pump be chosen which will only raise the water the height that may be necessary at any particular time This will avoid the necessity of purchasing an engine and boiler of too great capacity In some plantations that have been visited it has been found that the effective lift was only one half of the actual lift which it will be readily seen is a great waste of fuel and plant capacity When open flumes are used, which are placed at the ordinary water level the water in flood times can be prevented from flowing back by means of flood gates placed in the flume

As may be noted above in the description of the pumping equipments of the various plantations the engines and boilers selected vary greatly They should however be chosen with due regard to first cost capacity reliability and economy of operation On some of the old sugar plantations the condemned boilers from the sugar houses are used and run at a low pressure In cases where the plan is only operated a few days in each year the cost of operation is not such a determining feature as when the plants are called on for regular work during each month of the year In this latter case it will probably pay to put more money into a better plant including automatic high-speed engines feed water heaters and other fuel saving devices In the former case simple slide valve engines with any suitable boiler are about all that will be required A point to be kept in mind is that these plants are usually run by more or less inexperienced labor and therefore complicated machinery should be avoided Economy in plant capacity should not however prevent the selection of machinery of sufficient size to take care in as short a time as possible of the probable run off from excessive storms as upon such drainage depends the plantation's success

Engineers and Journalists

Tools and Words

ENGINEERS and journalists are two very modern words embodying two very modern ideas yet they illustrate a contrast as old as humanity—the antithesis between tools and words technical arts and religion nature mastery and nature worship At all times however and now more than ever before representatives of each of these tendencies occasionally go over to the opposite camp

The invention of a new tool leads to discoveries of undreamed of things by thousands of the masters of world knowledge In the course of a century the magnifying glass is so greatly improved by a silk worker a glass blower and a mechanic that dozens of professors win fame by discoveries which they could not have made without the improved tool and which hundreds of other men could have made as well with it

On the other hand a profound thinker spins a web of living words that takes root and grows like a mycelium in a million brains and in time produces new tools as well as words

The priests of forgotten religions sought to influence the sun the lightning and the rain by pompous oratory but the tool the machine gradually replaced the word as a more efficient controller of the forces of nature Yet to this day the spoken or written word still exerts its mystic spell and sways the destinies of nations

Engineers and journalists form two of the youngest of professions The engineers move mountains and construct machines that vastly augment the power of man the journalists exert equally great influence in the political and social world yet both lack the prestige enjoyed by the older professions In political influence the engineers are far surpassed by the journalists The German Reichstag includes many journalists and writers but not a single engineer unless one is concealed in one of the factory directors who sit in the Reichstag Yet the engineer by his inventions and activities exerts an immense practical influence in political economy

Dr George Biedenkapp whose article in *Technische Monatshefte* is here freely summarized points out that neither the engineering nor the journalistic profession is a unit or recognizes a uniform standard of fitness An astonishingly large part in the progress of engineering has been played by untutored laymen Even so modern an invention as the steam engine includes among its developers the lawyer Porter and the merchant Corliss In engineering enterprises university graduates work beside and even under men who have graduated from the factory So in a great newspaper office a former typesetter may be on the chief of a highly educated staff This lawlessness is not only a symptom of youth but also a reason why engineers and journalists should view without prejudice many things that would create scandal in the old academically educated professions

The influence of the press itself a creation of the engineer will go on increasing and the engineers are extending their influence not merely by their technical achievements but by entering the ranks of journalism which already contain many men of technical training Many celebrated engineers and inventors have possessed great literary talent James Watt was an admirable narrator and so was the American inventor Worthington Max Eyth and Heinrich Seidel were poets as well as engineers Vauban the famous French military engineer was one of the earliest and most important writers on national economy The German inventors Riggenbach and Siemens and the American Porter the father of the quick running steam engine have left fascinating autobiographies Friedrich Harkort who erected one of the first German steam engine factories and built one of the first German steamships was an influential political writer

Furthermore the solution of the difficult problems of organization and economics which arise in industrial practice fit the industrial engineer for the position of social engineer Abbé not only improved the microscope but also endeavored to improve the conditions of factory life Freese and Oechelhaeuser wrote essays on the labor question The engineer's training offers many inducements to attempt to combine men as well as iron and wood into a perfect machine

Or was it by pure chance that Vauban wrote on the principles of just taxation that Eyth founded the German Agricultural Society that Harkort interested himself in the political and social weal of his fellow countrymen?

Language and thought have derived great benefit from technical discoveries If wheels, wagons, clocks, compasses springs and screws had never been invented we should be poorer by thousands of words and ideas Two centuries ago the French mathematician and philosopher Sophie Germain drew a plan of an exact science of politics in which the mutual actions and reactions of the elements of population were illustrated by the mechanical analogy of forces acting between material particles This enrichment of language and thought will be accelerated by the influx of men of mathematical and mechanical training into the journalistic profession Both journalism and politics will gain by this development, which is a necessary consequence of the overcrowded condition of the engineering profession Max Eyth sought a position in vain and Porter was twice forced from his post by commercial wisdom The dependence of the engineer upon the factory owner or contractor may be more galling than even that of the journalist upon the publisher The newspapers are continually devoting more attention to industrial and technical subjects, and no novel is complete without a description of an automobile or airship adventure The door of journalism therefore is opened widely to the engineer and thus the tool again becomes a power in the realm of the word

Depth of Water and Speed.

A curious result of the speed tests of fast-driven vessels is the discovery alleged to have been made in England, that the depth of water strongly influences the speed But it is not true as was until recently believed, that increase of depth is invariably attended by increase of speed

Experiments with the 'river class' of torpedo-boat destroyers have shown that at certain depths it takes the same power to give a speed of twenty knots as to give a speed of twenty two knots when the depth of water is forty five feet. On the other hand, there are points of minimum resistance For instance a speed of thirty-two knots in sixty feet of water can be obtained with less horse-power than in two hundred feet. The result, it is claimed in England, is even better at forty feet.

It seems to be established that in moderate depths the square of the speed in knots divided by ten gives the depth of water in feet where a sudden increase of resistance is felt. It all depends upon the influence of the bottom of the water on wave formation.

Solid Ceilings Between Iron Girders

A Summary of German Studies

By Robert Grimshaw

The German Association of Steel Manufacturers has prepared for the benefit of the public a work treating very thoroughly the subject of ceilings and girders and although its main object is to systematise plans for the manufacturers of iron beams and girders it will also be of great service to the makers of terra-cotta cement and other artificial blocks

In Germany the conditions are somewhat different from those in England and America but for all that a study of these will be of use to architects and builders in both these latter countries

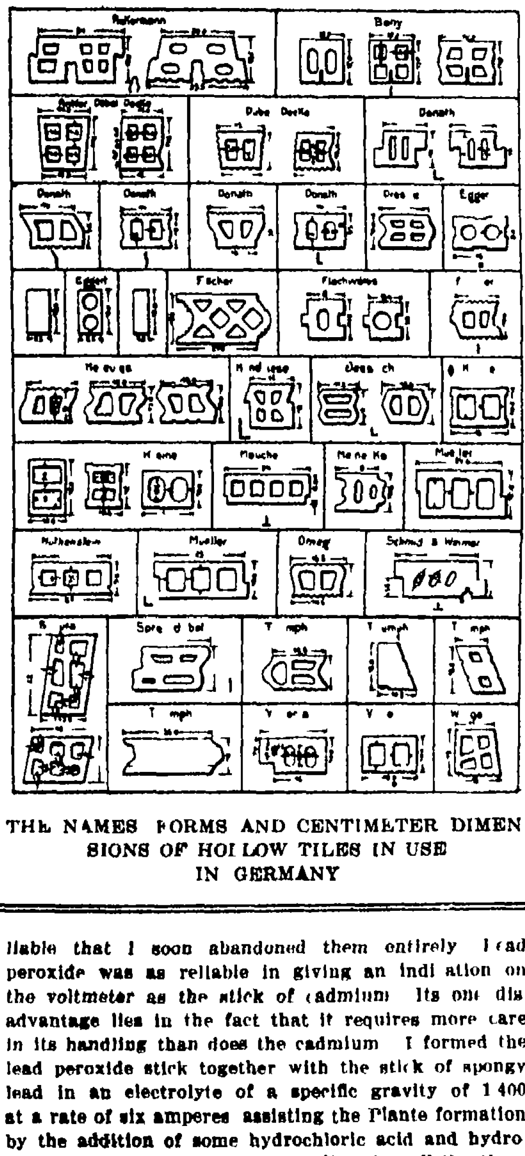
In Germany there are three general classes of ceilings—those with wooden joists those constructed entirely of concrete and those made of brick or tiles The first class was in the early days the only kind in use despite their insecurity from fire which it was vainly attempted to do away with by impregnating them with alkaline solutions In addition to this they transmit sound very readily which in these piano days is of importance in large cities Against this difficulty all sorts of filling have been tried but as one must reckon with the question of moisture many of these materials become rotten and unhealthful Further the wood itself when not properly seasoned and laid—and this is seldom done—gradually decays and once fungus steps in there is no salvation The trouble is brought from the forest and as the timber cutters and lumber merchants have no particular interest in saving the lumber from destruction once it has been sold this trouble will be likely to continue indefinitely The fungus which is only about 2 millimeters or 0 078 inch long passes through ordinary brick walls and infects one house from another

All these disadvantages are missing in the two other classes of ceilings

The concrete ceiling has its disadvantages also In the first place composing as it should a single built together structure it carries sound very readily and is also a good conductor of heat to and from the rooms covered This excludes it in many places from use in schools hospitals and private dwellings Concrete is also very heavy alkalies from the cement are apt to appear on the surface and the plastering does not adhere very well thereto In fact, in this last particular the Berlin Building Department allows its use only in such cases as do not require plastering of the under layer

The continuous nature of the concrete ceiling also renders difficult if not impossible any desired alteration And finally the laying of such ceilings requires a skilled personnel and it is often impracticable for the supervising architect to undertake any responsibility for the contractor because he cannot sufficiently well control the main conditions for a good concrete ceiling—namely the raw materials composing the mixture The concrete ceiling, however has its great advantages when it comes to the question of wide spans and heavy loads

The hollow tile ceiling between iron beams avoids all the above mentioned disadvantages In the first place as against the wooden ceiling it is absolutely fireproof—naturally if provision is made that the beams or girders shall not be exposed to the direct action of the flames Further because the tiles are hollow it does not conduct sound for the same reason it is a bad conductor of heat As it is composed of separate pieces which are not firmly bound together alterations therein may be made without difficulty or expense The ceiling plastering adheres well to the terra cotta there is no danger of shrinking and expansion such as cause cracks in buildings where wooden ceilings are used And finally it is easy to inspect and to control material and workmanship and no very skilled labor is necessary



THE NAMES FORMS AND CENTIMETER DIMENSIONS OF HOLLOW TILES IN USE IN GERMANY

The most simple kind of ceiling of its class is that in which there is a single arch between I beams (which by the way the Germans always call double T beams) of ordinary tiles porous bricks or light artificial slabs of ashes and plaster or the like Besides these there is a great number of more or less complicated fillings some of which have found great favor some very little or none Among those which have been introduced with success in Germany are the Forester Sekura and Klein types which are shown in the accompanying illustration in alphabetical order

As regards cost it is indisputable that in most cases the wooden ceiling is the cheapest A comparison of the cost of the concrete and the tile ceiling is difficult as here the cost of the raw materials comes more into consideration

The steel manufacturers have endeavored to aid builders in this particular and have come to the conclusions stated below

In the first place they have figured up an ordinary apartment house The cost per square meter (10 76 square feet) of all wooden ceiling and floor is 11 25 marks ($2 68) of reinforced concrete with wooden floor covering 13 2[illegible] marks ($3 16) hollow tile with wooden floor covering 12 95 marks ($3 08) For a one family house reinforced concrete with wooden floor covering 13 80 marks ($3 28) hollow tile with wooden floor covering 12 30 marks ($2 93) In this connection the manufacturers of tiles should look to their own interests by reducing the cost of their tiles and of laying also by preventing the wasteful use of mortar as for instance where it runs into the hollows of the tiles The practice of drawing paper tubes through the latter to prevent this is expensive Closed tiles such as were exhibited in the last Clay Industry Exhibition in Berlin will avoid this difficulty

The illustrations show about all the forms of hollow tiles which are in use in Germany the dimensions being given in centimeters (0 39 inch)

In cost figuring the mark may be taken as exactly 23 83 cents the square meter as 10 764 square feet

Some Interesting Storage Battery Plate Potentials

By Paul F Troi t

In experimenting to find a satisfactory substitute for the stick of metallic cadmium which is most commonly used in storage battery work when reading the charge on the separate plates I secured some very interesting results My purpose in conducting the experiments was to discover a means of taking complete battery readings where it was for any reason impossible to secure a stick of the comparatively rare cadmium This will be of especial importance to the man who must install peak load batteries in plants far from a large city

I confined my experiments to lead sticks free from any other metal because lead is always obtainable around a storage battery The sticks were taken in various states of oxidation and the following figures are representative of the readings obtained The readings were taken on cells containing Tate bifunctional accumulators with electrolyte of specific gravity 1 215

Some Interesting Storage Battery Plate Potentials

Cells	Volts	Cadmium +	Cadmium −	Lead Peroxide +	Lead Peroxide −	Spongy Lead +	Spongy Lead −	Unoxidised Lead +	Unoxidised Lead −
1	[illegible]	2 40	0 [illegible]	0 90	[illegible]	[illegible]	0 4[illegible]	2 06	0 [illegible]
2	2 70	2 40	0 [illegible]	0 90	2 60	[illegible]	0 46	1 90	0 50

5	[illegible]	[illegible]	0 0[illegible]	0 [illegible]	[illegible]				
6	[illegible]	[illegible]	0 0[illegible]	0 91	[illegible]				
7	[illegible]	[illegible]	0 0[illegible]	0 91	[illegible]				
8	[illegible]	[illegible]	[illegible]	0 [illegible]	[illegible]				
9	2 64	[illegible]	0 [illegible]	0 61	[illegible]				
10	[illegible]	[illegible]	0 [illegible]	0 [illegible]	[illegible]				
11	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]				
12	2 41	[illegible]	[illegible]	[illegible]	[illegible]				
13	2 4[illegible]	[illegible]	0 0[illegible]	0 [illegible]	[illegible]				

As can be readily seen from the figures, spongy lead and unoxidised lead proved so uncertain and unreliable that I soon abandoned them entirely Lead peroxide was as reliable in giving an indication on the voltmeter as the stick of cadmium Its one disadvantage lies in the fact that it requires more care in its handling than does the cadmium I formed the lead peroxide stick together with the stick of spongy lead in an electrolyte of a specific gravity of 1 400 at a rate of six amperes assisting the Planté formation by the addition of some hydrochloric acid and hydrogen peroxide I charged in one direction all the time in spite of the fact that to reverse the direction of the current tends to deepen the layer of oxide I wanted the layer of oxide to be as compact as possible and thought that to reverse the current would result in softening it too much A deep layer of soft oxide might have increased the uncertainty of the readings

The lead peroxide stick showed some rather peculiar characteristics. For instance when it was taken out of the 1 400 specific gravity acid and used for a reading it caused the volt meter needle to waver up and down the scale in a very unsteady manner But it was all right after it had been washed in dilute acid It gave the best results after it had been washed in water and dried retaining its efficiency or capacity to give a steady indication to the volt meter needle for over an hour after being immersed in the electrolyte It is useless if kept for any length of time in distilled water Like the cadmium stick it must be inclosed in a piece of rubber hose with small holes cut in it to admit the electrolyte Most battery authorities say that the purpose of this rubber jacket is to keep the stick from touching the sides of the jar or the plates of the cell but my experiments lead me to the conclusion that its real effect is to minimise the electro-chemical action on the stick

It is interesting to account for the indications which these different substances give on the volt meter needle First it is well to understand the part which the stick of oxide plays when it is immersed in the electrolyte of a cell In every case the stick no matter what its composition plays the part of a negative plate when it is used in reading the charge on the positive plate and the part of a positive plate when reading the charge on the negative plate of the cell Cadmium sticks are always allowed to sulphate before they are used thus giving a stick of cadmium sulphate which acts when used in taking a reading as a completely discharged plate Lead peroxide on the other hand is in reality a fully charged positive plate and consequently it gives indications with the volt meter needle which are strongly the opposite of those given by the stick of cadmium sulphate but nevertheless they are always relatively the same in value For instance a given indication with a stick of cadmium sulphate will always be equivalent to a certain indication with a stick of lead peroxide From this it can be readily seen that it would only require a series of carefully taken readings to make a table showing the relative values of the indications given by the two sticks all through charge and discharge of a battery

Excavations at Delos—Excavation work is still continuing at Delos by archæologists connected with the French School of Athens with funds furnished by Duc de Loubat Among the late finds is a sanctuary devoted to an Egyptian cult It was built on the slope of the Inopos and dates from the third century B C according to Messrs Roussel and Picard who discovered it The latter archæologist also uncovered the ground around the Sacred Lake and great stadium which was situated at the northeast end of the lake Many inscriptions were found on this spot He also explored the Roman walls of Delos these being built by Trarius in 70 B C

A Gravity Service for Handling Bricks

A Remarkable Labor-Saving Device

By Frank C Perkins

Many and varied are the labor saving devices scattered through all departments of the industry and commerce of the present day The desired result may be obtained sometimes merely through the assistance rendered to the hand by some specially designed tool or by a particularly favorable arrangement of parts Often however the contrivance employed does more than this it supplies the power which is required for

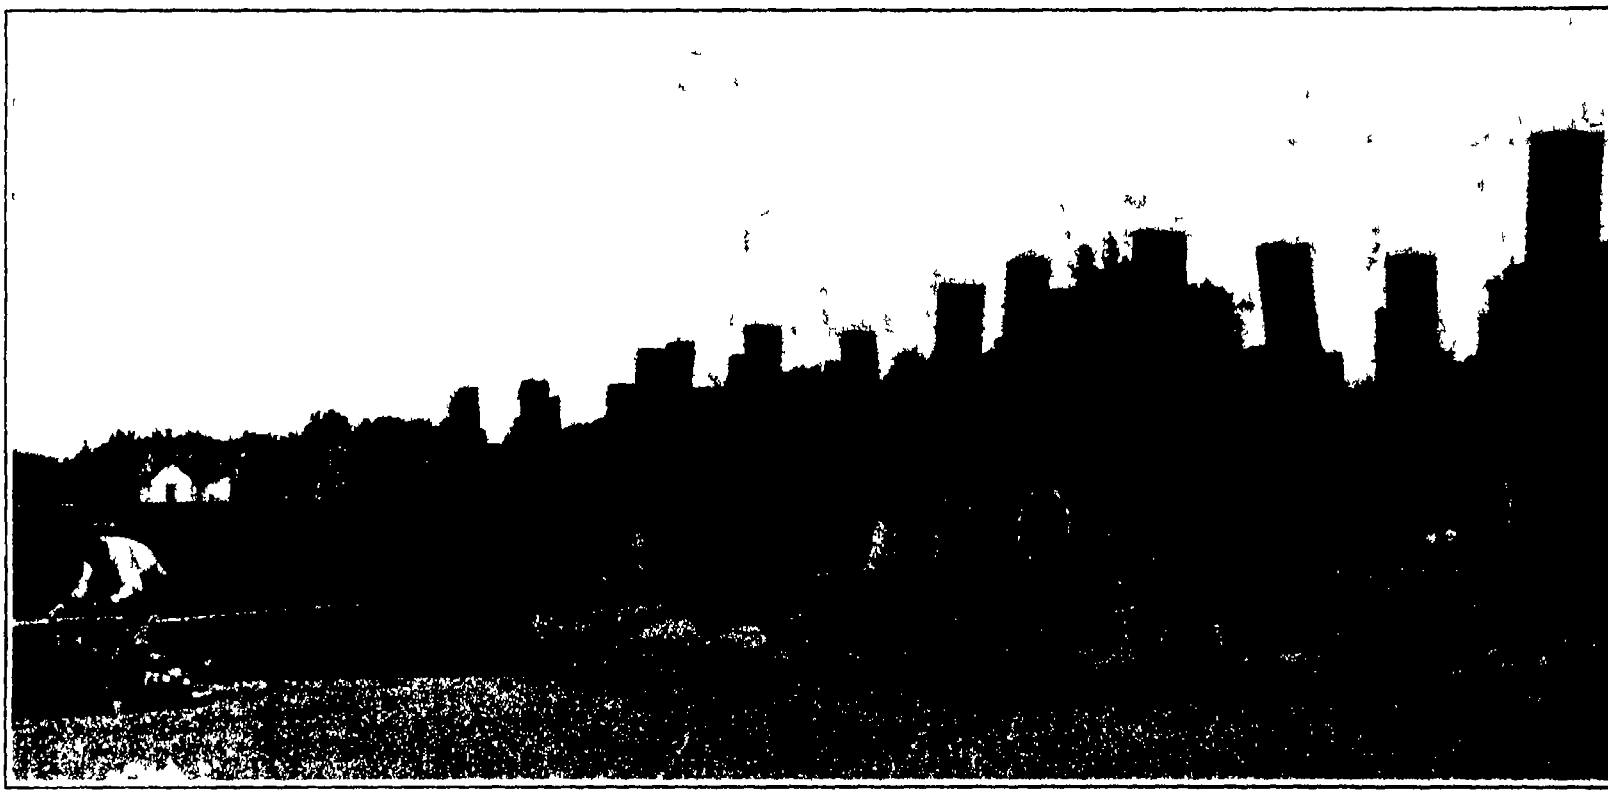

FIG 1—GRAVITY BRICK CONVEYOR AT THE WORKS OF THE LAWRENCE VITRIFIED BRICK AND TILE COMPANY KANSAS

FIG 4—LOADING BRICK UPON GONDOLA CAR

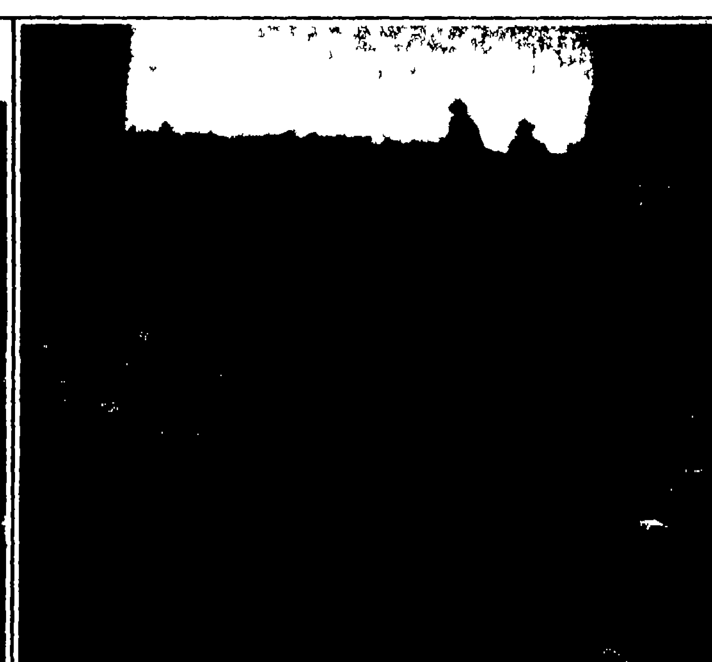

FIG 5—KILN END OF CONVEYOR

GRAVITY SERVICE FOR HANDLING BRICKS

the work incident to the operation The source of power is on the whole immaterial so long as it satisfies the ordinary requirements of convenience and cheapness A source of energy which in certain cases eminently fulfills these conditions is the gravitational work which all bodies are ready at all times and in all places to perform as soon as they are given an opportunity to travel downhill And in point of fact gravity feed is resorted to upon innumerable occasions in technical work A special instance of this kind is depicted in our illustrations which display several aspects of a gravity brick conveyer As will be seen by referring to our illustration and for detail especially to Fig 2 the conveyer consists simply of a roadway or bed whose bottom is formed of a series of transverse rollers, upon which the bricks are laid, and over the gently downward slope of which they proceed to their destination whether this be the brick stack in the factory in which they are made as in Fig 1 or the car (Fig 4) in which they are to be shipped or what not.

Some of the details of construction are exhibited in Fig 2 It will be seen that the rollers are mounted upon ball bearings The main portion of these rollers are cylindrical in shape but at the curves in the line they are made conical so as to give the requisite inward tilt to the moving material

Ten years ago little thought had been given to the great possibilities of gravity conveyers for transporting merchandise from point to point in and about factory plants To-day the system is a recognized element in factory and warehouse economy Its development has been rapid and scientific Practical men in all lines of manufacturing recognized its value the moment it was brought to their attention perceiving that its chief merits lay in economy of labor and time the two great essentials in profitable manufacturing The use of the gravity system often reduces the loading expense one-half over older methods besides making it possible to load more cars in a day than under former conditions.

Progress in Locomotive Design

The most remarkable step in the progress of steam locomotive design that has been made for many years is without doubt says the *London Times* the new method of arranging the cylinders which has just been introduced by the Nord Railway in France This method which consists in placing the inside cylinders one in front of the other instead of side by side according to the common plan adhered to until now since the earliest days of inside-cylinder locomotives, postpones to some undetermined period the limitation of the diameter of inside cylinders.

For many years past, writers have urged that finality in constructional limits for powerful locomotives would shortly be attained by reason of the impossibility of introducing cylinders of sufficient size for the power required within such limited loading gages as those of England and France It was in 1899 that

M. Polonceau, of the Paris-Orleans Railway affirmed that the French gage did not permit the building of two-cylinder compound locomotives of economical design, for the reason that the low pressure cylinder could not be made large enough to allow of an economical second expansion of the steam and the French railways thereafter adopted the multiple-cylinder compound system for rather small locomotives. Now, over twenty years later in building the largest and most powerful railway engines yet constructed on this side of the Atlantic the Nord Railway has found that even for four-cylinder engines as hitherto built all over the world with side by side cylinders the limits to the dimensions of low pressure cylinders have been reached and to overcome this difficulty the cylinders for its new Baltic type locomotives have been placed zig zag one just in front of the other. This arrangement enables cylinders to be made nearly half as large again as compared with the ordinary side-by side arrangement.

ADVANTAGES OF THE NORD SYSTEM

The new method adopted for the Nord Railway by M. Asselin the new chief engineer of motive power is of great interest to every main line locomotive engineer not so much for the ingenuity of the design with one piston rod working through the wall of the adjoining cylinder barrel as for the key it presents for the solution of the many problems in construction which have arisen as a consequence of the great increase in the size of locomotives and which involve notably the dimensions of the webs in cranked axles the width of the connecting rod big ends, and the length of the journals.

With the Nord system the centers of the two inside cylinders are brought very close together so allowing of considerable amplification of parts in the machinery which until now have been gradually thinned down to accommodate the lessened space available between the connecting rods and the frames in engines fitted with very large inside cylinders, such as have become common with the use of expanded or superheated steam as also for the low steam pressure expansion in compound locomotives. A great increase in the strength of turning parts now becomes possible and this considering the danger attending the failure of a cranked axle adds to the value of the immense power augmentation possible in the cylinders of either two-cylinder or four-cylinder engines.

The new arrangement is of utility for any class of steam locomotive but it is of greatest value in low pressure engines requiring large cylinders. At the present time there is a tendency to return to low steam pressures in order to economize in boiler repairs. To utilize these low pressures the piston areas have been increased correspondingly for given the possibility of using very large pistons the return to pressures of 120 pounds even with saturated steam becomes quite practicable and examples of very low steam pressures in saturated steam compound and simple engines are now to be found in current European practice.

ECONOMY OF LARGE CYLINDER RATIOS

The chief value of the Nord system for compound engines lies in the fact that it permits the use of low pressure cylinders having a rational volume three times greater than the high pressure cylinders. This ratio of volumes 1 3 has been found in practice to increase the efficiency of the compound engine per unit weight of volume of steam consumed by at least 35 per cent with respect to single expansion of the same quality of steam in a similar type of simple engine that is each pound or cubic volume of steam develops 35 per cent more horse-power averaged for a period of several years consecutive working than the same weight or volume of steam expanded once only in a similar type of locomotive working the same fast express train services. This economy however becomes less and less as the difference between the volumes of the two expansions decreases. With small low pressure cylinders of only twice the volume of the high pressure cylinders it is found that the increase of efficiency averages only about 5 per cent while with a low pressure cylinder volume of 2½ times the high pressure volume the increase of efficiency is about 18 to 20 per cent. This experience has been common to practically all countries where two stage expansion is used in locomotives and it shows the great value of large ratios of cylinder volumes if the construction gage permits of them.

LARGER CYLINDERS POSSIBLE

Hitherto in both England and France the realization of the great economy possible by two stage expansion has been restricted by the limits of the loading gage but the new stepped cylinder arrangement of the Nord Railway entirely removes this disability especially if it is combined with certain differences in the frame plates as employed for several years in France and Belgium—that is perforations in the frames allowing the inside cylinder to project through to the outside by a few inches and so considerably increasing their volume.

The new Baltic type engines of the Nord have straight unperforated frames and additional volume has been gained by lengthening the cylinders according to the practice of Bavarian builders. There are certain objections to this practice of lengthening the stroke and an alternative arrangement common in Italy consists in mounting the inside cylinders clear above the frames so that they may project over the edges of the frames without interfering with the outside cylinders placed on the same transverse level

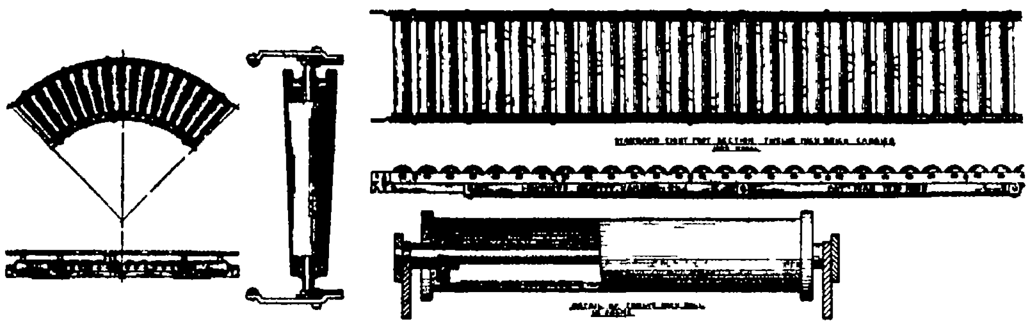

FIG. 2.—DETAILS OF CONSTRUCTION OF BRICK CARRIER SHOWING BALL BEARINGS AND THE CONICAL ROLLERS AT A CURVE

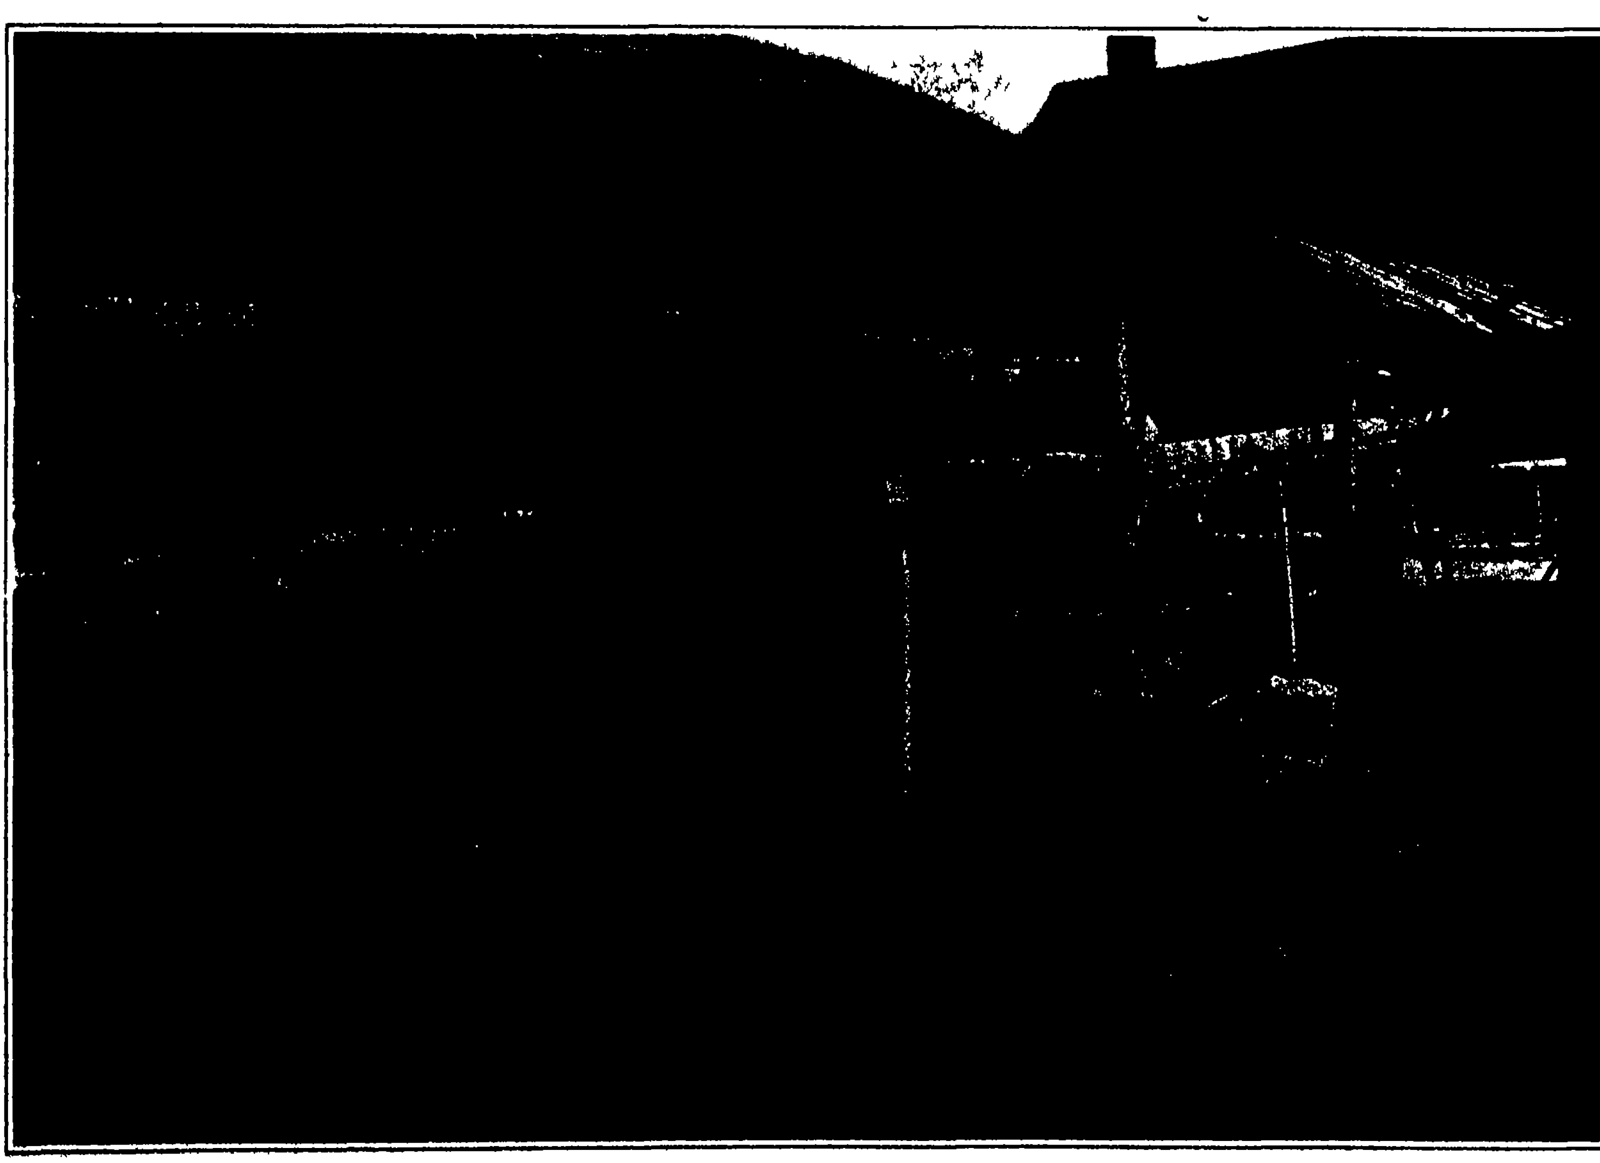

FIG. 3.—FROM KILN TO CAR BY GRAVITY

GRAVITY SERVICE FOR HANDLING BRICKS

With the Nord stepped cylinders and the Italian plate frames it becomes quite practicable to build two-cylinder compound locomotives having one 23 inch and one 40 inch cylinder both set very closely and compactly together inside the frames and able to develop the same power at full speeds as much more complicated four cylinder non compound locomotives with four 16-inch cylinders With an equal weight of steam from the boiler in each case the one 23 inch cylinder working single expansion develops the same power as two 16 inch cylinders In compound expansion the one 23 inch cylinder develops less power on a given steam admission for the reason that, with cylinders of 1 3 ratio its power capacity is reduced by the back pressure about 15 per cent but this exhaust steam producing the back pressure develops on the low pressure piston a power which is equivalent to the total effective power developed in the high pressure cylinder That is, if 500 horse-power is developed by boiler steam in the high-pressure cylinder, about 500 horse-power is developed by the high-pressure exhaust steam in the large cylinders and the larger the low pressure cylinders are made the less is the loss by the back pressure in the small cylinders and the greater is the total load on the large pistons With a loss of 15 per cent in the area of the high-pressure cylinder indicator diagram the net economy by the two-stage operation is 50 per cent—15 per cent = 35 per cent.

These figures are confirmed by years of practical experience on railways using large cylinder ratios where there is no restriction to the size of the low pressure cylinders. In general with such ratios one-third less steam is required for a given horse-power or one-third more power is produced on a given fuel or steam consumption But this result is dependent on high cylinder ratios, such as are now rendered feasible for the most restricted main-line loading gages of Europe. The importance of the saving that could thus be effected is apparent from the fact that with say, 100 compound locomotives the coal consumed would be worth £65 000 annually, whereas with the same number of simple-expansion engines, working with the same pressure and temperature of steam in the same train services it would be worth £100 000 Further with the Nord system it becomes practicable to develop the two-cylinder type with its advantages of simplicity as compared with the far more complicated and expensive four-cylinder non-compound engine In all details except in the boiler the locomotive designers of all countries are seeking for simplicity and the Nord arrangement especially appeals to those who would avoid four-cylinder engines of any type

Salving the German Submarine Boat "U 3"

An Authoritative Account

On January 17th 1911 the German submarine boat U 3 was sunk in the harbor of Kiel (Fig 1) by the imperfect closure of the after ventilation pipe The depth of water was about 40 feet and the stern of the vessel penetrated several yards in the soft clay bottom As the boat sank her irregular movements were observed by the submarine U 1 which hastened to the spot launched a folding boat to pick up the telephone buoy of the U 3 and then notified a warship which transmitted the news to the Kiel dock yard so promptly that two steamers and a crane were dispatched 28 minutes after the vessel sank Meanwhile the imprisoned men had informed the folding boat by telephone that the after part of the U 3 was full of water Communication then ceased

The disaster was observed also by the lookout stationed on the Kaiser Wilhelm Canal and by the canal pilot steamer which soon arrived on the scene and endeavored with the aid of a tug to tow to shore the foundered submarine the bow of which had risen to the surface The attempt failed as the stern of the submarine was held down by some 100 tons of water The crane arrived about an hour after the disaster and with the aid of divers attached to the canal service preparations to raise the sunken boat were commenced

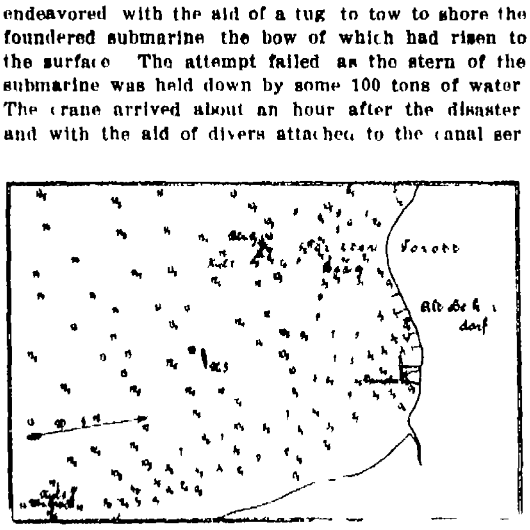

Fig 1 Part of the Harbor of Kiel Showing Position of the Foundered Submarine Boat U 3

(The arrow and its inscription show the direction of the wind and its velocity in meters per second The other figures indicate depths of water in meters.)

It appears probable that the extent of the leakage was not at first, fully appreciated by the crew of the U 3 as the partly opened valve was invisible and inaccessible and the mouth of the ventilation pipe through which the water entered the hull was covered and concealed by the motor Hence the inrush of water could only be heard and the water was not seen until it had reached the floor of the engine room It was then too late to take effective measures The boat sank stern foremost and its position aggravated the evil by increasing the hydrostatic pressure at the leak and in other ways

The tanks which had been so nearly filled in preparation for diving that only one ton of buoyancy remained before the accident were emptied by pumping and by compressed air Meanwhile the compartment bulkheads were closed the emergency weights dropped and the telephone and lifting buoys set afloat An attempt was then made to pump out the engine room bilge but the pump would not "draw" owing to the position of the vessel The water soon short circuited some of the accumulators producing results far more serious than the stoppage of the useless pump The sudden discharge so heated the forward cells which were not yet submerged that several plates became red hot and some of the hard rubber parts took fire. The heated cells evolved suffocating sulphurous and acid fumes which caused the commander to order a retreat to the forward or torpedo compartment The commander with two other officers remained in the middle compartment and turret and continued the work of emptying the forward tank by means of compressed air until the bow of the boat rose 20 inches above the surface of the water The 28 men imprisoned in the torpedo compartment owe their lives to this wise and heroic action of Lieut Commander Fischer and to the stanchness of the collision bulkhead which separated them from the turret compartment

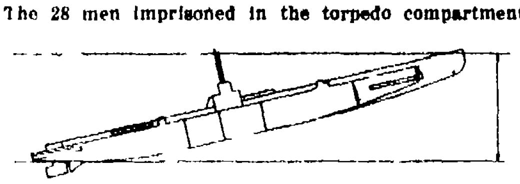

Fig 2

At 11 30 A M 65 minutes after the accident occurred an inspector of the torpedo service arrived on the scene and found the sunken vessel in the position described above with the prow and the periscope emerging slightly from the water and the stern embedded in the clay bottom (Fig 2) Assuming that the crew had taken refuge in the forward compartment he attempted their rescue by the method illustrated in Fig 3 The floating crane (represented by the large rectangle) was anchored close to the weather side of the "U 3 and made fast by a chain passed around the submarine with the aid of divers (The small rectangle represents the divers boat moored on the lee side of the U 3) Meanwhile other divers were working to attach the main tackle of the crane to the forward lifting hook of the U 3 The latter task was not accomplished until nearly 3 P M Soon after that hour the bow of the submarine was slowly raised by hauling on the main tackle and occasionally tightening the chain stirrup until the forehatch was just awash (Fig 4) The operation was then stopped in order to communicate with the imprisoned men by tapping according to the Morse code, on the exposed part of the hull. The first attempts were frustrated by irregular knocking from the inside It was afterwards learned that the imprisoned men were fastening the bulkhead doors, which opened inward (forward) and consequently did not entirely exclude the poisonous gases which were forced upward from the central compartment by the pressure of the water After this work had been finished communication in Morse signals was established, and the imprisoned men reported All is well ' When they learned that the bow was out of water they announced their intention of opening the torpedo launching tubes Boats provided with sounding lines were then stationed beneath the mouths of the torpedo tubes and the bow of the U 3 was lowered until these mouths nearly touched the water Meanwhile the imprisoned men working by the light of a single pocket lantern had succeeded in opening the starboard torpedo tube At 4 30 P M the first man was drawn out by means of the sounding line The work of rescue proceeded smoothly until an increased influx of poisonous gases caused the man who was being drawn out to let go the line and fall back unconscious A call was then made for volunteers to go down and attach the imprisoned men to the line In this way several men were rescued by a boatswain s mate who was finally drawn out unconscious Two officers, carrying an electric lamp connected with a cable and a compressed air tube from the D 5 which was moored beside the crane (Fig 3) then went down and rescued the remaining men most of whom were unconscious The work of rescue was completed at 5 20 P M The starboard torpedo tube was necessarily left open

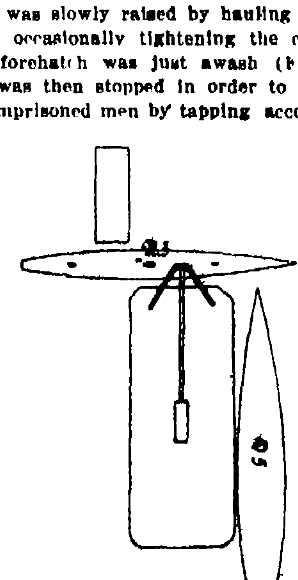

Fig 3

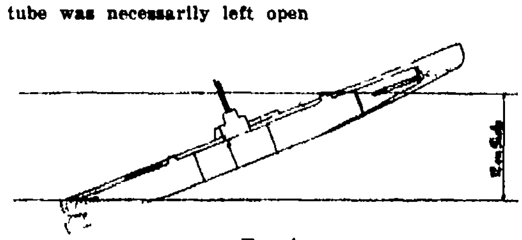

Fig 4

Nearly one-third of the men rescued from the forward compartment were unconscious They were taken to the lower deck of the crane float and revived by oxygen inhalations and other treatment In less than two hours they were in condition to be removed to a hospital where most of them fully recovered in a few days

During the work of rescue preparations were made to raise the stern of the U 3 in order to rescue the captain and the other two officers who were imprisoned in the turret For this purpose a stout cable was attached by divers to the after lifting hook of the sunken boat At the same time efforts were made to put into service the emergency ventilating apparatus but the attempt failed because as was learned aferward the valves in the middle compartment were closed

Meanwhile imperfect communication with the imprisoned officers had been established by means of a board on which questions were written and which was held in front of the periscope The prisoners answered 'Yes' and "No' by turning the periscope to left and right This conversation continued from 3 to 5 P. M.

The hawser which had been fastened to the after part of the "U 3" was attached to a second and more powerful crane (Fig. 5) At 5 30 P M., ten minutes after the last man had left the torpedo tube, this second crane began hauling with great caution, pausing at intervals to give the stern of the "U 3" time to work out of the soft clay in which it was imbedded, while the forward crane exerted a steady pull of about 100 tons. When the stern of the "U 3" had thus been raised about 4 feet, the hawser parted and the boat sank back. The divers then substituted two new hawsers for the broken one, and the work of raising the vessel was resumed at 6 30 P. M., but the operation was soon stopped and the fate of the imprisoned

officers sealed by the breaking of a post of the after crane.

These two failures proved that the "U 3" could not be raised in this way. Nothing remained but to raise the sunken boat by means of the salvage ship Vulcan, a sure but tedious method, which practically excluded all hope of saving the lives of the three heroic officers.

The "Vulcan" was used, in connection with the submarines "U 3" and "U 1," as a school of submarine navigation, the pupils and the crews of the submarines being quartered on the mother ship.

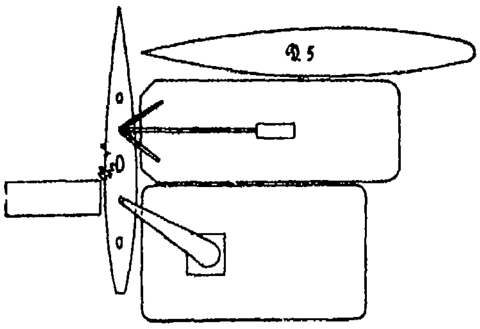

Fig. 5

There was good reason for her previous inaction and her absence at the moment of the disaster which need not be explained here.

On the morning when the accident occurred the Vulcan was in dock at Kiel, and for this reason the submarines were practising in Kiel harbor, one always remaining afloat when the other dived. The Vulcan arrived on the scene at 1.30 P. M., but remained idle because it would have taken her at least six hours to raise the U 3, which even in its lowest position (Fig. 6) was too high to allow the Vulcan to employ her usual and most expeditious method of anchoring at bow and stern to windward of the sunken vessel and drifting over it.

After the crane broke the best method of employing the Vulcan was discussed and every detail was decided while the divers detached the hawsers and the sling from the U 3. The disabled crane was removed and the other crane was drawn back about 40 yards. The scene was brightly illuminated by the searchlights of two vessels. The U 3 now lay in the position shown in Fig. 6, entirely under water, though the top of the periscope could be seen just beneath the surface. The positions of the periscope and the bow were marked by small boats.

The difficult work of the divers was not completed until 8.55 P. M. Then the Vulcan was brought alongside the remaining crane and attached by bow and stern lines (Fig. 7). With the aid of these lines the Vulcan was swung around through a right angle so that she lay parallel to the U 3, and was held in this position by the starboard stern anchor which had been dropped midway (Fig. 7).

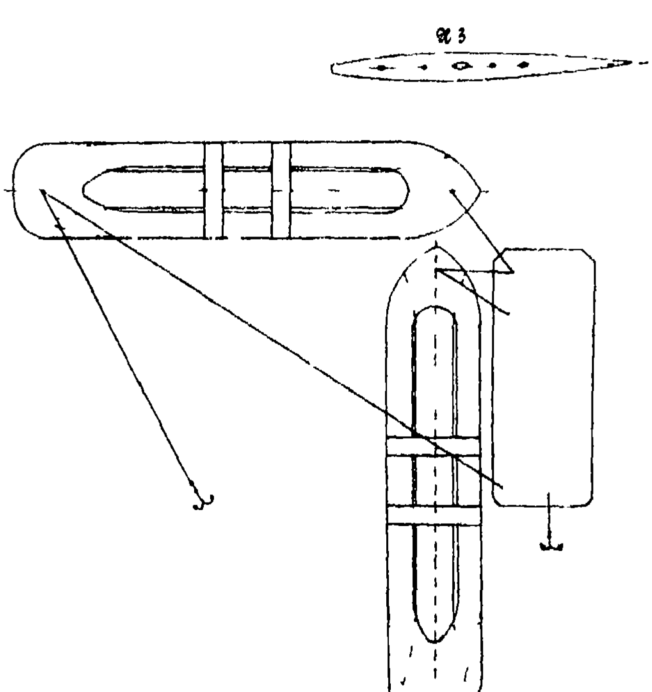

Fig. 7

The moorings of the "Vulcan" and the crane were then cautiously relaxed and the two vessels, retaining their relative positions, were allowed to drift toward the "U 3," until the bow of the double-hulled "Vulcan" was directly over the stern of the sunken vessel and immediately behind the periscope (Fig. 8). Now came the delicate task of moving the "Vulcan" forward with one of its twin hulls on each side of the "U 3," without breaking the periscope and thus flooding the turret and central compartment. This maneuver, the difficulty of which was increased by a strong side wind, was successfully accomplished with the aid of the port stern anchor and several small steamers which served as bow anchors and tugs.

The Vulcan was thus brought into the position shown in Fig. 9, with her hoisting tackle directly over the lifting hooks of the U 3. The tackle was attached by divers (a task which occupied two hours) and the work of hoisting began at 4 A. M. The turret appeared above water at 4.35, and was opened ten minutes later. The abnormal pressure in the confined space caused an outrush of foul air which smelled strongly of chlorine. The turret was ventilated with compressed air, a lamp attached to an electric cable was lowered, and two officers entered. They found their three ill-fated comrades dead at their posts in peaceful attitudes which appeared to exclude all possibility of a death struggle. Although they had evidently been dead for hours, two hours were employed in fruitless attempts at resuscitation.

After the bodies had been removed the turret was closed and the U 3 was securely fastened to the Vulcan, brought into the inner harbor and docked.—Condensed from *Marine Rundschau*.

Improvements in Street-car Wheels

Before the Alabama Light and Traction Association Mr. S. M. Coffin recently read a paper on *improvements in street-car wheels*, in which he reviewed the developments in weight, size and shape of car wheels and detailed the experience with steel wheels of the Mobile Light and Traction Company. The company have two makes of wheels which vary in weight from 500 pounds to 645 pounds per wheel, with a rim thickness of 2½ inches to 3 inches and web thickness ¾ inch to 1¾ inches, with 2¼-inch tread or 3 11/16-

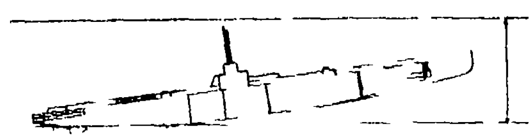

Fig. 6

inch width of rim, and also varying considerably in hardness. Two pairs tried under a single-truck car have shown more difference in wear than any others. For instance, one pair ran but 21.8 6 miles with a wear of 0.0183 inch per 1,000 miles and had to be turned. This took off 0.0272 inch per 1,000 miles or about 50 per cent more than the wear. They then ran 19,400 miles with 0.0211 inch per 1,000 miles. They were then taken out and the one which had developed a thick flange was ground 0.13 inch, making it 0.05 inch smaller than its mate, which was not touched. After this the wheels made 21,180 miles when they had to be reground. The flanges were now very thin, but they were allowed to run again as an experiment in flange wear. An additional wear of 8,000 miles was obtained before another turning. During all this time the other pair of wheels had never been out and their flanges were wearing uniformly, although they were getting thin by this time. They were turned after running 93,482 miles with a wear of 0.0105 inch per 1,000 miles. The stock removed in turning was 1.3 inch (0.0141 inch per 1,000 miles) or a total for wear and tool of 0.0173 inch per 1,000 miles. A large number of wheels have run 60,000 to 90,000 miles without removal with the wear as low as 0.006 inch per 1,000 miles and with an average for ten pairs selected at random of 0.0109 inch service wear and total wear and tool of 0.0122 inch per 1,000 miles. However, by deducting the first two pairs of wheels mentioned an average of 57,888 miles

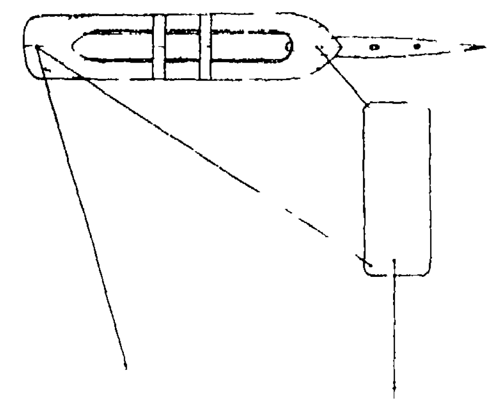

Fig. 8

is obtained with an average wear of 0.00992 inch and wear and tool of 0.0098 inch per 1,000 miles. This result, however, was attained by grinding instead of turning.

The Repin Refrigerating Process

In the ordinary type of chemical or affinity refrigerating apparatus the reduction of temperature is produced by the rapid evaporation of liquefied ammonia. The gaseous ammonia is recovered by means of its affinity for water, which absorbs it in great quantities. By heating the solution thus obtained the ammonia is expelled into a cooled receiver, where it is liquefied by its own pressure. This apparatus possesses a serious defect which has gradually driven it out of use. The ammonia expelled from the solution carries with it about 25 per cent of water.

According to *La Nature* Dr. Repin has devised a *chemical refrigerating process which is free from this objection*. The refrigerant is sulphur dioxide, which is easily liquefied and absorbs much heat in its evaporation. The absorbent is camphor, which takes up 30 per cent of sulphur dioxide, forming a very stable solution of low vapor tension, which when heated evolves all of its sulphur dioxide in gaseous form. The heated mixture, however, foams excessively and the camphor is left in the melted form in which it is unsuitable for further use as an absorbent.

Dr. Repin has remedied these defects by mixing with the camphor 20 per cent of naphthol. The only liquid thus obtained retains all the power of the camphor to absorb sulphur dioxide, which it disengages completely at a temperature below 212 deg. F. The pressure of the gas during the distillation does not exceed 5 or 6 atmospheres and a temperature of 17½ deg. F. can be obtained. This method appears especially well adapted to economical refrigeration on a small scale, in laboratories and elsewhere.

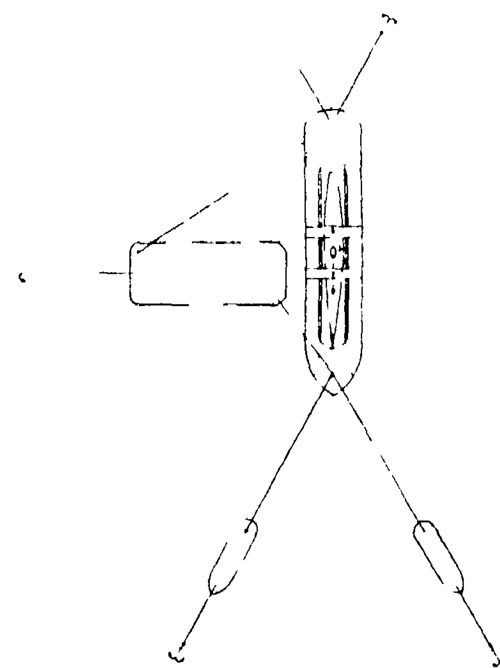

Fig. 9

The Light of Living Animals

The Structure of Photogenic Organs

By F Alexander McDermott, Washington, D. C

THE power of producing light in living tissues—the photogenic function—is a property widely distributed in the animal and vegetable kingdoms especially in marine organisms In general the light produced by the various living photogenic forms is very similar in character being in most cases confined to those radiations which have the highest illuminating effects, with the lowest actinic and thermal effects The maximum brightness of the light given out by such organisms is usually at or about wave length 0 57 μ[1] in the yellow green where the light has an illuminating efficiency of practically 100 per cent Moreover the production of light in all cases where definite studies have been made appears to be the result of the oxidation in the presence of water of some product of the life processes of the creature But in spite of these general similarities there are wide differences between different forms in the apparatus by means of which this production of light is effected Many of the lower forms possess no definite organs for the function—the emission of light like their sensitiveness to it being a property of the cell as a whole Among the higher forms also we find some in which the light is produced within special cellular masses having no very definite structure Both of these cases may be classed as simple intracellular photogenicity Still higher in the scale we find those forms in which the light is produced within definite organs of more or less complicated structure—usually glandular—and in these the production may be either intracellular and intraglandular or extracellular and intraglandular In still other forms the glands and secretions may both be luminous (intra and extraglandular) and in still others the secretion of a non luminous gland may be luminous when the photogenicity becomes entirely extraglandular An attempt will be made here to describe some of these peculiar variations of the photogenic function and to give what is known of the structures used in its production

Probably the simplest forms possessing the photogenic power are the luminous bacteria of which there are a large number of species known On account of their extremely small size no definite organs for the production of light have been observed but the luminosity appears to result from the oxidation of some product of the metabolism of the cell and usually necessitates the presence of some mineral salt—notably sodium chloride for its manifestation Higher vegetable forms—fungi mycelia algæ etc—do exist however which do not appear to require the presence of mineral salts for the development of light at least not in the same amount as the bacteria require sodium chloride or some similar compound and which yet give a light not unlike that of the less highly organized forms In these however no special photogenic organs have been shown to exist and it seems not improbable that in the bacteria fungi and other luminous vegetable forms the photogenicity is a property of the individual cells inherent in them and consisting of the oxidation of some portion of the cell constituents

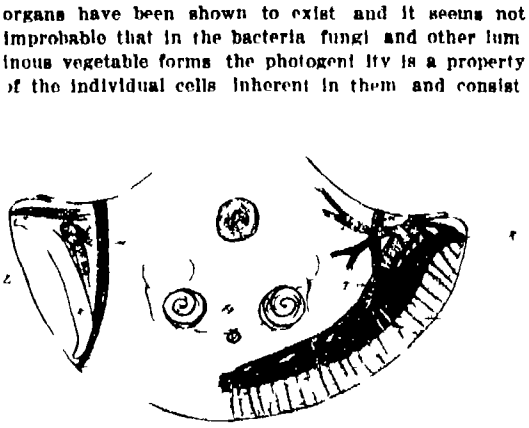

Fig 1 Transverse Section of *Photinus Pyralis* (Diagrammatic)

The right hand half shows the arrangement and distribution of the tracheæ while the left hand half shows the modification of the luminous tissue at the point of attachment of the breathing muscles
C testes I intestine L true photogenic tissue R reflecting layer S spiracle or stigmatum Sp spiral organs (function uncertain) T main tracheæ to photogenic organ Tb main respiratory tracheæ M muscle fibers

Among those classes which constitute the lowest forms of organized matter it becomes somewhat difficult to distinguish between those which should be classed as vegetables and those which belong to the animal kingdom Many of the bacteria known to produce light are marine in origin, and with them may be grouped the numerous simple marine animal forms which also possess this power *Noctiluca miliaris* the *Pyrocystæ* and many other animal forms of low organization possess no definite organs for the photogenic function Under the microscope however, the light in these forms is seen to proceed from a multitude of tiny points and it may sometime be shown that these points of light are true luminous organs having some more or less complex structure

The higher we go in the scale of animal life the more specialized and complex become the organs for the production of light. For instance Pyrosoma, a Tunicate ascidian shows the restriction of the phenomenon to certain portions of its constituent animalcules and while but little of the structure has as yet been made out these portions are doubtless definite photogenic organs Panceri has estimated that in a Pyrosoma eight centimeters long there are 6 400 of these liminous organs two to each of the constituent animacules In the molluscs insects crustaceans myriapods cephalopods and fishes the photogenic organs show definite and characteristic structures In all of these groups there are one or more species known which have complex organs for the production of light In the different types and species however the structures of the photogenic organs vary considerably Those of the sea living organisms for instance as might be expected differ widely from those of the air breathing forms

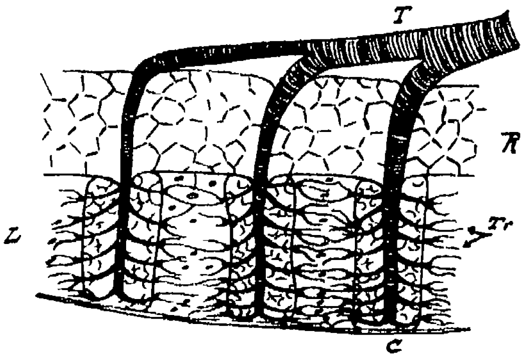

Fig 2a —Vertical Section of Photogenic Organ Showing Trachea T With Three Branches Passing Through the Reflecting Layer R and the Photogenic Layer L Surrounded by the Cylinders C and Branching into Tracheoles Tr

The luminous forms most familiar to the majority of us are the Lampyridæ—the fireflies lightning bugs glow worms etc —and upon these the bulk of the work on the structure of photogenic organs has been done It is common knowledge that if a firefly is crushed and the luminous tissue exposed to the air it glows this suggests that the phenomenon is dependent on the presence of air or some of the constituents thereof This view is borne out by the structure of the photogenic organs of these insects Perhaps a dozen different species of the Lampyridæ have been submitted to examination as to the structure of these organs and in general the structures have been found to be the same slight differences mainly in the finer structures have been described and illustrated but for all practical purposes the photogenic organs of the different species of this family of insects may be regarded as substantially the same Fig 1 represents a diagrammatic cross-section through a Lampyrid at about the middle of the fifth abdominal segment the particular species from which this is taken is *Photinus pyralis* one of the commonest and most widely distributed varieties in the United States

In this drawing *C* is one of the testes *I* is the intestine *L* is the photogenic tissue proper *R* is the reflecting layer *S* is the spiracles or stigmatum *Sp* are spiral organs connected with the reproductive systems *T* are the main tracheæ and their branches leading to the photogenic-organ *Tb* are the tracheæ leading to the other organs—the general respiratory system of the insect—and *M* the breathing muscles The luminous organ consists of two layers, *R* and *L* *R* is primarily a reflector and consists mainly of a layer of guanine or ammonium urate or both, contained in polygonal cells *L* consists of cells of irregular size and shape and constitutes the true photogenic layer, in which the biologic oxidation and its consequent light production take place The main tracheæ begin at the spiracles, just below which they divide from the breathing tracheæ, and continue downward and inward towards the middle of the ventral side of the abdominal cavity, continually throwing off branches which again subdivide, and so the subdivision goes on to the fine tracheæ which plunge through the photogenic organ The larger tracheæ all show the spiral winding structure, and at least as far as the inner surface of the reflecting layer their interior is provided with fine chitinous, hair-like projections pointing inward Both the layers *R* and *L* are penetrated almost perpendicularly by the tracheæ which supply the air to the finer tracheoles connecting them, these tracheæ are usually simple and nearly straight in their course through the reflecting and photogenic tissues though forked and curved tracheæ in these layers are occasionally met with Throughout their length through the photogenic layer the tracheæ send out very fine branches, the tracheoles which anastomose with the tracheoles from adjacent tracheæ, forming a network of fine passages around the cells of the photogenic tissue These tracheoles are so small as to appear merely as lines even under a powerful microscope Each tracheæ as it passes through the luminous layer is surrounded by a cylindrical mass of cells of a character quite distinct from those of the true light-giving tissue and under the microscope these cylinders show as non luminous spots on the background of light in the living insect Fig 2 represents this finer structure *a* in vertical and *b* in horizontal cross-section

In the four American species of Lampyridæ which have been studied—*Photinus marginellus P pyralis P consanguineus* and *Photuris pennsylvanica* these structures have been found to be identical and it is probable that they are very similar as regards their general character in all species of this family There are some slight differences in minor points even among the local species however for instance in *Photuris* the thickness of the true photogenic tissue was found to be very much less than in *Photinus* both actually and in proportion to the thickness of the reflecting layer and the tracheæ seem to be a little more sparsely distributed through the luminous layer This may have some relation to the fact which has often been observed that the light of *Photuris* is more greenish than that of *Photinus*

While the Lampyridæ constitute the largest class of light-emitting insects one other family of Coleoptera includes several brightly luminous species—the group *Pyrophorini* of the family Elateridæ the best known of which are the Cuban cucuyo *Pyrophorus noctilucus* and the smaller elaterid firefly of our Southern States *P Physoderus* The former has been the most studied and a few words regarding it will not be amiss The cucuyo is a large hard shelled snapping beetle or elater and emits light from three photogenic organs, two on the dorsal side of the thorax and the third on the ventral side at the forward end of the abdomen The emitted light is very similar to that of the Lampyridæ in quality but differs in that it is continuous, varying in intensity but not being entirely extinguished under ordinary circumstances. In structure, the light-emitting organs are very like those of the Lampyridæ. Under the outer chitin (which is thicker and harder than in the Lampyridæ) is a layer of true photogenic tissue, and back of this is a reflecting layer, the whole being

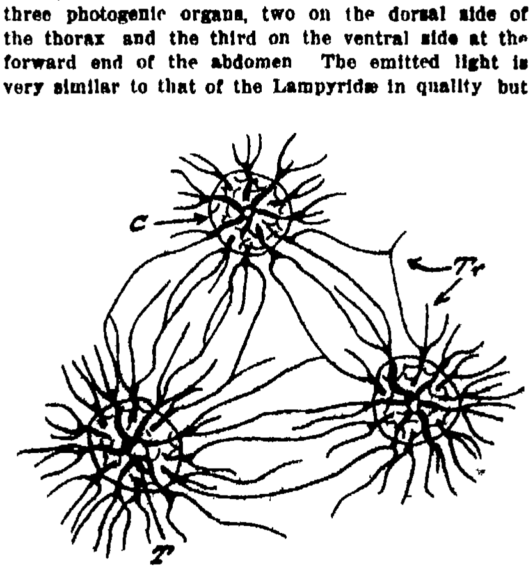

Fig 2b —Cross Section (Horizontal) Through Three of the Vertical Tracheæ Within the True Photogenic Tissue, Showing Cylinders *C* and Tracheoles *Tr*

[1] μ = 0 001 mm = 0.00004 inch

supplied with air through a system of tracheæ connecting the main respiratory system of the insects, in very much the same way as the more common insects.

Still another group of luminous insects should not be passed without mention although regrettably no studies have been made as to the structure of their photogenic organs. This group is the *Phengodini* of which a few species are known in the United States. All species appear to be rare In this remarkable group the females, in their adult stage retain the form of larvæ, while the adult males are provided with powerful wings though with only short elytra, and have very large eyes. The larviform

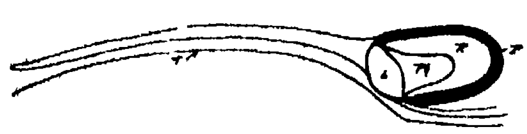

Fig 3a—Section of Photogenic Organ of Histioteuthis Rüppelli a Cephalopod After Hoyle

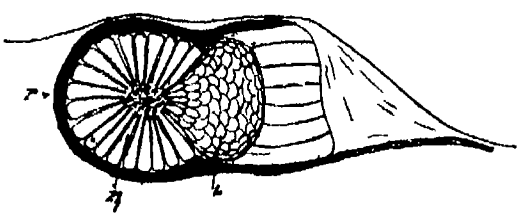

Fig 3b—Section of Photogenic Organ of *Chauliodus* Barbatus a Deep-sea Fish After von Lenderfeld

L, lens M external mirror P pigment layer Ph photogenic body R, internal reflector

females are very luminous there being two or three luminous organs at each segment and sometimes additional organs at the head More remarkable yet the light emitted from the organs of the body is different from that emitted from the organ at the head the former being greenish or bluish and the latter reddish. These insects are very beautiful though but rarely seen The males of some tropical species are said to possess photogenicity but no light has been observed from the males of our species

Of the other insects which have been reported to be luminous, but little can be said No confirmation has been found obtainable of the statement of Latrielle that the brilliant *Buprestis ocellata* of India is luminous the spots to which luminosity is attributed are upon the elytra and if they are realy luminous it is a very anomalous case So far as the Fulgoridæ the lantern flies are concerned it seems to have been pretty definitely shown that they are not photogenic under ordinary circumstances It would be interesting to try Waxasé s test by placing the supposedly luminous beaks of these insects in dilute ammonia when according to this author if they are really photogenic organs light should be evolved The light of the luminous midgets will o the wisps ignes fatui etc appears to be due to the infection of non photogenic insects with bacteria having this power and is therefore not properly classed with that of the true photogenic insects

Next to the luminous insects the most brilliant luminous forms seem to be the cephalopods—the cuttle fishes Prof C Chun and Prof W E Hoyle have made interesting studies of these organs but the

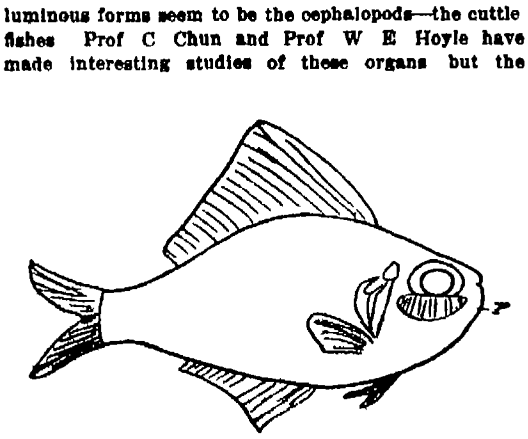

Fig 4a—*Photoblepharon Palpebratus* After Steche Showing Location of Large Photogenic Organ *P*

actual number of times at which they have been observed to emit light is surprisingly small With the Cephalopoda we may consider certain of the luminous fish, many of them caught at great depths in the sea, since some of their photogenic organs are not unlike those of the cuttlefishes. The organs which we will first describe are those classed by Prof. Hoyle as "non-glandular" In both the fish and the cephalopods these organs present a typical 'searchlight" structure. The organs are inclosed within protuberances on the creature s surface and each consists of a layer of dark pigment cells *P* a reflector *R*, a photogenic mass *Ph* and a lens *L* Fig 3a, adapted from Hoyle, shows this structure as seen in a cephalopod and *b* shows the same type of organ from a deep-sea fish, adapted from Von Lendenfeld In the cephalopods these organs have been said to emit very brilliant lights of various tones of red yellow and blue as well as white and greenish In the fish the emitted light appears to be of a pale greenish color not unlike that of some fireflies The photogenic tissue proper in the luminous organs of this class is richly supplied with nerves and blood vessels, and it is probable that in them, as in the Lampyridæ the photogenic process is one of oxidation the oxygen however being supplied to the tissue through the blood of the animal instead of being directly applied in the gaseous state from the air

An interesting point to be noted here is the location of these photogenic organs in marine forms. Hoyle mentions that in the Cephalopods the great majority of the organs on the body are directed downward In this group of animals, however many species are provided with photogenic organs situated immediately upon the eyeball a situation which leaves but little doubt of its usefulness to the bearer It has also been noticed that in the luminous fish the photogenic organs frequently are arranged so as to present the appearance of two or more parallel rows of bright points when the creature is viewed from below The fishes also very frequently have luminous appendages barbels etc where the photogenicity undoubtedly has an alluring significance and further while as yet no true fish has been found with photogenic organs situated upon the eyeball as in the Cephalopods a number of fish have been observed to have such organs situated in close proximity to the eye in such a way as to undoubtedly assist the vision of the creature

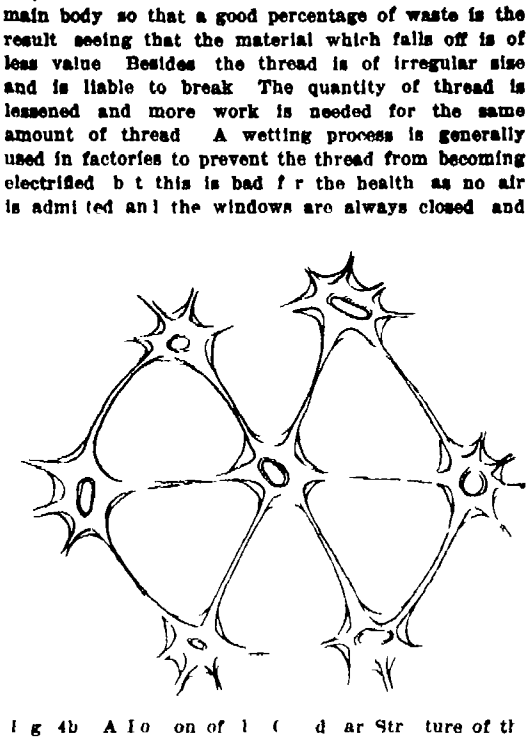
Another different type of photogenic organ is also found in a few Cephalopods and in a number of fish this is the strictly glandular type of organ in which the luminous process is restri ted to the interior of the organs Dr Otto Steche has made some interesting observations upon the structure of these organs in the fishes known as *Anomalops katoptron* and *Photoblepharon palpebratus* The photogenic organs of these species are the largest both actually and in proportion to the size of the fish so far observed The creatures themselves are very small—8 to 10 centimeters long—and the luminous organs occupy an area immediately below the eye-socket Dr Steche states that the lumino s tissue proper is a typical gland Although the process of light production by these organs must be very different from that in the organs of the Lampyridæ some of the structures remind one very much of those in the insect organs Figs 4a and b taken from Steche s paper show the location of the light-organ and a section of a portion of the gland respectively

Another interesting type of luminous organ is present in at least one species of Cephalopod in the mollusc *Pholas dactylus* and in certain myriapods These are organs that secrete a mucus which is discharged into the air or water and there becomes luminous through oxidation Organs of this type are of course true glands and tho gh their structure in different creatures need not be the same their functions are very similar Dubois has made a very extensive study of the glands of *Pholas* the interesting luminous bivalve that has formed the basis of the oldest scientific observations of biophotogenesis on record The structure is not distinctive being typically glandular but a reproduction of one of Panceri s drawings Fig 5 showing the location of the organs is given herewith

It is a little difficult in view of the wide diversity of the structures of the photogenic organs and the variations in the modes of light production to ascribe to the photogenic function of all forms a common origin In the majority of cases the photogenic tissues appear to be a derivative or extension of the adipose tissues of the organism It is certain that in a considerable number of forms of very different habitude and structure Nature has reached the point of the production of the cheapest form of light by very different methods—that is living creatures belonging to widely separated groups and families and even orders and kingdoms may produce light of very similar quality and spectral constitution through the agency of very different structures Surely among these various methods there should be at least one which would offer possibilities for artificial reproduction But for the realization of this we must as yet look to the future.

Textile Manufacturing

In the manufacture of textile and other products such as wool silk, paper or fiber in order to obtain a good quality and avoid too much waste of material, it is required to resort to methods which are very objectionable from the standpoint of hygiene For instance in the preparation of wood threads these become electrified and this causes the fibers to spread out, and a considerable amount is detached from the main body so that a good percentage of waste is the result seeing that the material which falls off is of less value Besides the thread is of irregular size and is liable to break The quantity of thread is lessened and more work is needed for the same amount of thread A wetting process is generally used in factories to prevent the thread from becoming electrified b t this is bad f r the health as no air is admi ted an l the windows are always closed and



I g 4b A I o on of l (d ar Str ture of tl Photogenic Organ of *An mal ps kat η tr n* After Steche

besides the rooms ar much overheated The excess of dampness is also a disadvan age in that it causes the products to stick to the m hines and th s is anotl er source of waste Electrical n ethods have been tried such as distributing an electric charge along the machines by insulated conductors so as to annul the static charge Induction coils or electro static machines were used b t without success for various reasons High tension alternating c irrents are too dangerous to use here New experin ents were made in France by M. Paillet and in an acco nt presented to the Académie des Scien es he states that he secured good results by using c rrents of high frequency and high tension such as e used in electro medical work af er the researches of Professor D Arsonval and others and nore re ently in wireless telegraphy Such c rrents have no la ger and much power can be used without any harm Condensers are supplied with high tension current from a transformer so as to give the oscillatory discharge Wires are stretched along the machines and near the textile matter and have small metal br shes s as to direct the elec ric discharge where it is nee le l Tl e results show th t the threads were s ronger and he breaking strain is from 7 to 1 per cent higher In s me cases this reached 22 pe cent The threads are more elastic about 19 per ent and tl e waste is lessened about 3 per cent On low grade wools where the waste is high this is lessened ev n by 28 per cent Bette hygiene can be observed as air in the rooms

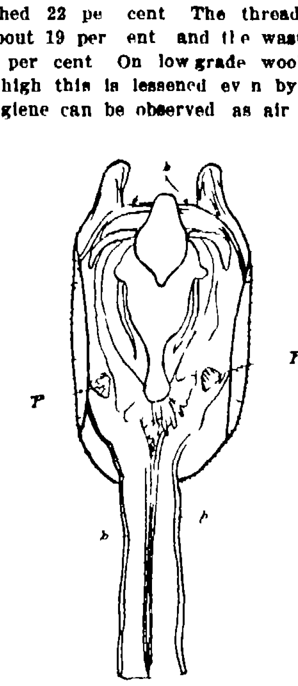


Fig 5—*Pholas Dactylus* (After Panceri) Showing Location of Photogenic Organs *P* and Parts Ordinarily Luminous From the Mucus Secreted by the Organs *p*

need not be as damp and the heat is less In this way the work is carried on under much better conditions in every way

Dynamics of the Flying Machine*

Some of the Dangers of Mechanical Flight.

By James S Stephens, M. W S. E.

It should be understood that while it is the writer's belief that this paper contains a plausible theory to account for some of the dangers of mechanical flight he hopes it will be chiefly instrumental in interesting some of the engineering profession who have heretofore given the matter little serious thought or attention also that it may promote a discussion of some of the phases of the question and thus bring out information that may assist in the advancement of the art.

The writer is aware of the fact that some of the statements and deductions made herein when considered from certain viewpoints are not in accord with the laws of dynamics as commonly accepted but this in his opinion should aid rather than prevent a liberal discussion as some of the peculiar conditions involved may cause the majority of those who consider the matter to at least question the exactness of some of the laws of dynamics as commonly understood when applied to the operation of a flying machine

During the past decade public opinion of the flying machine may be said to have passed through three stages

First viewed as ridiculous then as sublime and now on account of the great number of fatal accidents which have occurred as tragical

All of these accidents have had some specific cause and numerous explanations and theories have been offered to account for them Unfortunately the man who would have best been able to offer a satisfactory solution has in practically every case lost his life

Theories have been advanced by some of the aviators blaming the so-called *Swiss cheese* sky and *holes in the air* for many of these accidents

It is generally admitted that there are many varying currents in the air and that these changes of speed and direction in the motion of the air are undoubtedly greater near the surface of the earth than they are higher up and while some of the difficulties of flying are chargeable to this cause it has the writer believes been blamed for a great deal more than it is accountable for Such variations as do occur in the trend of the wind or air currents are not sufficiently abrupt to make flying extra hazardous from that cause alone

Once a machine is off the ground it would be immaterial whether the wind was blowing steadily in one direction 1 mile or 100 miles an hour if it were not for the fact that it is necessary to give due consideration to the laws of inertia acceleration retardation momentum centrifugal force and gravity in their proper relation to the speed of the machine both relative to the air and relative to the earth

The writer will not undertake to discuss in mathematical detail these various factors governing the conditions of mechanical flight but will confine himself to some simple illustrations which he believes will provide an explanation of the causes of many of the aeroplane accidents which have lately happened

In still air a flying machine in maneuvering in a horizontal plane would have to accommodate itself to practically the same conditions as a vehicle on the ground In starting up increasing or decreasing the speed the inertia of the weight of the machine must be overcome thus introducing the elements of time and power In turning some positive resistance such as banking the machine must be depended upon to counteract the centrifugal or tangential forces

All of the men who have flown these machines have learned to do so in comparatively still air and have been thoroughly familiar with the conditional requirements just referred to as a result of their experience with vehicles running on the ground

Flying in a wind the writer believes introduces the effect of some of Nature's laws in a way that up to the present time has not been fully appreciated and therefore has not had the consideration which is due

To illustrate imagine a machine flying at the rate of 40 miles an hour which is in round numbers 60 feet per second directly against a wind blowing at the same speed While such a machine would maintain itself in the air just as surely and safely as if it were flying on a calm day and covering a distance of 40 miles an hour as measured on the earth's surface it would in fact actually be standing still in so far as its relative position to the earth is concerned and the entire output of its engine would be expended in supporting it against the action of gravity and preventing it from drifting backward in the wind

Now for the sake of the illustration consider what would happen if the 40-mile wind could be suddenly stopped The machine having no initial velocity or momentum could get no support from the air until it could acquire a sufficiently high relative velocity This on account of inertia, and the limited power available requires time and during such time-interval the machine must fall While the abrupt stopping of a 40-mile wind is not possible a somewhat analogous condition may be brought about by an abrupt turning of the machine when it is stationary relative to the earth through flying against a high wind as above mentioned

Under the most favorable conditions it would take considerable time to bring a machine weighing about 1 200 pounds from a standing position up to a speed of 60 feet per second or double this speed as the writer will endeavor to show may be necessary under certain practical conditions

The following is quoted from *Aircraft* the December issue describing the flight of Johnstone and Hoxsey at the Belmont Park international aviation meet both of whom have since lost their lives as martyrs to the cause of progress They faced the wind coming in from the ocean and as they went higher their speed in relation to the ground rapidly diminished as that of the air they were meeting became greater Soon they appeared to be standing still the velocity of the wind being just even to theirs (about 38 miles) and then as they went higher they started to lose ground and the higher they went the faster they went backwards Close together they appeared like two great kites on a string—a string being slowly paid out

How great a wind Johnstone faced at his maximum altitude of 8 500 feet no one can say but with his machine going close on to 40 miles an hour he was blown backward some 40 miles in the course of less than two hours and 75 miles an hour is not an exaggerated estimate of the maximum velocity of the wind met by him

Brookins Johnstone and Hoxsey on Wright machines have made complete circles in the air in about six seconds Let us suppose one of them had undertaken to make such a turn when flying against a head wind a quarter of a turn would be made in less than two seconds with the result that whereas the machine before the turn had the necessary supporting power to maintain it in the air in less than two seconds of time it would have turned around a quarter of a turn in the air and with respect to its relative position to the earth would have practically turned upon its own center and have begun to drift sideways having practically lost all of its sustaining power it had no initial forward motion when commencing to make the turn the time allowed not being sufficient to acquire the necessary acceleration and the power available not being great enough

Should he be able to get his machine around a full half turn which he might be able to do in three seconds the machine even though assisted by all the power of its engine and the effect of the wind in the direction it had turned could not in that limited time have gotten up sufficient headway against its own inertia so as to be moving as fast as the wind itself and the wind would actually be blowing from behind and aiding gravity in forcing the machine downward It seems hardly probable that under such conditions it would be possible for the operator to again right the machine even though it were falling head first especially if he was not aware of the actual cause of the trouble

As a matter of fact a machine under such conditions as above outlined would in so far as the forces of gravity and inertia are concerned have to start from a standstill and acquire a velocity of 80 miles per hour relative to the earth before again obtaining its normal supporting power of 40 miles per hour relative to the air in which it would be flying

A further complication would be the fact that once commencing a turn under the conditions above stated the machine would have a tendency to turn practically on its own center and having thus acquired an initial rotary motion with little forward motion in the same plane it would be much harder to check or reverse the turn Any effort which might be made by the operator would probably be such as would result in just the reverse to that intended, as the conditions of support would for the time be reversed

The support of a flying machine in the air depends upon a nice adjustment of the speed relative to the air its surface and power as opposed to the action of gravity The power may be so applied when flying as to store up within the machine dynamic force which would be the product of its speed relative to the earth and its weight, or simply to overcome the static force caused by gravity, if the machine were flying against a wind blowing at the same speed required for sustention In fact if the machine were flying against a wind blowing relative to the earth at greater speed than the speed of the machine through the air it would then have stored up within itself dynamic force acting in the opposite direction to which the machine would be actually moving through the air

It seems evident that a flying machine may be turned very quickly and may on account of the small frictional hold it has upon the air and due to momentum, or centrifugal force skid a considerable distance in making a turn unless the resistance available by banking the machine is adjusted very nicely to the relative forces brought about by the speed of the machine

It is the writer's belief that such quick turns if made in a wind are extremely dangerous and are responsible for at least some of the fatal accidents which have occurred

Prof Langley the writer believes was the first to compare the flight of an aeroplane to a skater passing rapidly over thin ice which would sustain him safely so long as he maintained sufficient speed to distribute his weight over a sufficient area Let us go a little further with this illustration we know that the skater might turn his body around while passing swiftly over such thin ice and still continue on in safety but should he check his speed and endeavor to reverse the direction of motion he would surely break through So with a flying machine if turned too quickly its momentum would tend to carry it along in the direction in which it had been flying until it reached a critical position without sufficient support from speed in the direction it had been turned

Safety in either case could be assured only by making a long turn that would meet the requirements of time weight and surface and while the skater might turn on his own center skating either face forward or backward without affecting his safety so long as he maintained his speed the flying machine must of necessity at all times present its front directly toward its direction of motion and at the same time maintain its proper angle of incidence and forward speed relative to the air to prevent its falling

This essential condition that the machine must be moving at its full speed relative to the air and in the direction it has turned irrespective of the speed of the wind or the relative speed of the machine to the earth and the fact that such changes in direction when flying in a wind may bring about or require rapid changes in the actual velocity of the machine itself so that at all times it may have a normal speed relative to the wind is the writer believes responsible for conditions which we have not had to consider in other methods of transportation prior to the advent of the flying machine

It is believed that a greater power is required to get a machine off of the ground than that necessary to maintain it in the air in horizontal flight

If making a flight in still air the machine might start in any direction on level ground The power required would be that which would be necessary to overcome the head resistance of the air the frictional resistance of the air the action of gravity and the inertia of the weight of the machine in bringing it up to the speed necessary for sustention in a given time After attaining this speed that portion of the power required for overcoming inertia would remain in the machine as kinetic energy and when flying in still air would remain constant irrespective of the direction in which the machine might be flying

If a machine were started from a stationary position on the ground against a head wind blowing at a speed equal to that necessary for the support of the machine no power would be required to overcome the inertia of the machine in a horizontal plane It would maintain its relative position to the earth and if it were possible for the wind to instantly stop blowing the machine would fall during the time necessary to accelerate the machine up to a speed necessary for support

If a machine were started from a stationary position on the ground moving in the same direction with a wind blowing at a speed equal to that necessary for the support of the machine, it may be assumed that, if sufficient time is allowed, the force of the wind will accelerate the speed of the machine up to the speed of the wind, but from this time until the machine obtains a speed necessary for support greater than the speed of the wind, the same elements of resistance will have to be overcome as in starting from the

* Read before the Western Society of Engineers

turning in still air, including the power and time necessary to overcome the inertia of the machine.

The above statements, the writer believes demon strate the fact that in flying in a wind and making a turn, the necessity for quick changes in the actual velocity of the machine, required to accommodate the speed of the machine to the speed of the wind when the direction of the machine is changed may be such as to cause the machine to fall for want of sufficient surplus power to meet such variable conditions, or on account of not allowing sufficient time for the small amount of power available to meet the requirements of changes in the actual velocity of the machine

In flying in a wind it would seem as if there must always be a variable resistance or momentum to be considered when making a turn that this variable will be proportionate to the speed of the wind and must be provided for when turning by the allowance of ample time for increase or decrease of the actual speed of the machine so that it may at all times maintain its normal speed relative to the air Also that, in making such adjustments of time and speed the weight of the machine the normal speed the amount of surface and the surplus power available will all have to receive due consideration—in the hands of an expert operator who has become thoroughly familiar with these conditions and their relative values—if safety in flight is to be attained

A flying machine cannot without risk of falling be turned in its course through the air without allowing the necessary time relative to the power and weight to overcome its inertia and maintain its speed in the direction it has turned

For the sake of argument consider what would actually happen to a flying machine weighing 1 000 pounds *moving through the air* at the rate of 60 feet per second or 40 miles per hour and making a complete turn in the air in six seconds while the wind was blowing at a speed of 40 miles per hour the turn to commence when the machine was flying against the wind and practically standing still relative to the earth In making such a turn in still air the machine would traverse a true circle about 360 feet in circumference both in the air and relative to the earth commencing and completing the turn with the normal speed *necessary for sustention* 60 feet per second in the air and relative to the earth s surface at all points of the turn

In making a turn in the air with the wind blowing 40 miles per hour the machine would if it were not *for the effect of inertia* traverse a true circle relative to the air just as when turning in still air but relative to the earth it would move in the direction in which the wind was blowing 60 feet per second But on account of inertia, in making such a complete turn the weight of the *machine* 1 000 *pounds* would have to be accelerated from a standing position to a speed of 120 feet per second in the first three seconds of the turn and retarded from this speed to a full stop in the last three seconds of the turn

As a matter of *fact* a flying *machine may be* turned around in about six seconds and with comparative safety in still air but to make such a turn and at the same time increase the speed of 1 000 pounds weight to 120 feet per second and again retard it the same amount in six seconds is beyond the power available for acceleration or the strength of the machine to act in retardation especially if we consider the fact that the power available for acceleration would be very small practically all of the power being actually necessary to support the machine in the air The amount of power available over and above that required for sustention may be approximated by the ability of the machine to rise For instance if a machine weighing 1 000 pounds were capable of rising 100 feet per minute, this would indicate that it had 3 horse-power or 100,000 foot pounds per minute of surplus power above that required to maintain speed of sustention Three seconds is one-twentieth of a minute so that we would have 5,000 foot pounds available for three seconds to increase the velocity of 1 000 pounds weight to 120 feet per second It would take about 140 000 foot pounds to do this in three seconds or about a minute and a half to accelerate 1 000 pounds weight with the energy available 5 000 foot pounds

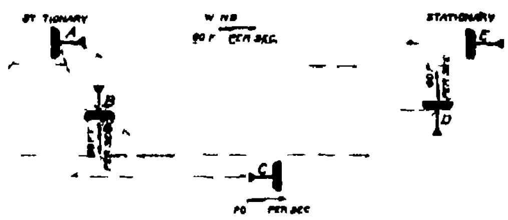
These figures are merely approximations made to illustrate the conditions involved

The wind would assist in acceleration on the first half of the turn and the resistance of the air to forward motion would help decrease the time necessary on the last half of the turn This would materially decrease the time required for the complete turn The arbitrary conditions mentioned herein are used for illustration only The actual time in which a safe turn may be made in the air may be closely estimated if we have the weight of the machine know how much surplus power it has know the speed of the machine relative to the air and the speed of the wind

The product of these factors would be varied somewhat by the area of the surface of the machine the form of the machine and the ability of the operator to control it to the best advantage

A diagram may be made graphically showing any *combination of the conditions* governing *the turning* of a flying machine in the air

To illustrate the conditions above mentioned the following method is suggested



Let *A B C D* and *F* represent five different locations of a machine relative to the earth when flying 40 miles per hour against a wind blowing 40 miles per hour and making a complete turn the dotted line representing the course of the machine relative to the earth in making the turn and *A B C D* and *F* relative *positions of the machine during the turn* The machine would be standing still at *A* It would have turned a quarter of a turn and increased its speed to 60 feet per second at *B* half a turn and a total acceleration of 120 feet per second at *C* three *fourths of a turn and retarded 60 feet per second at* *D* and a full turn to a stationary position relative to the earth at *E* It would therefore appear that such a turn could not be made safely in much less than a minute and a half under conditions previously stated

If the machine were flying in still air it would have completed a true circle both relative to the air and earth and location *E* would coincide with location *A* on one side of the circle This it might do safely in a few seconds of time

Such a diagram might be made to show time weight distance speeds etc and their relation to each other for any specific construction of machine and in this way establish limiting conditions which would be a guide to the aviator in governing the movements of the machine so as to be able at all times to keep it under safe control

It is believed that some of the accidents referred to have been due to a combination of the above named causes and the failure of the aviator to appreciate their varying influence as compared to his speed through the air and his relative speed over the earth due to the speed of the wind It is only when quite near the earth that the relative speed of the machine may be judged of when higher up the aviator s attention is given to necessary adjustments to meet the changing conditions in the air

On approaching the ground he has no way of determining the direction or speed of the wind except by noting some object such as smoke or a flag or by first flying in a circle near the earth and noting the *amount and direction of the side drift of the machine* And it must be admitted that to do this even approximately must require a highly cultivated sense of speed and direction Any speed indicator placed upon a machine can only show the speed through the air Nevertheless such an instrument is of the highest importance as a guide to limit speed in gliding and to maintain necessary speed for sustention It is quite possible that accidents have occurred on account of lack of knowledge of these relative speeds

This paper has been presented with a belief that it will give rise to a discussion of the subject which may lead to further investigation and perhaps develop a greater interest in the possibilities of the flying machine from the standpoint of the engineer

The writer has long been interested in this subject and determined about a year ago to commence the construction of an experimental machine with a view to in some measure safeguard the operator by devising a construction which will he believes have a large margin of natural inherent stability in the air

Before commencing this construction he had become thoroughly convinced that a machine could be built to meet the following requirements which it is believed are fundamentally essential to safety in flight

1st That the machine should be designed so that without manual control it will automatically assume and maintain a straight horizontal line of flight when operated under power and a proper minimum gliding angle forward when the power is shut off

2nd It must at all times automatically maintain its transverse stability when in flight or when gliding *without attention of the operator or the intervention* of intermediatory mechanically operated devices

3rd It must be capable of being positively controlled by the operator by a single simple controlling member to accomplish all of the operations of steering in *any direction or of changing the lateral inclination* of the machine to meet unusual requirements which may be met with in flying or brought about by the operator in steering

4th Such a machine should be built so as to have the same factor of safety relative to the strains involved in actual flying conditions as would be allowed for any other refined construction upon which it is intended to carry the risk of human life

These requirements have been stated simply to indicate the line of thought which has led up to a belief that some combination of the conditions as outlined in this paper have been responsible for a number of the fatal accidents with flying machines

Acrobatic stunts and thrillers involving quick turns have been accomplished with apparent safety by competent aviators in still air To attempt such demonstrations in a strong wind whether it be blowing steadily or not before we know definitely about all the various factors involved in safety in flight seems to be an endeavor to beat some of the well known laws of the resistance of weight to a change of motion and likely to prove suicidal for the experimenter

---

Canada s Asbestos Industry

CANADA produces 82 per cent of the world s supply of asbestos The companies operating asbestos quarries and factories in the Dominion are capitalized at $24 290 000 In 1880 only 380 tons of asbestos were produced valued at $24 700 whereas in 1909 the production amounted to 63 300 tons, valued at $2 300 000 In 1909 3 000 men were employed in the asbestos industry and received wages amounting to $1 350 000 These facts and much valuable technical information of practical value to the general public are contained in a finely printed and well illustrated volume of 316 pages, just issued by the Mines Branch of the Department of Mines Ottawa This valuable addition to the series of monographs being issued under the direction of Dr Haanel was written by Fritz Cirkel M E and treats the subject of asbestos from every viewpoint history geology peculiarities of Canadian occurrences, quarrying and milling together with statistics, cost of extraction, its occurrence in foreign countries, and its practical application in the arts and manufactures To give an idea of the enormous reserves in some of the asbestos deposits, Mr Cirkel mentions the case of one, the Blake Lake quarries Quebec, where there are some 45,000,000 tons of asbestos rock in sight The author goes fully into the discussion of foreign asbestos occurrences and considers Russia the only real rival as regards extent of asbestos resources But inasmuch as the Russians are heavily handicapped by the excessive cost of transportation—$35 to $40 per ton to London—serious competition is not feared in the leading markets of the world Dealing with the practical application of asbestos Mr Cirkel lays special emphasis on the prospective increased use of asbestos in the manufacture of slate He says on page 246

It will not be long before the asbestos slate or shingle business which is just commencing to be felt will push its way more and more to the front Indeed it is not too much to say that the time is not far distant when fully 75 per cent of all asbestos produced in the world will be used in the manufacture of asbestos slate and shingles The asbestos slate business is only four years old but during that short space of time the demand for this article has increased to such an extent that factories for this purpose are being established all over the world

The report covers over three hundred pages containing 66 photo-engravings, 88 drawings and two maps of the Quebec asbestos districts. It is one of the handsomest practical technical reports that has been issued by the Dominion government

---

G O CASES an English engineer has suggested a novel type of reinforced concrete in which wooden beams and laths take the place of iron rods and wires The new *material* which its inventor calls ligno-concrete is intended as a substitute not for ferro concrete in general but chiefly for wood as employed in the construction of roofs footways posts et The wooden parts acts as traction members and the concrete as a compression member

It has been demonstrated by many tests that ligno concrete is as strong as ferro-concrete when the wooden beams of the former have a cross-section which makes them as strong as the steel bars of the latter The tractile strength of steel is eight or nine times that of wood but steel is ten to fifteen times as costly as timber Hence ligno-concrete if it proves durable may advantageously be substituted for ferro-concrete in many cases The question of durability can be decided only by time and experience but the many known instances of the permanence of wood protected by cement indicate that the decision will be favorable

New Researches on Quartz Lamps

Leblanc's Experiments

AS THE result of a series of researches made at Paris by M Maurice Leblanc upon the properties of quartz mercury vapor lamps he has succeeded in constructing a lamp which gives a much greater economy than the usual mercury lamp and at the same time he has greatly improved the color of the light so that it approaches the quality of white light At the same time the power consumption has been greatly reduced amounting to only 0 25 to 0 30 watts per candle power a figure hitherto attained only by flaming arc lamps which however have many disadvantages such as rapid wear of the carbons difficult regulation and necessity of frequently cleaning the globes The new quartz lamp will burn for 1 000 hours and involves no continuous consumption of perishable material In point of running expense it appears therefore to be the most economical lamp existing though the first cost of manufacturing the quartz lamp is of course high M Leblanc gives the following account of his researches

In the mercury vapor lamp the amount of illumination which is produced for a certain given power depends upon the pressure of the mercury vapor in the tube This relation is quite variable however For the ordinary mercury lamps in which the pressure is about 0 04 inch of mercury the ratio is about 0 36 watt per candle-power and this is the best result which can be obtained with an arc in a glass tube It would be a great advantage to increase the pressure of the mercury vapor This can readily be done by working the lamp at a higher temperature—for instance by preventing the cooling of the walls of the lamp But at such temperatures the glass would melt so that in the case of a glass tube lamp a limit is soon reached beyond which the yield in light per unit cannot be raised by working at increased temperature The problem is solved however by using a quartz tube for the lamp This material is much more difficult to shape in the form required than glass and thus causes some extra expense but the resulting economy in running cost is very great This will be noticed from the fact that at pressures of about 1 atmosphere we have but 0 25 watt per candle power as compared with the above quoted figure and thus we use much less power for the same light This high temperature has also the advantage of greatly improving the color of the light which acquires a yellowish hue analogous to what certain flaming arc lamps give and is rendered more agreeable to the eye

It is well known that the quartz mercury vapor lamp gives off powerful ultra violet rays which are stopped entirely by the glass tube in the case of the ordinary vapor lamp Such rays would be dangerous to the eyes but by using a glass globe they can be quite cut off The use of quartz for the new lamp gave rise to a number of difficulties such as for instance the problem of sealing the conducting wire in through the tube So long as glass tubes were used there was no trouble in sealing a platinum wire through the glass for as the expansion of this metal with temperature takes place at very nearly the same rate as that of glass the joint always holds good But with quartz the matter is quite different seeing that the expansion rate of quartz is very low and is about eight times less than that of platinum Should we seal in a platinum wire the joint would soon give way owing to the very unequal expansion An alloy however is known which also has a very small coefficient of expansion—namely the nickel steel made by M C Guillaume of Paris and known as invar It is valuable for many purposes owing to its small expansion when heated or cooled and is used for standard measures clock pendulums etc It therefore comes in very well to match the low expansion of quartz However the invar alloy is a forged metal which loses its characteristic properties when brought to a red heat It cannot, therefore be sealed into the glass but instead is inserted by a ground joint like a glass bottle stopper so that a relatively tight joint is obtained As however there will always be slight leaks in such a joint a mercury filling is put around it and the mercury is held in place by a solid cement covering (Fig 1)

Another difficulty arises from the fact that in the mercury arc the fall of electric potential at the surface of the anode is greater than at the cathode surface and thus the anode is always hotter than the cathode For this reason there is a gradual transportation of all the mercury of the anode towards the cathode At first sight it would seem that the simplest plan to avoid the accumulation of mercury at the colder electrode would be to place this at a higher level than the other When the mercury accumulates, it would overflow and would fall back into the lower electrode But in the quartz lamp this movement of the liquid mercury would have the effect of putting out the arc for the reason that the relatively cold mercury of the electrode when passing into the very hot arc tube would be partly vaporized and there would be a sudden rise in the pressure inside the tube causing the extinction of the arc A compensating method had to be found which would automatically hold the

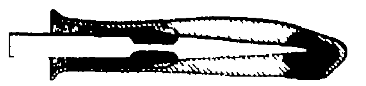


Fig 1—Method of Inserting the Invar Electrode with Mercury Seal

level of the two electrodes constant in spite of their difference of temperature This M Leblanc has succeeded in doing He connects the negative electrode with the vapor tube proper by a conical tube whose top is near the arc tube (Fig 2) Should the mercury accumulate at the negative electrode the level rises in the conical tube The arc now starts from a smaller surface of mercury, which is therefore heated more strongly giving rise to an increased evaporation Thus the mercury tends to be driven off by the evaporation Should the level be lowered

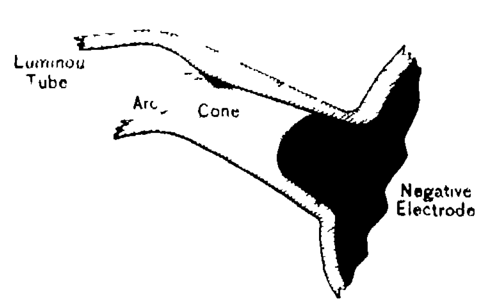

Fig 2—Arrangement for Automatically Controlling the Distillation of Mercury from the Anode

in the conical tube the reverse effect takes place and thus prevents the mercury from accumulating at the positive electrode In practice by designing the conical tube properly we secure an automatic action and this is found to work very well

Another point which requires attention is to assure proper cooling of the tube in order that the pressure of the vapor should not rise too high This cooling is effected by surrounding the electrodes by a set of copper cooling wings (Fig 3) which act as a radiator

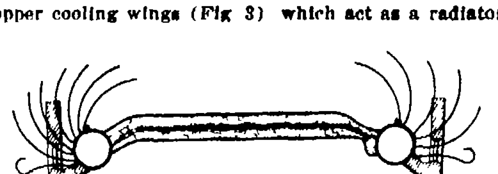

Fig 3—Mercury Lamp with Cooling Vanes or Wings

to dissipate the heat This arrangement has been used for some time past in quartz lamps Another method is to use a chamber in which the mercury condenses so as to fall back into the tube in the liquid form (Fig 4) The conditions of the tube are found to vary somewhat with the temperature of the certain size to the cooling wings or to the condensing cooling of the tube and for a given voltage used on the lamp a greater current is passed through the lamp These variations are especially noticed when

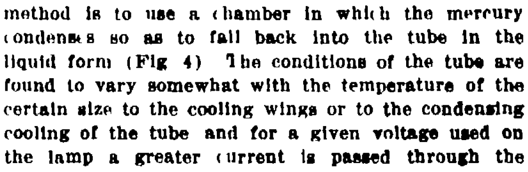

Fig 4—Mercury Lamp with Bulb-Cooler

the metal wing cooling is used In the case of the condensing chamber the temperature of this latter is always high enough so that the quantity of heat which it dissipates is but slightly affected by any outside changes in temperature The current in the lamp is adjusted at the required value by giving a certain size to the cooling wings or to the condensing chamber taking into account also the radiating surface of the tube proper

The above principles are embodied in a new lamp which has been brought out at Paris and is known as the "Westinghouse-Silica The quartz tube is mounted with an electro-magnetic device for tilting it and is surrounded by a large globe, so that it has the general appearance of an arc lamp The economy of current is almost as great as in the flaming arc, which it will be remembered has 75 per cent economy over the ordinary arc. But this is counterbalanced by the great consumption of carbons and the cost of cleaning of the globe. Briefly stated the quartz lamp has the following advantages First, absence of carbons second no cleaning of the globe is required, third better diffusion of light, owing to the fact that the source is of larger volume than an arc, fourth, no trembling of the light from mechanical regulation fifth an agreeable white and soft light, without red rays which is not harmful to the eyes.

Style in Original Scientific Articles

SCIENTIFIC ability and literary skill do not always keep company in the same individual The time spent in the acquisition of experimental skill in the laboratory perforce imposes some sacrifice upon the individual in the development of his literary faculties. Moreover, the work of the devotee of science cultivates in him attention to substance rather than to form He is more concerned with the establishing of facts than with their presentation in "flowing terms. And indeed so long as this attitude merely leads to an unembellished though perfectly clear and sound style it is entirely beneficial

Unfortunately however the matter does not end there if we may judge by complaints voiced now and again criticisms which it may be mentioned apply not only to writers in the English language but to others also The matter is referred to by Prof Sedgwick Minot in his vice-presidential address before the American Association in words which are well worth quoting

We are probably all ready to admit that the care bestowed on the presentation in print and picture of original discoveries is often insufficient. Do we not all know articles which are bungled in form and weakened by prolixity? Surely the heads of laboratories should insist by example and precept that all the workers under their influence should write clearly and briefly—for if an author fails to show respect for his own scientific work how can he expect others to respect it? Yet there are few matters so important as intensifying the world s respect for science For us, whose language is English the standard should be highest Rivarol in his famous prize essay said Ce qui n est pas clair n est pas Francais—but we might say what is not true is not English By its wealth of synonyms and its logical construction the English language is preeminently adapted to the exact statement of scientific truth We should not misuse so fine an instrument, which if well employed is sure to win for Anglo-Saxon science the wide influence it deserves Good thinking is the blastema of good style therefore our learning will never appear good if our learned articles are written badly

An Aerial Ferry

AT Rouen in France on the River Seine there is a bridge that is a sort of aerial ferry In order to avoid interference with shipping at this point it was determined to place no structure in the stream or near its surface Instead of a bridge in any of the ordinary forms a horizontal flooring sustained by steel towers and suspension cables was stretched across the river at an elevation of 167 feet On this flooring run electrically-driven rollers, from which is suspended by means of steel ropes a car that moves at the level of the wharves on the river banks, The car is 36 feet wide and 42 feet long and is furnished like a ferryboat with accommodations for carriages and foot passengers. The ropes that carry the hanging car are interlaced diagonally in such a manner that the support is rigid and a swinging motion is avoided

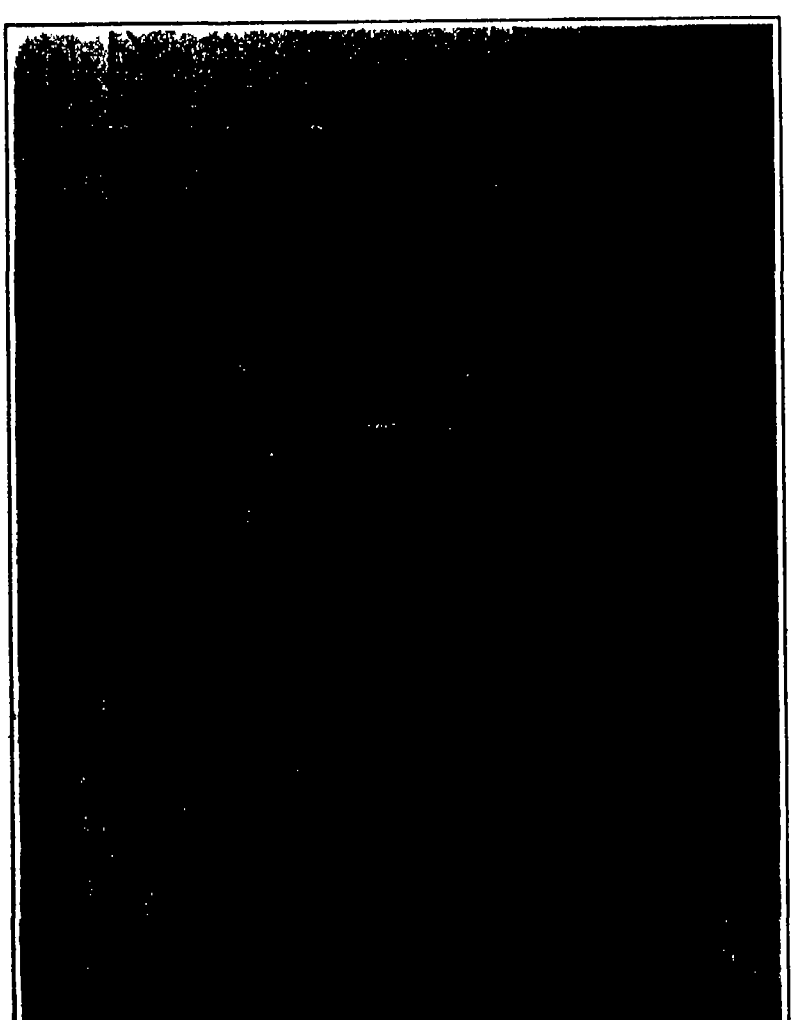
The Aeroplane Military Scout

IT may as well be recognized at once that the aeroplane can never be seriously considered as a means of transportation on any extended scale. The present indications are that a single machine can never hope to carry more than two or three passengers. For the carriage of heavy freight it is altogether out of the question, although it is possible that it may have a field of usefulness in the post office and express service for the transmission of important mail and light packages with the least possible delay.

Undoubtedly the greatest field of usefulness of the aeroplane will be in military operations, although even in this field its work will be of a limited character. Its small carrying capacity will prevent its being used on any extensive scale for the carrying and dropping of high explosives. The amount of explosive which it could take up would be so insignificant as to have no particular value for this purpose. The attack on fortifications, arsenals, dockyards, fortified camps and cities by landing within them high explosive shells can only have any decisive effect upon the outcome of a war if the high explosives can be thrown in enormous quantities. The dropping of a few isolated shells could work only a limited amount of damage, and unless they could be accurately aimed

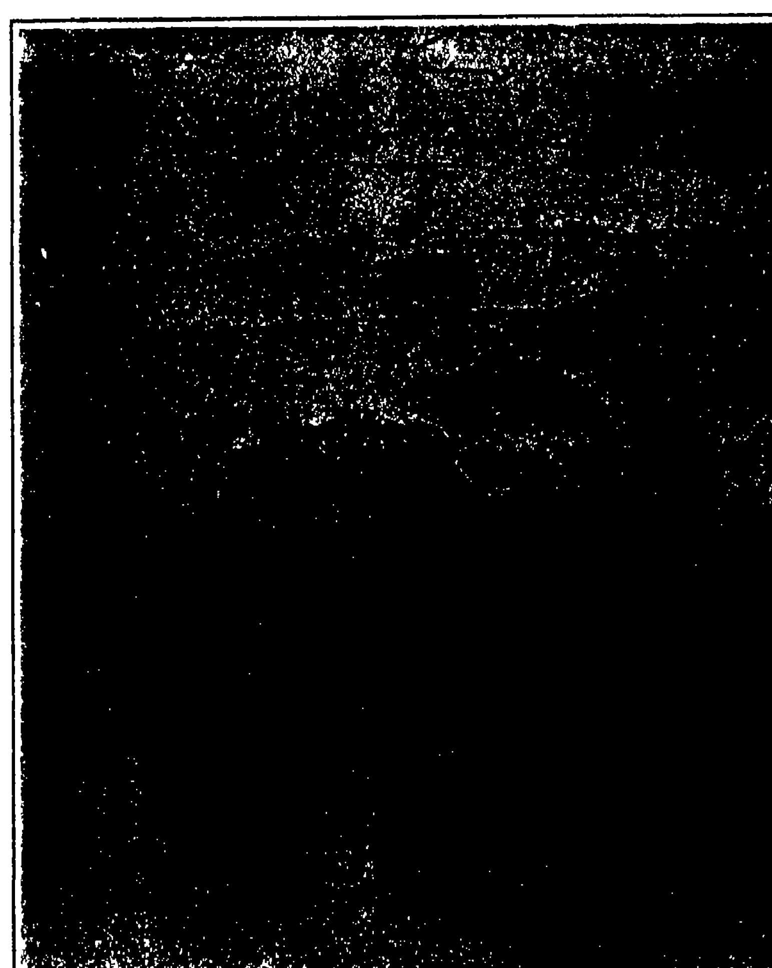
FAC-SIMILE OF A DRAWING MADE BY MR. C. FLEMING WILLIAMS WHILE FLYING ON A BIPLANE. THE SUBJECT IS THE MOTOR RACE TRACK AT BROOKLANDS, ENGLAND.

A VIEW FROM THE PASSENGER'S SEAT, SHOWING THE PILOT AND THE COUNTRY IN FRONT.



HOW SKETCHES WERE MADE IN MID-AIR BY MR. C. FLEMING WILLIAMS TO SHOW THE POSSIBILITIES OF THE MILITARY DRAFTSMAN.

Drawings reproduced from the *Illustrated London News*.



A MILITARY PLAN SKETCHED BY MR. C. FLEMING WILLIAMS FROM A BIPLANE, SHOWING THE POSSIBILITIES OF THE AVIATOR SCOUT.

THE MILITARY SCOUT AND HIS POSSIBILITIES

they would represent so much time and money thrown away Experience in bombardments has proved this fact conclusively It was only after the capture of 203 Meter Hill outside Port Arthur when the fire of the guns could be accurately directed that the heavy mortar batteries were able to do any very effective work Now to aim the one or two high explosive shells which an aeroplane could carry so that they would unerringly hit some particular point below would be a practical impossibility for reasons which it is not necessary here to enter into

From the *Illustrated London News*

A ROUGH PLAN OF BROOKLANDS MADE BY MR. C. FLEMING WILLIAMS

Mr. Fleming Williams writes [illegible] the racing track towards the hangars at a height of 45 a weird thing on which shaped like a cigar with a hud [illegible] land [illegible] as though we were sta[illegible] [illegible] roar a [illegible] of air slightly warm a little discol red with blue smoke and it [illegible] and the head of the track

The military aeroplane of the future will find its greatest field of usefulness in the important work of scouting The military scout will carry two men one to operate the machine and the other to take photographs and make reconnaissance sketches of the country The striking picture shown on the front page of this issue is no mere dream of the enthusiast It would be entirely possible for Wilbur Wright to take up with him an officer rise to a height of 1 000 or 1 500 feet sweep over 25 or 30 miles of an enemy s country and secure a thoroughly accurate sketch of the lay of the land the disposition and strength of the enemy the various roads by which he might attack or be attacked and all the other information which it would be the duty of the reconnoitering officer to secure Because of the height at which the aeroplane would travel and the uncertainty as to its speed and direction of flight it would be an extremely difficult object to hit and it would be possible for several shells of the small caliber which would be used in an attack to pass through the canvas of the aeroplane without impairing its stability

Mechanical Handling of Materials*

By Richard Devens

Manager Eastern Office of the Brown Hoisting Machinery Company New York City

Within the last few years some of our railroad industrial and steamship companies have begun to realize the important part mechanical transference plays in the quick and economical handling of material

The most efficient advances have been made in the handling of bulk material such as ore coal and grain while package freight, comprising boxes barrels bags and other packages which make up the load of a freight car or the cargo of a steamship has just begun to receive serious consideration

It is no doubt a fact that the proficiency in handling bulk material was due to the difficulties to be overcome in the transportation and handling of iron ore to the center of the iron industry

I have reference to the iron ore that was discovered in the Lake Superior country

The first problem was the transportation and this was overcome in 1855 when the federal government completed its first system of locks at the falls of the Sault Saint Marie River at Sault Saint Marie Michigan

The second problem was the loading and unloading of the vessel The loading was readily accomplished by the building of a long line of pockets on a dock extending into the lake and the equipping of each pocket with chutes The pockets were of such height that the ore would flow from them over the chutes and into the vessel by gravity The railroad cars of the bottom dump type were brought over the top of the pockets and dumped into them

It is interesting to note that the method used in the first loading dock is the one on which all docks have been constructed since

The unloading has been the most difficult to accomplish in a quick and economical manner

The first vessels to carry iron ore were not constructed for the purpose, and while they carried some ore in the hold most of it was carried on deck. When it was carried in the hold, it was hoisted to the deck by horse-power and dumped into barrows and then like the deck cargo, wheeled ashore

The next step was the substitution of a small hoisting engine for the horse-power

This early method was in operation many years, and it was not until the dock managers were forced into it by the great expense in carrying large storage on the dock that any mechanical devices were attempted

A cableway machine built and erected at Cleveland Ohio in 1880 under Mr Alex E Brown s design and supervision was the first mechanical plant

The next machines were of the bridge type

The method of handling the iron ore over either the cableway or bridge was to fill iron buckets by hand in the hold of the vessel and then hoist them by the machine and dump them automatically into railway cars or storage In the hold there were from twelve to fifteen shovellers to each machine and there were two men on the machine one an operator and the other a fireman

Both of the above equipments were a great improvement over the early methods and handled the iron ore in a satisfactory manner yet they did not cut down the cost of the hand labor in filling the buckets in the hold This was a very large part of the cost of unloading

An automatic filling bucket had been worked successfully for a number of years in coal and similar soft material but on account of the hard and lumpy nature of the early iron ores it could not be operated in them

With the use of the soft Messaba ores interest in the automatic filling or grab bucket was renewed and about ten years ago the first successful grab bucket machines were erected and operated at the Illinois Steel Company s plant at Chicago by the Hoover & Mason Company This plant was designed to unload from the vessel direct into railway cars

The success of this plant was the beginning of the present methods of unloading iron ore

There have developed two types of grab bucket machines one with the grab bucket suspended from wire ropes and the other with the grab bucket carried on a rigid arm

The cost of filling the buckets by hand was about 13 to 15 cents per gross ton, and the cost of hoisting and dumping into railway cars or storage from 1½ to 2 cents per gross ton, making the total cost of unloading from 14½ to 17 cents.

With the grab bucket machines, this total cost has been reduced to from 1 to 2 cents per gross ton, depending on the distance the ore is carried from the vessel

The hand-filled buckets were of about 1 ton capacity, as this size had been found to be the most practical for filling and handling in the hold.

With the grab bucket the size is only limited by the dimensions of the hatch and the shape of the vessel

The first grab buckets for iron ore were of 5 tons capacity but since then machines have been built to handle 7½ 10 and 15 tons

Besides reducing the cost of unloading the ability to handle in larger units has reduced the time whereas with the hand filled buckets to unload a 6 000-ton vessel was a question of days, it is now only a question of hours

The steamer Morgan of the Pittsburg Steamship Company with a cargo of 11 319 tons of ore was recently unloaded at Fairport in five hours and fifty eight minutes The work was done with six Brown Electric Unloaders

These improvements have also increased the earning capacity of the vessel by making possible a greater number of trips during the season This is shown by the following comparative statement for the years 1906 and 1910 showing the average stay at upper and lower ports of the vessels of the Pittsburg Steamship Company

	Year 1906		Year 1910	
	Hr	Min	Hr	Min
Average stay in lower lake ports	36	15	22	22
Average stay in upper lake ports	22	25	12	22
Average time spent in port receiving and discharging cargoes	58	38	34	44
	Gross Tons		Gross Tons	
Average cargo carried	5 954		6 634	
Largest cargo carried	13 333		13 296	
	In 70 Min		In 45 Min	
Fastest loading record	9 277		9 788	
	Tons per Hour		Tons per Hour	
Rate of fastest loading record	7 280		13 051	

In the foregoing I have outlined the development of handling bulk material using iron ore as an example The handling of package freight has not been brought to the same degree of perfection

In many manufacturing concerns mechanical devices have been installed to reduce the cost of handling and to hasten the transportation of their products but for quick and economical handling of freight at shipping docks and railway terminals little has been done in this country

In Europe greater advances have been made due largely to the encouragement given by the city or government which frequently itself equips the docks

At Hamburg Antwerp Bremerhaven Glasgow London Manchester Havre and many other ports are found mechanical appliances each to meet the local requirements but all aiming to reduce the number of handlings and the cost of the same

In England at the freight stations and warehouses the practice is to install jib cranes so arranged that they can serve all the floor space from car or wagon.

In this country many of the railroads have put in hand cranes of the pillar or bridge type, for handling freight from cars to wagons, or vice versa, but they are mostly for heavy lifts, and are slow in operation and cover only a limited area.

Some of the railroads have put in electric cranes in their freight yards and water terminals, as for example, the Pennsylvania Railroad Company on its

THE ROUGH SKETCH OF BROOKLANDS ELABORATED AFTER REACHING THE GROUND

Mr Fleming Williams the artist writes Should a general be doubtful as to the best road to choose to reach a certain spot an aviator could, in a few minutes ascend and not only see the best way but sketch a map of it or write a report Should the position of an enemy be doubtful the aviator could easily locate tents or moving columns from a height and distance that would render him practically immune from gun fire

* Read before the Congress of Technology at the Fiftieth Anniversary of the granting of the Charter of the Massachusetts Institute of Technology

Greenville docks, the New York Central & Hudson River Railroad Company at Port Morris, the Philadelphia & Reading Railroad Company at Port Richmond, and the Central Railroad of New Jersey at Communipaw

Many of the railroads are coaling their locomotives at greatly reduced cost and time by mechanical appliances, but the question of handling their package freight at terminals is still open

Most managers have known that there is a great loss of time in transferring freight at terminal and intermediate points but few seem to realize the high costs that this involves

Perhaps the most complex movements in the handling of package freight are at the large steamship piers due to the great carrying capacity of the large vessels the many consignees each having his allotted space and the limited floor area that has to be cleared quickly to make room for the next vessel The larger railroad terminals also have their many consignees but the floor area is not so restricted

The placing of the packages in the proper space is done by the hand truck A sling load from the vessel or a railway car may contain packages for several consignees The truckman cannot wait to sort as he receives them so must load his truck with them as they come This means a long travel to get the packages to their alloted space In order to tier them several more handlings are necessary All this leads to congestion and increasing cost per ton

This is further effected by the rise in the cost of labor materials rent and larger terminals

Each terminal is a problem in itself as is each manufacturing establishment, so that it is necessary to make a careful study of the conditions to be met before any mechanical method can be proposed

In the last thirty years there has been a steady increase in the capital invested in manufactures which means an increase of tonnage of all kinds of package freight carried by the steamship and railroad companies To meet this the railroads have increased their rolling stock and either enlarged their terminals or built more In large cities this has been at great cost for land and buildings The method of handling the freight has remained the same

At a terminal there are two kinds of freight—out bound and inbound The outbound is transferred from wagons into the outbound freight house and thence to the railway cars or directly from the wagons to the cars

The inbound is *vice versa*

All the above movements except between wagons and cars involve the sorting and distributing of each package to its designated space It is also necessary to transfer cars from one freight house to the other as the use of the hand truck necessitates bringing the cars to the freight

A mechanical equipment to be satisfactory must be able to distribute the outbound and inbound freight simultaneously there should be no rehandling and every square foot of floor space should be served with a single handling

All motions of lifting and conveying should be done by power The machinery should be designed to give the greatest lift required and to transfer to any reasonable distance and then tier or lower into cars

Continuous operation should be sought for to avoid delay

No part of the transference should be along the floor and the equipment should not take up any floor space that can be used for other purposes

All movements of the mechanical equipment should allow of the assorting and distributing according to classification and allotted space readily and quickly

There must be reserve capacity to prevent congestion in case of extra demands

The justification for the investment of the mechanical installation lies in the reduction of cost and the saving of time in handling

The expense should be in proportion to the size of the terminal

There are many companies in this country engaged in the manufacture of hoisting and conveying machinery While perhaps no one makes all the necessary appliances yet a combination of their product could be used to fill the special requirements of each terminal point

Fully to cover the floor space and obtain all the different requirements for the satisfactory handling of the package freight three units or different types of conveying machinery are necessary These are the single rail electric trolley the bridge traveler and the cross traveler The electric trolley is the actual load carrying part of the equipment the single rail bridge traveler and cross traveler furnishing a combination of loop track system on which the trolley can reach any part of the area to be covered All movements should be so regulated that there will be no interference and many trolleys can be in operation following one another Each trolley can draw a number of trailer trolleys so that many packages can be hoisted and transported under the control of one man

This arrangement allows many loads to be transported in close sequence simultaneously and with maximum hoisting and traversing speeds gives the greatest range and capacity at a minimum of labor and maintenance

At some freight terminals it may be necessary to have in combination with the above mechanical conveyors motor trucks on the surface in others belt conveyors

There is no doubt that some such scheme as outlined above when properly carried out to meet the special requirements at any terminal would materially reduce the time and cost involved in the present method This has already been exemplified in the handling of bulk material

Considering the special attention now being given this question by several engineers and the interest shown by many steamship and railroad managers it can be safely stated that within the next few years great changes and developments will be accomplished

Electrical and Chemical Effect of Ultra-violet Rays

The Hertz Effect

Hertz discovered in 1887 that a polished metal plate charged with negative electricity was quickly discharged by the impact of ultra violet rays Almost all that is yet known concerning this remarkable photo-electric phenomenon which has been called the Hertz effect was soon discovered by Hertz and other skilful experimenters and no satisfying explanation of the phenomenon has been furnished by the numerous researches that have since been made

The Hertz effect is easily produced The spectrum of an electric arc is thrown by means of a slit *S* a quartz lens *L* and a quartz prism *P* upon a polished plate of metal *M* which has been substituted for the ball of a gold leaf electroscope *E* and has been charged negatively so that the leaves *ff* diverge widely Any desired portion of the spectrum can thus be allowed to fall on the metal plate the remainder being cut off by screens attached to the electroscope The electrical condition of the plate is not affected by the rays of the visible spectrum but the gold leaves rapidly fall showing loss of electric charge when ultra violet rays strike the plate No similar effect is produced when the plate is positively electrified

Hertz was led to the discovery of this curious effect by observing that the discharge between the polished metal balls of an electrical apparatus with which he was working was facilitated by the production of electric sparks in their vicinity It would be interesting but it would require too much space says a writer in *La Nature* to follow the long course of experiment and deduction by which Hertz successively eliminated every other possible cause and finally traced the last mentioned phenomenon to the influence of the ultra violet rays emitted by the spark

The Hertz effect cannot be reproduced indefinitely with the same plate without repolishing After a time the ultra violet rays fail to dissipate the negative electric charge The metal is then said to be fatigued but its sensitiveness to ultra violet rays can be restored by polishing it with emery paper Various ingenious explanations of this mysterious phenomenon of photo-electric fatigue have been given but none of them is satisfactory The different metals vary considerably in their photo-electric properties. Zinc and aluminium exhibit the Hertz effect very strongly, while copper and silver are much less sensitive to ultra-violet rays In general the photo electric order of the metals agrees closely with the electro-chemical order, the most strongly electro-positive metals being the most sensitive to ultra violet radiation.

The chemical effects of ultra violet rays have, until recently been observed only incidentally in connection with other researches In this way an apparent formation of ozone in air and of hydrogen peroxide in water was noted but even these simple effects have

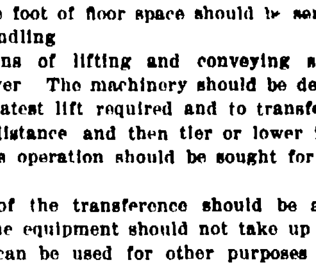

Fig 1—ARRANGEMENT OF APPARATUS FOR PRODUCING THE HERTZ EFFECT

been the subject of controversy Last year some direct experiments were made which appear to prove that ultra violet rays possess great chemical powers By their agency Berthelot and Gaudechon have transformed cyanogen into paracyanogen and oxygen into ozone polymerized acetylene and ethylene converted a mixture of ammonia and oxygen into nitrogen and water and oxidized acetylene to carbon monoxide carbon dioxide and formic acid

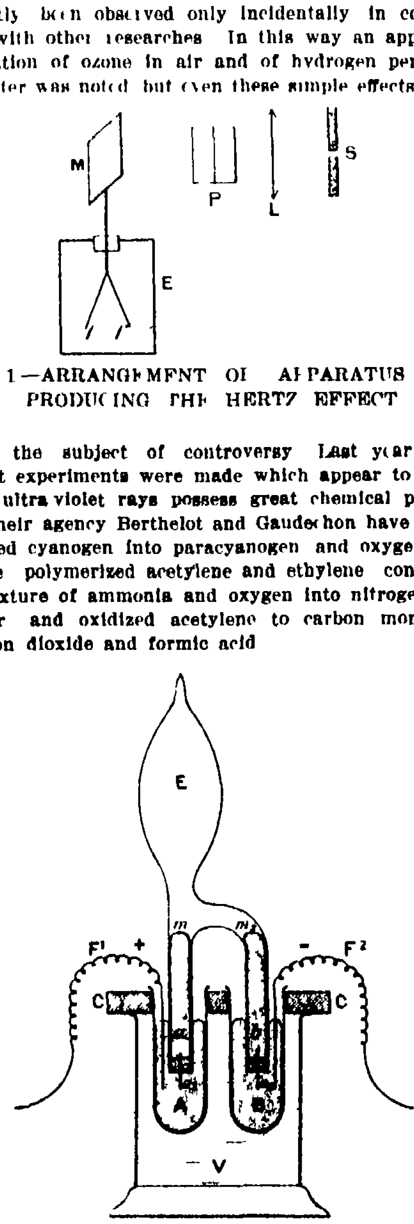

Fig 2—PEROT MERCURY VAPOR LAMP

The ultra violet rays are still enveloped in mystery and many years may elapse before their effects are thoroughly known and explained Researches in this field promise to contribute much toward the formation of a satisfactory theory of the constitution of matter which is one of the most audacious enterprises of modern science

Ultra violet rays are produced by the electric arc and their intensity is increased by employing carbons with zinc or aluminium cores In experiments which require the isolation of the source from the surrounding medium a mercury vapor lamp should be employed Prof Pérot has devised a lamp of this type which is easily managed of small dimensions and much less expensive than the lamps generally employed The quartz vessel (Fig 2) in which the light is generated has the general shape of the small letter h consisting of two vertical tubes *a b* and an olive-shaped bulb *F* placed directly over the tube *a* The tubes are filled to the level with mercury and stand in two wide open mouthed glass tubes *AB* which also contain mercury Electrical connection between the mercury in the inner and outer tubes is maintained by two platinum wires *e* which traverse the closed ends of the quartz tubes The mercury in the glass tubes *AB* is connected with a source of current by the wires *F F* the tube *A* being connected to the positive pole The glass tubes are suspended from the cover *CC* of a vessel *V* which is filled with water for the purpose of preventing overheating When the circuit is closed an arc forms spontaneously between the anode meniscus *m* and the cathode meniscus *m* The tendency of particles of mercury to travel with the current from the anode to the cathode is counteracted in the Pérot lamp by the fact that all of the mercury which rises as vapor from both tubes and is condensed on the walls of the bulb *F* falls back into the anode tube *a* Experience shows that the mercury remains constantly at the same level in both tubes with a current of 10 volts and 2 or 3 amperes In these conditions the lamp furnishes a perfectly steady constant light

A 60 watt tungsten filament lamp will illuminate very satisfactorily a fairly large room yet its filament if crushed to powder would make a cube of less than one-twentieth of an inch on each side Nevertheless few substances are subjected to such severe treatment as the bit of matter that composes the filament of an incandescent lamp and the number of materials which can be used for that purpose is consequently very limited

The German Antarctic Expedition

Its Personnel and Its Equipment

The German Antarctic Expedition will start in the early part of May 1911 Its principal object is to explore the interior of the Antarctic Continent and to establish a connection between its eastern and western parts The expedition will proceed from Hamburg to Buenos Aires and thence to the island of South Georgia where it will refill its bunkers from a store of coal which has been sent ahead after which it will push on southward to Weddell Sea It is the intention to search for Coats Land discovered by Bruce in 1904 on the eastern side of Weddell Sea, to follow the coast as far southward as possible and establish a base and scientific station which will be maintained for at least one year and will serve as the point of departure for expeditions by sledge into the interior For this purpose a detachment of eleven or twelve men has been specially assigned

A detailed account of the scientific program of the expedition is given in a memorial circular from which we quote the following information as reproduced in *Illustrirte Zeitung* The honorary chief of the expedition is the venerable Prince Regent Luitpold of Bavaria. The personel consists of thirty five men The actual leader of the expedition is Dr Wilhelm Filchner a Bavarian officer well known through his explorations in China and Tibet who has been assigned to the command of the expedition by the Prussian General Staff The second in command is Dr Seelheim the geographer of the expedition The meteorological observations will be conducted by Dr Barkow of the Royal Meteorological Institute at Potsdam the oceanographer is Dr Brennecke of the Hamburg Naval Observatory who occupied the same position in the Planet Expedition to the South Sea the geological work is in the hands of Dr Heim of Heidelberg and the physicians are Dr Kohl of Munich and Dr Wachter of Vienna both of whom are trained alpinists and snow shoe experts Dr Felix Koenig has been added to the party because of his expert knowledge of sledging Prof Lohmann will accompany the expedition from Kiel to Buenos Aires as biologist. The astronomical and magnetic observations will be conducted by Dr Przybyllok of the Potsdam Geodetic Institute Herr Neuberger an expert automobile machinist will look after the motor vehicles The nautical command is in the hands of Capt Vahsel of the Hamburg-American Line who was second officer of the Gauss" in the first German Antarctic Expedition and who commanded the Pelho in the recent German South Sea Expedition. The first officer is Herr Lorenzen who occupied the same position on the Pelho The second officer is Herr Mueller of the North German Lloyd who has long been navigator on the cable steamer Stephan The third officer Herr Slosarczyk, has prepared himself for his work as wireless operator of the expedition by similar work on the transatlantic liner Patricia

The chief engineer is Herr Heyneck of the Hamburg American Line Several of the best men of the Gauss expedition have been secured including the cook Klick the carpenter and diver Heinrich the steward Besenbrock and the preparator Noack.

The outfitting of the expedition falls naturally into three parts the ship the provisioning and the means of land transport. All the experience accumulated in former polar expeditions has been utilized in the preparations and Dr Filchner made a special expedition from Spitzbergen last year in which he accumulated much valuable experience and formed the acquaintance of several scientific men of the expedition who accompanied him

The expedition is provisioned for three and one-half years and carries more than 200 tons of food stuffs Automobiles of peculiar construction which have been very successfully employed for drawing sledges in extensive experiments in Norway and the Bavarian mountains will be carried for that purpose. Capt. Scott will employ similar vehicles in the English Antarctic Expedition which is now fitting out. In addition dogs will be carried and also ponies which Shackleton found very useful for drawing sledges The sledges carried by the expedition are of the type used so successfully by Nansen Most of them are about ten feet long, two feet wide and very low The dogs were obtained from Greenland, the ponies from Eastern Asia.

The ship, the "Deutschland" was purchased in Norway last autumn It is a whaler and has proved its staunchness in ice It was built in 1905 of spruce, oak and pitch pine, with ice breakers and an ice shield of "greenheart." It is bark rigged, and has an auxiliary engine of 300 horse-power which, with favorable weather and a daily consumption of five tons of coal can drive it at the rate of seven knots, Under sail the ship can make nine or ten knots with a favoring wind. The gross tonnage capacity was originally 527 tons but alterations have been made which increase the capacity by more than 100 tons. The ready-built houses, sledges and building timber will be stowed on deck on leaving Buenos Aires. The cabins for the officers, scientists cook and steward, the kitchen and pantry and a large and a small saloon are located in a well protected deck house occupying the after half of the ship Each officer and scientist has a separate cabin. On the forward deck is a large laboratory flanked on each side by stalls for ten ponies Between decks are the men s quarters and lavatory The dogs are quartered under the forward deck The ship has been equipped with an electric plant, and all its parts will be lighted by electricity except in case of a shortage of coal. The dynamo will also serve to operate the wireless transmitter Two tanks of 11 tons capacity and two of ¾ ton capacity will contain the supply of drinking and boiler water The vessel is provided with a device for raising the propeller Three propellers are carried two of nickel steel and one of iron The boats include two whale boats, two large lifeboats and a seven-horse-power motor boat.

The total cost of the expedition is estimated at $350,000 To defray this cost the governments of most of the German States have authorized lotteries, the guaranteed net proceeds of which will be about $200 000. Large subscriptions have also been received from various persons Nevertheless, additional funds are required to carry out the expedition to success, and it is to be hoped that the appeal issued by the committee will meet with a generous response.

A Modern X-Ray Laboratory

The Interrupter or "Break"

By Reginald Morton, M D

ONE of the most important elements in the modern X-ray equipment is the interrupter or break" as it is generally called As its name indicates its function is to interrupt or break the flow of current through the primary coil of the inductorium A sudden interruption is essential for the working of the coil, and the more sudden and complete it is the

FIG 1 AN X RAY CABLE TESTING OUTFIT

better is the discharge from the coil. A review of some of the principal types of 'breaks" in use at the present day is given by Reginald Morton M D

Up to the time of Roentgen s discovery breaks were of a simple and not very efficient form they were only used in circuit with batteries of low voltage and as the induction coils were as a rule small in size and giving short spark length they answered well enough

The demand for greater discharges to excite heavier and stronger tubes soon made it evident that the interrupter would have to be modified especially as it was desired to make use of the comparatively high pressure currents from the street mains The platinum hammer break (see Fig 2) was one of the first, and though it is seldom used now for heavy work and mostly on portable apparatus in its most modern form it can be made to give very good results It requires care in adjustment and manipulation but is practically the only kind that can be used in military service in the field

A disadvantage of this form is the flashing that takes place between the platinum points every time the current is broken this is troublesome when it is desired to make use of the fluorescent screen in a dark room

It was found that when the break was so modified that one of the points was replaced by a dish of mercury the spark from the coil was intensified In one of the earliest types a copper wire was made to dip in and out of the mercury by the action of a small electric motor and a number of interrupters

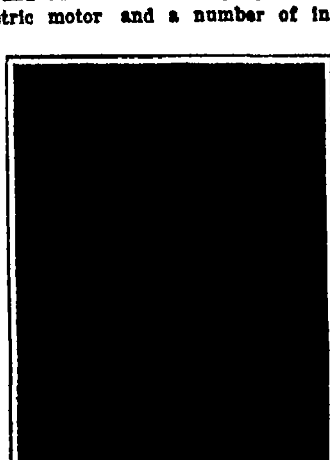

FIG 2 A PLATINUM BREAK

of this kind are in use, for X ray treatment especially (see Fig. 4)

Following on this we have the mercury jet breaks which were a great improvement in that they gave a much higher rate of interruption for the same quality of discharge from the coil. In these a small jet of mercury is made to impinge upon a copper blade or blades. It is immaterial whether the jet revolves or whether the copper teeth revolve around the jet, the result is the same. The mechanism is inclosed in a glass or iron vessel which contains a quantity of mercury at the bottom and is then filled up with spirit or paraffin oil The break thus taking place under the surface of the fluid is all the more sudden and complete and this type of mercury break has been, and is very popular The great disadvantage is the large quantity of mercury required (20 to 30 pounds in some) and the rapidity with which the latter becomes emulsified and useless for the time being Most of the mercury can be recovered but the process is very messy (See Fig 3)

Owing to this difficulty of cleaning efforts were made to find some gaseous medium to replace the liquid in common use and it was found that ordinary house gas was all that could be desired It may be said that any mercury break designed for the use of liquid will work equally well or even better if the gas is used instead The case has of course to be made tightly fitting so as not to allow free escape of the gas Used in this way the mercury does not become emulsified only a small quantity is required and the small amount of black mercury compound that gradually forms need only be removed at long intervals.

The most recent development of the mercury break is a more or less radical departure from the jet type we have been considering but the change is a very important one and the system upon which they work is one that is likely to prevail The principle involved is an old one though its application to interrupters is quite new It is well known that if we fill a hollow sphere with liquids of different densities and then

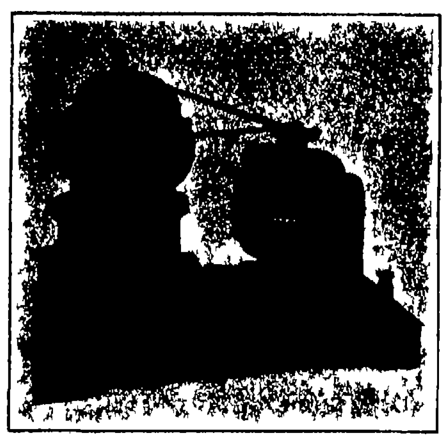

FIG 3 A JET BREAK

rotate the sphere rapidly the various liquids will tend to arrange themselves around the equator of the sphere with the heaviest liquid against the wall and the lightest liquid nearest the center of rotation Applying this principle to an interrupter the hollow space is flattened at the poles and the equator is bulged out This form is found to give the best results, as might be supposed (See Fig 5) Into this jar is placed some mercury and paraffin oil and the whole is mounted upon the end of the shaft of an electric motor which is placed vertically As the latter is set in motion the jar turns with it and the mercury by virtue of its greater weight at once takes up its position at the widest part Its rate of rotation is a little less than that of the jar which is made of cast iron both for its strength and its resistance to the action of mercury There are several forms of interrupter working on this principle but the above arrangement forms the basis of them all In one of them a fiber disk with a metal segment and about the size of a five-shilling piece, is mounted so that its edge engages the whirling band of mercury This causes the disk to rotate rapidly and as the metal segment touches the mercury the circuit is completed to be suddenly and completely broken when it leaves

When we consider the remarkable property of the X rays in readily passing through substances that are quite opaque to ordinary light it would seem that they ought to be of the greatest use under many and diverse conditions In the early days of their discovery many extravagant predictions were made as to their probable value and these were treated more or less seriously As a matter of fact if we take away their application in medical and surgical work so little remains that the demand for the necessary apparatus would be too small to be worthy of the serious attention of any manufacturer except in the fulfillment of a special order

It will be thus easily understood how difficult it is, when treating of the uses of the X rays to avoid reference to medical matters Their limited use in other directions is due to several causes and the chief one is that the X ray image is a silhouette and not a photograph as it is sometimes erroneously termed The property of arresting the passage of

FIG 4 A DIPPER BREAK

the X rays and thus casting a shadow is purely a question of the atomic weight of the elements that make up any substance Speaking generally substances of vegetable and animal origin except the bones are very transparent With the exception of aluminium all the metals in common use are more or less uniformly opaque Calcium having an intermediate atomic weight is semi transparent, and as lime salts enter very largely into the structure of most living organisms the X rays are very valuable in studying their normal structure as well as tracing departures from the normal, whether from disease or accident Any inequalities in thickness are registered on the screen or plate and so accurately is this done under favorable conditions that the details of structure can often be made out a good radiograph of the hand or foot shows this very well

Some very interesting discoveries have been made in this way regarding the internal structure of shells and the rays have been used in examining oysters for the presence of pearls If no pearls are present the oyster is returned to the sea which is presumably an advantage to the oyster In a like manner electrical cables are examined (see Fig 1) both for the continuity of the conductor and to see that it maintains its proper relation to the other members of the system The modern electric cable is in many instances a very highly specialized structure that has to stand very severe strains both mechanical and electrical and as an apparently small fault may give rise to very serious trouble the final inspection has to be carried out with the greatest care before it is passed as fit for service

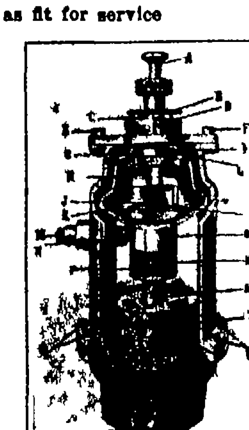

FIG 5 SECTION THROUGH ROTATING DISK BREAK

With regard to the medical and surgical uses of the X rays most people are inclined to think that the examination of fractures and the detection of foreign bodies within the human organism constitute the main field of their usefulness These are of course very important applications and ones that count for much in hospital practice particularly but they do not by any means constitute the whole An ordinary simple fracture occurring in the shaft of a long bone such as in the middle of the upper arm

can be dealt with quite satisfactorily, whether examined by the X rays or not but the surgeon who attempts to deal with a fracture close to or involving a joint without having it properly examined by this method takes a risk to his patient as well as to his own reputation that is not justifiable In an instance of this kind an injured wrist was declared to be a severe sprain and treated as such Fortunately the patient decided to come to the hospital where it was X rayed as a matter of routine This showed that the bone was not only broken in at least three fragments but that one of the lines of fracture entered the wrist joint The fact that there was no displacement of the fragments led to the erroneous diagnosis being made and had this been treated in the ordinary way a stiff wrist joint would have resulted almost certainly

In the early days of the X rays their use was almost entirely confined to strictly surgical cases nowadays the method is used almost as much for the investigation of medical cases such as disease of the respiratory organs the heart and great blood vessels tumors and obstructions in the digestive system The last mentioned application is a comparatively recent development and one of great interest The method consists of giving jelly or other food containing a large amount of a bismuth compound which is quite harmless The bismuth being opaque to the X rays the progress of the food can be watched in its advance along the digestive canal and at times the information gained is very valuable There is a great danger however in misinterpreting the appearances because similar shadows may be made by very different conditions In no instance is the opinion of an expert more necessary than in this

By means of very powerful apparatus more or less instantaneous radiographs can be made of the heart when the X ray tube is placed no less than two meters from the plate Owing to the great distance of the tube the size of the shadow of the heart is very nearly the same as that of the heart itself and it is the best method at our disposal for accurately determining the dimensions of that organ Changes in these dimensions can be detected by making examinations at intervals This by no means exhausts the list of applications of the X rays in the diagnosis of disorders of mankind but enough has been said to show how much progress has been made and the science is by no means at a standstill Improvements in methods and in personal skill are being introduced every day and scarcely a month passes that does not give us something new in the way of improved appliances

It was comparatively soon after the discovery of the X rays that some investigators began to employ the radiation for purposes of treatment They were led to do this from the good results that were being obtained with the ultra-violet rays, and from the fact that many X ray workers had begun to suffer from a form of dermatitis which was rightly attributed to the influence of the X rays themselves It was at this stage that the foundations were laid for the immense amount of suffering that has been endured by many of the pioneers of X ray work, many of whom still continue to suffer in one way or other in spite of the fact that they have taken every possible precaution since the first attack of the dermatitis. The danger from these rays is only incurred by those who are working with them more or less continuously there is not the slightest danger to any one who undergoes an examination or a course of treatment by the X rays so long as the work is done by one who is a recognized expert in such matters

It may be taken as an axiom that any agent that is capable of doing so much harm as this can also be made to do a great deal of good if only its powers are properly controlled and directed into the right channels The great trouble in administering thes rays therapeutically was that of knowing how large or how small a dose was being given and even at the present time the methods at our disposal are not anything like so simple and scientific as that of giving ordinary drugs We have no satisfactory method of ascertaining the exact strength of radiation the patient is getting at any given moment our methods will only tell us how much has been given and that rather crudely The means mostly employed are sufficiently accurate in the hands of one who has had a considerable experience of the work and who has become more or less familiar with the vagaries of the X ray tube The day is not yet that the novice can dip into this work without running considerable risk

When the platino-cyanide of barium is exposed for a certain time to the influence of the X rays it turns from its usual greenish yellow tint to that of a light orange This material is spread upon stiff paper and cut into small circular pastilles The X ray tube is inclosed in a ray proof shield from which the rays can escape only by an opening made for the purpose the size and shape of which can be altered to suit any ordinary conditions The pastille is held in a clip exactly half the distance between the source of the rays and the area to be treated and is so arranged that it can be removed for examination from time to time With each set of pastilles is supplies a standard tint to which the pastille must change before the ordinary full dose is given This is in outline the method in use at the present time by the majority of radiologists It is admittedly a crude one when judged by other standards of measurement but in the hands of the expert it gives very good results.

With regard to the conditions that are benefited by this form of treatment, it may be said that the more superficial is the disorder the more likely is it to be favorably influenced, this is only another way of saying that the method finds its greatest field of usefulness in the treatment of the diseases of the skin, and the results that have been obtained are at times quite remarkable It is a very fortunate thing that it is among those conditions that are, as a rule very resistent to all ordinary methods of treatment, that some of the greatest successes have been made

Before closing this article it may be of interest to indulge in a little speculation as regards future developments While we have seen that improvements in the electrical appliances have been going on from the very beginning and show little sign of any falling off in this gradual but steady improvement the X ray tube itself has undergone no radical change since the invention of the focus tube by Prof Herbert Jackson

It is quite true that the X ray tube of the present day is a great improvement on the original Jackson tube It is larger in size more steady in action and more capable of withstanding the various and severe stresses to which it is subjected and is also provided with a means of regulating its vacuum but it remains in principle as it always was and great as its improvement has been it has not kept pace with the development of the electrical side of the X ray equipment Any modern coil can completely wreck any X ray tube in a few seconds if desired Our greatest want now is a tube that is steady in action and in vacuum that will give out a certain quality of radiation as required and continue to give this no matter how great power is applied to it within the limit of reasonable requirements With a view of meeting some of the conditions it has been suggested to make the bulbs of quartz instead of glass but so far no one seems to have attacked the problem seriously Quartz is much more transparent to the X rays than any form of glass it is independent of any changes of temperature and will stand any amount of rough usage within reasonable limits It certainly should be well worth giving a thorough trial if only for the advantages already mentioned But even with these advantages it could not be said that the X ray tube was in the nature of a perfectly satisfactory instrument In the present state of our knowledge it is very difficult to see how the X ray tube can be radically improved upon We can only wait patiently, and for all we know some means of getting our X rays may be discovered that is much more simple and reliable and entirely different from the methods we use at present

The Past and Present Geographical Distribution of the Iron Industry of the United States

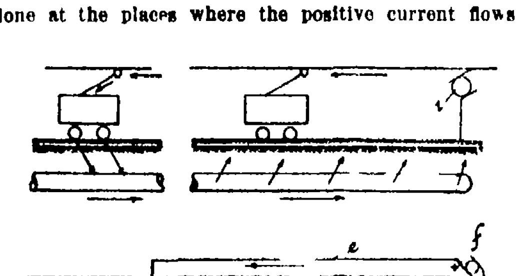
In his address on Geology and Economics speaking before the New York Academy of Sciences Prof J A Kemp referred as follows to the geographical distribution of iron producing centers and the changes which have taken place in their relative importance

The iron industry in the United States took its rise in the colonies along the Atlantic seaboard—and at the outset was based upon the magnetic ores and brown hematites there occurring For one hundred and fifty years its growth was slow In the decade of the forties and fifties of the past century it had spread to the Adirondacks and in the fifties began its development in the Lake Superior region Not until after the close of the civil war and the resumption of peaceful activities did this great industry manifest its possibilities With improved facilities of navigation which placed Lake Superior in easy communication with the coal producing States of Pennsylvania and Ohio the iron-ore producing States of Michigan Wisconsin and later Minnesota, came rapidly into prominence In somewhat slower growth Alabama during the seventies and eighties gathered headway At present four fifths of our ore supply comes from the three Lake Superior States and three out of the four fifths from Minnesota alone Alabama Tennessee and Georgia together yield one tenth and the remaining tenth is divided among a dozen or more other States of which New York is the leader Since 1880 the total has increased about seven fold and Pennsylvania then the source of about one quarter the supply now yields approximately one and one half per cent Minnesota, now the great source of ore only entered the lists in 1884 and only began to utilize its present great mines about ten years later

Thus in the brief course of thirty years there have been very great rearrangements not only in geographical sources of supply but still more in actual amount of output. In normal prosperous years the annual production is somewhat more than fifty million tons of ore."

Protection of Underground Pipes from Electric Currents

Gas pipes and water pipes laid near electric rail way tracks are frequently corroded by the action of stray earth currents If the parts attacked are protected by a coat of tar the mischief is simply shifted to the adjacent unprotected portions The damage is done at the places where the positive current flows



PROTECTION OF UNDERGROUND PIPES FROM ELECTRIC CURRENTS

from the pipe to the earth because here oxygen is set free while in places where the positive current flows from the earth to the pipe the metal is protected by an evolution of hydrogen The arrows in the upper diagram of the accompanying illustration show the course of the current generated by the dynamo *e* flowing through an overhead trolley wire and a number of cars to the rails and leaking to the water pipe beneath The pipe is corroded only in the right hand portion where the positive current flows out of it According to a note in *Prometheus* a German railway manager has succeeded in protecting such pipes by superimposing on the injurious current, a current flowing in the opposite direction

The lower diagram shows how this result is accomplished A second overhead wire *c* is stretched parallel to the trolley wire and is supplied by the dynamo *f* with a current flowing in the same direction as the working current The distant end of this wire is connected with a return wire *d* which is buried near the pipe and rails The negative pole of the dynamo however is connected not with the return wire but with the pipe Hence positive current flows from the return wire *d* through the earth to the right hand part of the pipe neutralizing the injurious current flowing from the pipe to the rails This device has given satisfactory results during fifteen months service

Waterproofing Fabrics

The French army is interested in a new method for waterproofing fabrics which is claimed to be superior to usual processes English manufacturers have been in the lead in bringing out waterproof fabrics for many years past Besides rubber for fabrics, we have the use of insoluble gelatine boiled linseed oil shellac metallic soaps and others, which have had more or less success It appears that the best product for waterproofing is acetate of aluminum, and when applied to the fabric it can be made to form alumina in a gelatinous state and volatile acetic acid When such fabric is dried it is waterproof, but has not the objectionable feature of rubber and other material as it allows the air to circulate through it The fabric is also quite supple, and this is especially necessary so that clothing can be made of it. As the French army department is looking for the best method of waterproofing which can be used for military cloaks as well as for tents some experiments were made, and it was found that the above process is the best, according to the opinion of the best authorities This is especially true now that acetate of alumina solution can be found on the market and does not need to be prepared specially M Balland recommends a bath of one part acetate (7 deg B) and forty parts water Fabrics are soaked in it for twenty four hours, and are then dried in the air This method is being used in the army headquarters at present.

Fire and Burglar-Proof Safes.—I.*

Recent Advances in the Construction

By E. E. Watson

In order to place before you the recent advances in the construction of fire and burglar proof safes, it is necessary to cover a brief history of the industry from its actual beginning in the early part of the nineteenth century down to the present time.

Practically speaking, the more recent advances have had to do principally with refinements in mechanical processes, the development of factory organization and the perfection of elements of design that were conceived long before the means were at hand for their proper realization.

The development of any industry is in a large measure dependent upon the activity in other related industries, and the progress in the one must mean a general forward movement on the part of all.

The development of the art of building safes for the protection of valuables is interwoven so closely with that of the art of lock building that the two subjects necessarily must be treated together.

It is a fact that is apparent to anyone who gives consideration to the subject, that a safe, however secure from the standpoint of construction, would be useless without an opening giving free access to its interior and that opening guarded by a lock at least as secure in point of design and construction as the safe itself.

The conclusion must be drawn from this that safe building in point of relative security could only keep pace with the development and with the design and construction of locks. The history, therefore, of the development of the safe building art is in reality first the history of the development of locks.

Locks as we know them to-day and as they have been known ever since they were first used consist primarily of a bolt and a key for operating the bolt and some means interposed between the key and the bolt to render the operation of the bolt either more or less difficult or impossible without the use of the proper key.

The means employed for housing the working mechanism of the lock and for applying it to the protected structure are of little importance in this consideration. All of the different locks possess these features. They may be divided into several general classes.

First, not only in point of simplicity, but naturally also in point of historical origin, is the latch lock, in which there is a bolt pivoted on a fixed point and raised by some sort of a key.

Locks were later rendered more secure by the introduction of the warded type, in which the introduction of the key into the hole provided for it was rendered more or less difficult by means of interposed wards, making it, to a degree at least, impossible to introduce the wrong key.

The warded type of lock was succeeded by the present day lever tumbler type, in which tumblers are interposed between the key and the bolt, making it necessary for the key to lift the different tumblers before the bolt can be withdrawn. This type of lock is considered secure in proportion to the number of tumblers used and the means provided for varying the relative amount of lift.

The bolt of this type of lock has fitted to it a member that passes into slots in the lever tumblers in the operation of its withdrawal, and the province of the key is to line up these slots in the lever tumblers so that they register with the fixed member on the bolt.

A later development of the tumbler type of lock is that known as the cylinder pin tumbler lock. In this type of lock the obstruction consists of divided pins preventing the turning of the plug until these pins have been raised to a point where the division line between the different sets of pins coincides with the outer surface of the plug and the inner surface of the cylinder, in which it rotates. When these points have been so lined up by the introduction of the proper key the cylinder may be rotated and the bolt withdrawn.

The inconvenience resulting from the use of the ordinary type of key lock, by reason of the fact that keys could be wrongfully duplicated, or they might in various ways come into the possession of persons not entitled to them, gave the necessary impetus to inventive genius, and the modern dial or combination lock was the result.

Coincident with the development of the dial lock is that of the changeable type of key lock, in which the arrangement of the tumblers or obstacles may be almost indefinitely varied. It practically after being set up to a new key becomes an entirely new lock and cannot be operated by any other key than that to which it is set up.

The development of the changeable-key type of lock is of great importance for the reason that a limited amount of security is frequently needed of a kind that cannot be afforded by the ordinary type of lock. This security is frequently furnished by combination or dial locks that are much more expensive.

The changeable key locks until recently have been of a design and construction that were very apt to get out of order and cause considerable inconvenience to the user.

Many efforts have been made to produce a simple lock of the changeable key type, all of them depending upon the introduction of a double tumbler between the key and the bolt. The changeable key lock that is being manufactured by the Herring-Hall-Marvin Safe Co. is the only one in which the obstacle that is interposed consists of a single member. The tumbler of this lock departs from the lever tumbler type previously employed in that it has no fixed pivot, but can be properly called a balanced tumbler.

Its greatest merit is its simplicity and its substantial construction. In all other types of changeable-key locks the means provided for changing the combination are delicate, and in the ordinary operation of the lock the wear on these delicate parts is constant. In this lock the means provided for changing the combination are not in the least delicate, and the ordinary operation of the lock in opening and closing after it has been set up to a key causes absolutely no wear on the combination part of the tumbler, making the lock just as substantial and as little liable to get out of order as the simple lever tumbler type of lock.

It is generally conceded by those who are interested in the manufacture and sale of locks that the changeable key type of lock has been greatly limited in its use heretofore by reason of its delicacy and its propensity for getting out of order.

As an evidence of the simplicity of the Herring-Hall-Marvin Safe Co. lock, it is necessary only to call attention to the fact that in this lock, which admits of over 59,000 different changes, there are but 14 parts, while in the highest type of changeable key lock previously invented, which afforded but about 8,000 changes, there were over 40 parts.

Its application, while not exactly universal, is broad enough to enable it almost entirely to supplant the other types of key locks.

In the case of apartment houses, where tenants are constantly changing, the ordinary type of lock affords absolutely no security, for the reason that keys may be duplicated. With the changeable key type of lock it requires but an instant of time to set up the lock to a new key and thereby render all previous keys inoperative.

The combination lock, as it is known to-day to distinguish it from the key lock, became a necessity when it had been demonstrated that practically all key locks could be picked. This fact was developed in the historic lock controversy of 1851 in England, when Mr. Hobbs succeeded in picking all of the best makes of locks.

A few years later, in 1856, Mr. Linus Yale, Jr., succeeded in picking several of the Hobbs locks. It then became generally conceded that no difference what the obstacles were that were interposed between the key and the bolt, so long as an opening was left for the insertion of the key, this same opening provided means for the insertion of picks to raise the tumblers. Mr. Yale then turned his attention to the designing of a lock that could be operated in some manner other than by the insertion of a key, and the early type of combination lock was the result.

The combination lock being in such general use today needs no lengthy description. It consists of the tumblers, the bolt, a lever member interposed between the tumblers and the bolt, and a spindle or arbor having on its inner end a driving tumbler and on its outer end a dial. The lever member, usually characterized as a fence, is from the standpoint of security a very important part of the combination lock.

The first locks were fitted with a gravity fence, and it was later found that the disk tumblers could be rotated so as to bring their notches in line with the fence even when the combination was unknown. The fence rested upon the periphery of the disks, and could with patience and a delicate sense of touch be felt into the notches one at a time until all of the disks were lined up, when the bolt could be retracted by simply turning the dial. This defect was a serious one. It was finally overcome by Mr. Emory Stockwell, of the Yale Bank Lock Department, by the invention in 1884 of the balanced fence. This fence was so supported that it brought no weight to bear upon the periphery of the tumblers. It was fitted with a friction bearing and could be moved out of its neutral balanced position only when the tumblers or disks had all been lined up in registry with it.

This improvement rendered the combination lock absolutely unpickable. It however remained for the ingenuity of the burglar to devise ways and means for defeating even this supposedly perfect lock. It was evolved out of the fertile brain of some enemy to organized society that a mental key always existed, and could be secured by torture—the combination numbers were always known by some one. There began in the year 1874 a series of bank robberies all over the United States, the most important of which were carried to a successful termination by reason of this one weakness of the combination lock.

It immediately became evident that a lock with absolutely no communication with the outside of the protected structure was necessary and essential to security, and the invention of the time lock followed. This was and still is to a large extent used in connection with the combination lock. Its use prevents the operation of the combination lock until such time as the time lock has run down, and by so doing withdrawn its obstruction to the operation of the combination locks themselves or the means provided for opening.

Meanwhile, in an entirely different field, inventive genius had been equally active by the invention of liquid high explosives, the fluidity of which could be increased by the addition of liquefied ether, so that it could be made to flow into the space surrounding the lock spindles or into the joint between the door and the frame. The burglar, without first securing any proprietary rights in the invention, adopted this method, and the battle of wits began over again, with the result that the lock makers finally evolved a motor device working in conjunction with a time lock, which made it unnecessary to connect the outside of the door with the inside by means of spindles. The motor after being set would throw the bolts when the door was seated into the jambs, and would instantly retract them when tripped by the running down of the time lock.

The motor device has not been universally adopted for several reasons, mainly because spindles can be and are made so that they cannot be driven in or pulled out, and they can be and are made drill-proof. They are ground into the doors so closely that no liquid can be forced around them.

In concluding that part of this paper which relates to locks, I desire to call attention to the fact that while practically all types of key locks can be picked, it does not follow that the key lock should be discarded, for the reason that the measure of security afforded by the lock need not be greater than that afforded by the protected structure itself. Manifestly a light wooden door affords very little security, yet millions of them are fitted with locks. Some with the common warded type, others with the lever and pin tumbler types—all at least affording a measure of security equal to that of the protected structure itself.

That these locks can be picked is no argument against their use, because entrance could be had in nearly all cases in an easier way. The inherent defect in all key locks other than the changeable key type lies in the facility with which keys may be wrongfully duplicated and used, rendering such locks of no security whatever.

(To be continued.)

* Journal of the Franklin Institute.

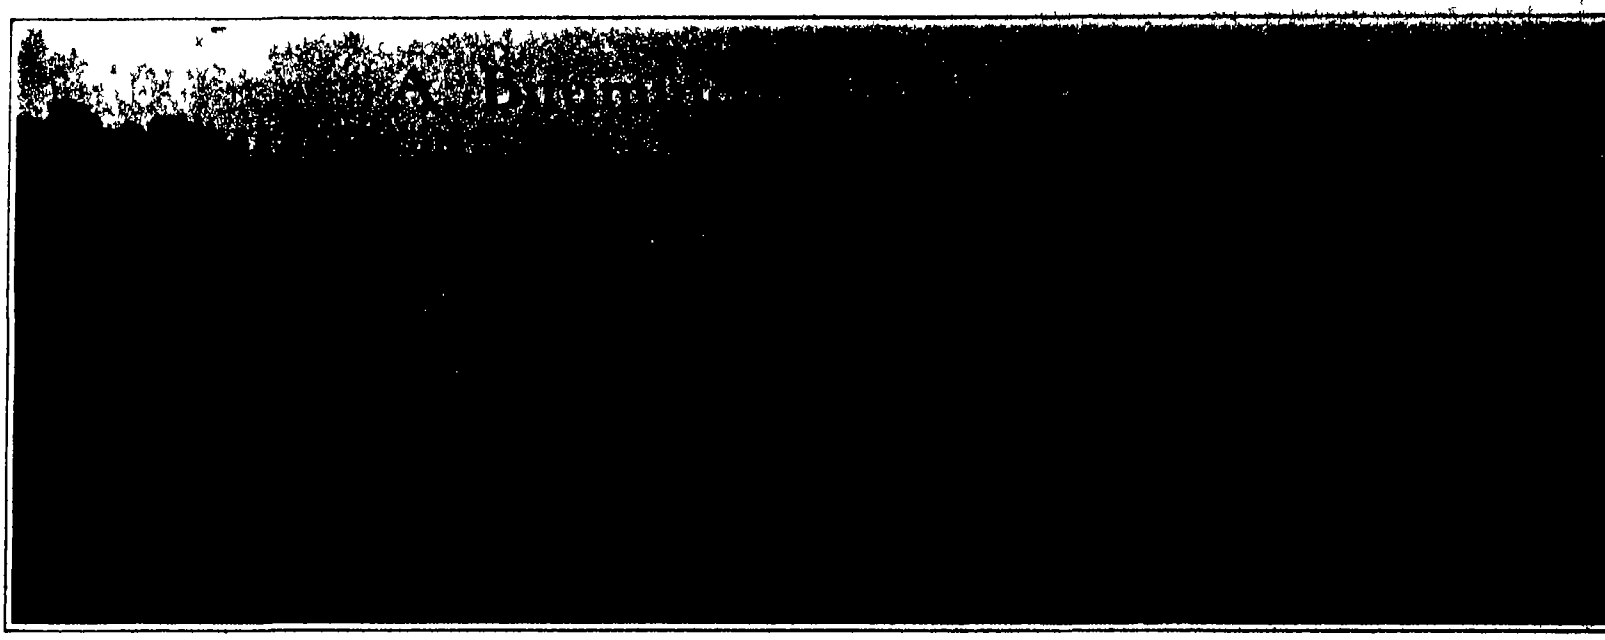
The Hoof of the Horse

There are toes on a horse's hoof just as there are on the foot of a human being or on the foot of any animal that resembles the human foot. Furthermore, a horse has toe nails. The horn of the hoof grows in pretty much the same way that a toe nail does.

The growth of the hoof is more rapid in unshod horses than in the case of those wearing shoes. It grows still more rapidly in the case of horses that are well groomed and well fed. Generally speaking, however, the horn grows about one third of an inch each month.

Hind hoofs grow faster than fore hoofs. The toe of the hoof being the longest part, it takes longer for the horn to grow there than at the heel. For example, the toe will grow entirely down in from eleven to thirteen months, while the heel will grow down in from three to five months.

As the new horn grows out, any cracks or defects in the old gradually work down to where they may be cut off, just as in the case of the growth of human nails one can watch the progress of a bruise from the root to the tip.



THE WASTE TAKEN OFF THE LEDGE SHOWS THAT PART OF QUARRY IS ABOUT WORKED OUT

TEN miles northwest of Santa Cruz California there is an interesting deposit of bituminous rock Here fifty five men work the year round to get out 40 000 tons of the best road making material known Of all the mines and quarries I have seen this seems to be the most pleasant one in which to labor High up on the side of a hill three miles away and a thousand feet above the level of the sea with a fine breeze most of the time and where it is never too cold and with but a few days in summer when it is warm—is situated this clean safe and profitable mine

After taking off 125 feet of waste shale there is exposed a 40 foot stratum of bituminous rock except for a 10 foot layer of waste near the middle

By running this rock through a steam cooker or heater and without the addition of any binder such as tar or asphaltum it is spread upon the rock foundation and makes a clean and lasting surface for a street

Asphalt m is the binder or mineral that makes this out rock of sand valuable It is found in many parts of the world sometimes in a pure state but more often mixed with fine sand earthy matter or pebbles It melts at about 212 deg F and in this form is known as bituminous rock California is the only State in the Union in which it is worked commercially

Macadam foundation covered with two inches of bituminous rock will cost about 23 cents per square foot concrete foundation with two inches of bituminous rock will cost about 32 cents per square foot Side walk will cost about 10 cents per square foot In all this paving work one of the most important things to do is to make a good foundation without this no matter how thorough the cooking and the laying of the cover may be the work will go to pieces

The fresh broken rock is very tough and waxy and in color it is not black but a fine steel gray Black powder is used to blow off a great mass before it is broken up into small pieces with giant powder and with wedges picks and bars It weighs 80 pounds per cubic foot and 10 tons make a load for a six horse wagon to draw down to the railroad

One of the stories told about this mine is that it was first worked in the 60 s for the distillation of kerosene and another is that later they tried to use it for paving material but always got it too hard or too soft.

The man is still living near here to whom it was offered for little or nothing if he would take it off the owners hands and make some use of it He is poor and working for his living while there is in sight 3 000 000 tons of rock worth $3 per ton F O B

Some fossils and bones and teeth of animals are found in the 10 foot stratum near the middle of the outcrop

This bituminous rock has probably been formed by a layer of sand becoming charged or saturated with crude oil the lighter parts of which dry out or are vaporized leaving the heavy asphaltum bare to bind the grains of sand together

Charles Darwin—III*

By AUGUST WEISMANN

Concluded from SUPPLEMENT No 1844 page 275

THE principle of selection shows us how the thousands of adaptations in living beings which arouse our constant admiration may have arisen in a purely mechanical way And they must necessarily have done so if the evolution of the living has resulted from the same forces and laws as the not living in other words if in explaining natural phenomena, we can leave out of account altogether any forces outside of or beyond nature The principle of selection enables us to do this and therein lies its far reaching significance It is I believe the discovery of this principle that will make the name of Darwin immortal Wallace too deserves a full share of the credit, although he did not base his theory on such a broad foundation of facts, and did not apply it in so many directions

This principle is fully developed in "The Origin of Species by Means of Natural Selection as indeed the title of the book shows It might be thought that the publication of this book finished the labors of the hermit of Down but this was not the case It was followed by the richest creative period of his life Between 1860 and his death in 1882 he issued a whole series of works small and large each of them based upon numerous observations and experiments and most of them containing wholly fresh associations of ideas usually connected directly or indirectly with the theory of evolution and sometimes extending and corroborating it more fully I must at least give a few indications as to the nature of these books

In 1862 Darwin published his book The Various Contrivances by Which Orchids are Fertilized by Insects Orchids often exhibit the most special and diverse adaptations to the visits of insects and they help to make clear to us how flowers may have been developed in all their manifoldness in relation to the needs of their insect visitors

In the same year and those following there appeared several treatises on Dimorphism in the Flowers of Primula Darwin had discovered minute differences in the length of the stamens in the same species and he demonstrated that these differences are not mere chance variations but are adaptations which secure the crossing of individuals and prevent self fertilization He obtained the proof of this through many careful experiments

This was followed in 1864 by a treatise on The Movements and Habits of Climbing Plants showing the different ways in which they climb—another study in plant adaptations In 1868 appeared the great work begun in 1860 The Variation of Plants and Animals under Domestication and this book greatly extended and strengthened the basis of his theory of selection The phenomena and laws of variation and heredity are discussed and illustrated by a wealth of examples and the work concludes with a theory of heredity which he called Pangenesis

A BITUMINOUS ROCK QUARRY

"The Descent of Man" appeared in 1870 Up till that time Darwin had made no definite pronouncement upon this subject, though of course he must from the very first have deduced from the variability of species that man also was a product of evolution He now discussed this view in detail in a two-volumed work which also contained a fuller treatment of an aspect of the theory of selection only briefly sketched in "The Origin of Species. Here the phenomena of sexual selection" are traced throughout all the animal groups in which preferential mating plays a part The principle is illustrated by a positively overwhelming mass of detailed facts and is shown to have been a factor even in the differentiation of the sexes in the human race

Closely associated with this work is the one which followed it in 1872 on "The Expression of the Emotions in Man and in Animals The birth of Darwin s first child in 1839 had induced him to record in a special note book all his observations on the gradual awakening of the sensations and their expression on the features of the child for he was convinced that even the most complex and delicate emotional expressions of man had their natural roots in animals just in the same way as the part of the body and the mental faculties For thirty two years he followed out this idea experimenting observing collecting facts until finally he was able to write his remarkable and fascinating book, the first English edition of which consisted of 5 000 copies

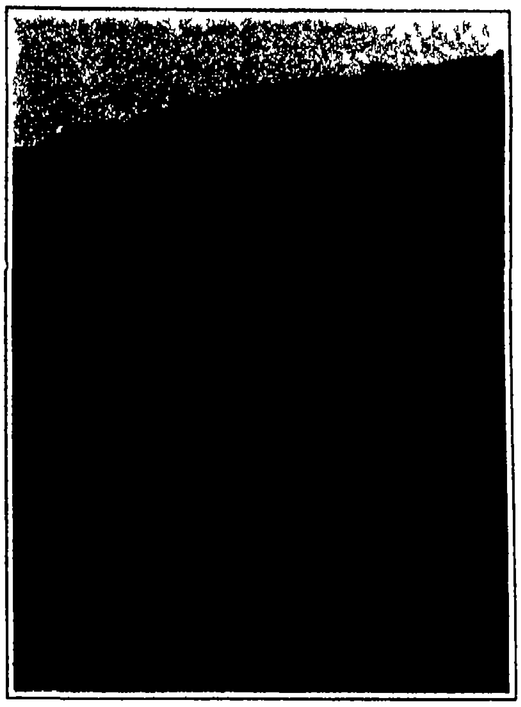
Darwin s next book appeared in 1875 and this also had been a long time in course of preparation In ranging about the country during a summer holiday in 1860 he had noticed a dainty little plant, the sun dew (*Drosera rotundifolia*) to the viscous leaves of which several small insects were usually found adhering Many other collectors had noticed this because of the difficulty of procuring a clean specimen for the herbarium Darwin took a few of the plants home with him and soon discovered that certain parts of the leaves exhibit movement as soon as small insects are brought into contact with them This led him to the discovery of Insectivorous Plants and his book bearing that title was published fifteen years later

In 1876 Darwin published a work on Different Forms of Flowers on Plants of the Same Species, and in 1880 jointly with his son Francis The Movements of Plants" Finally in 1881 the year before his death there appeared The Formation of Vegetable Mould through the Action of Worms This last book like some of the earlier short treatises had no direct connection with the theory of evolution but it illustrates in a very characteristic manner Darwin s eminently scientific mood which led him to note everything that seemed unusual or interesting in the most ordinary things and to follow it out till it led him on to new discoveries How many hundreds of people and even of naturalists had seen the little earth-castings that cover the damper parts of our garden paths on summer mornings These are due to earthworms and are the remains of the decaying leaves on which they feed The earthworms cover the whole land with fertile mold and through their agency in the course of time the surface of the ground is raised and bad soil is transformed into good [1]

But no one had deemed the phenomenon worthy of attention It is a case parallel with that of the sun dew which hundreds of botanists had passed by without ever suspecting that the adherence of the insects was more than a matter of chance.

The fruitful discovery of the struggle for existence" too was due to this vision of the true naturalist, who sees in what lies before him much that others pass by unheeding It was certainly no chance that the struggle for existence first revealed itself to men who had spent the greater part of their lives in the open air no chance that it was two travelers like Darwin and Wallace who first perceived the dependence of one species upon another and the competition between them

From the little that I have been able to tell you of Darwin s life in Down you can gather what a rich



MASS OF ROCK BLASTED OFF THE LEDGE AND BEING BROKEN UP

full life it was You will now wish to hear something of the man himself and his character Unfortunately I never saw him An affection of the eyes which has troubled me for forty five years and has restricted my activities in many directions prevented my traveling to England while Darwin still lived and was relatively vigorous Therefore I can not sketch the impression made by his personality from experience But we have a short autobiography which reveals his nature clearly and in addition a most detailed and sympathetic picture of him by his son Francis.

He was tall nearly six feet in height and his most striking features the high forehead the large prominent and bushy eyebrows the blunt nose and energetic mouth are well known No one interested in Darwin s personality should fail to read both Francis Darwin s account of him and his autobiography Taken together they give a picture of the man which could not be more truthful and could hardly be more complete

Add to this picture what we can gather from his scientific works and especially from the accounts of his journey and we find that he had a great and comprehensive mind concerned in the main with general conceptions yet possessing in a high degree the faculty of becoming sympathetically absorbed in detail He took pleasure in small things as in large and was able alike to study with the most painstaking minuteness the structural details of a flower or a crustacean or to draw far reaching conclusions from an enormous number of isolated facts He possessed the fundamental qualities of a naturalist great powers of observation and absolute accuracy the most extreme caution in judgment is revealed in all his writings and his presentment of his ideas is always simple and entirely free from arrogance or vanity for a great natural modesty was one of the main features of his character But his theories clearly show that he was not lacking in imagination for they could never have been thought out without it He was not a keen critic grasping a thing quickly and illuminating it at once he was on the contrary rather inclined to take too favorable a view of the work of others and had a tendency by no means very common to acknowledge the achievements of strangers and to take a positive delight in them His mind was of the penetrating order which work persistently at any problem until he began to see light on it

He was not concerned with practical aims he was an idealist who desired knowledge for its own sake, and not for any utilitarian end a naturalist who worked for pleasure in the work itself and rejoiced in the advancement of science his work brought about

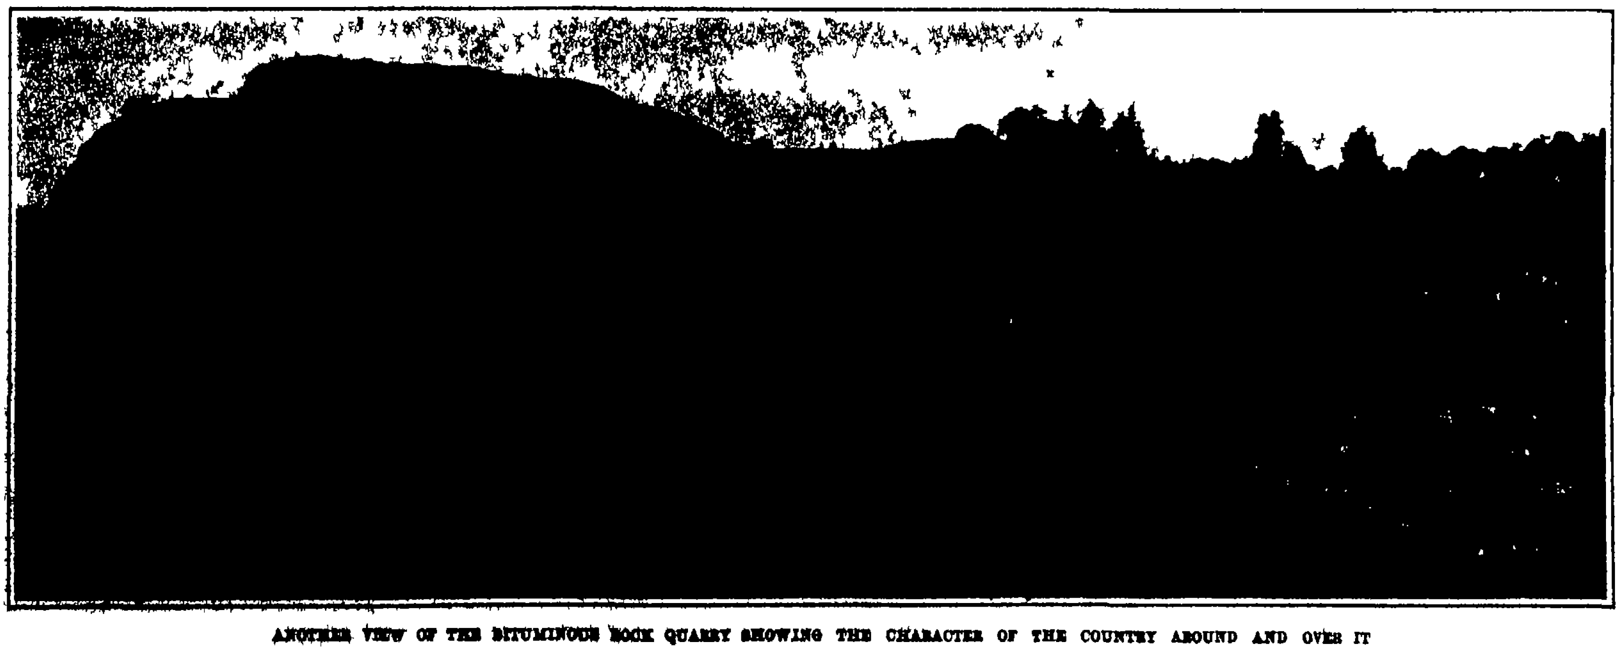
He was not lacking in ambition but it was ambition on a large scale not to gain fame and position but to create works which should seem to him worthy Fame came unsought and as he tells us it was a satisfaction to him to feel that he was held in esteem by those whom he himself esteemed

He has sometimes been called an amateur and in a certain sense this is true in as far as he worked in several different scientific provinces each of which requires a man s whole strength But he had full command over these different provinces at least as far as was necessary for the end he had in view He was certainly not a restricted specialist The zoologists accepted him as a zoologist the botanists as a botanist, perhaps also the geologists as a geologist But he was not an expert in any or rather it would be more correct to say he was so wherever he himself had done productive work For he was essentially self taught and had passed through no normal school of zoology or botany but with his great energy and unflagging industry he had acquired a profound knowledge from books and from personal intercourse with specialists and every piece of work he did added to this store of knowledge He was perhaps the last not merely to survey but to do productive work in every domain of biological science Yet I will not assert this for we have all been convinced in recent times through the evolution theory that it is not enough to be at home in a single science it is necessary also to have at least a general acquaintance with the essentials of allied branches

Darwin has sometimes been accused of being one sided of caring for nothing but his science But this was not the case it is less true of him than of many specialists in natural science He had a wide knowl

[1] In regard to the earthworm I must note that my countryman, Professor Hensen the excellent zoologist of Kiel displayed the same acuteness of observation and drew the same conclusions from the castings at the same time as Darwin did

Life and Letters of Charles Darwin including an Autobiographical Chapter Edited by his son Francis Darwin London 1887



ANOTHER VIEW OF THE BITUMINOUS ROCK QUARRY SHOWING THE CHARACTER OF THE COUNTRY AROUND AND OVER IT

A BITUMINOUS ROCK QUARRY

edge of English literature Milton and Shakespeare having been his favorite readings in his youth In later life he had novels historical works and books of travel read aloud to him every day He was fond of music too though as we have said, he had no musical ear

Darwin was a man not only of lofty noble spirit but of the tenderest feeling Let anyone who doubts this read the touching pages in memory of his little daughter Annie who died young they form one of the most beautiful memorials ever dedicated by a father to his child His son s picture of him too reveals the beautiful and intimate relations that prevailed between them and the whole quiet and joyous life of the Darwin family testifies to the cheerful and affectionate disposition of its head

It remains to estimate the influence of Darwin s theories on his time and on the future But this is a task for which a whole book would not be too much and a task moreover which could be better accomplished on the two hundredth than on the one hundredth anniversary of his birth

We can at least say however that the influence was a great and many-sided one and that it will endure throughout all time All who know the position of science before 1859 will be ready to admit this the younger generation have grown up so thoroughly under the influence of Darwin s ideas that it must be difficult for them to realize the state of matters before his day

Let us speak of biology first But was there a biology then? Strictly speaking there was not there was zoology botany and even anthropology Each of these sciences consisted of a very large and well arranged mass of facts but with no intrinsic coherence among them This was supplied by the theory of evolution The different departments of science were not even then regarded as complete It was well known that there were many gaps in our knowledge but we were only seeking for missing details whereas in reality it was the main thing that was lacking—the unifying idea which Goethe had sought for and tried to supply in his theories of the plant prototype and of the skull

The science of embryology or as we now call it ontogenesis at that time consisted of a great number of observations interesting enough but without any recognized unity It was not a harmonious structure but a collection of finely-cut building stones But what a change when the luminous idea of evolution was added! Life seemed to be infused into the stones and almost spontaneously they formed a magic edifice The ovum now at last recognized as a cell was seen to be a reminiscence of the descent of all higher animals from unicellular organisms rudimentary organs such as the rudimentary eyes of blind cave animals were found to be sign posts indicating the racial history of those animals and pointing back to their sight-endowed ancestors This evolutionary view illuminated the whole science and not embryology alone but also comparative anatomy the understanding of the structure of animals. It became plain why the New Zealand kiwi should have little rudimentary wings under its skin, although it does not fly It is not in order that it may conform to an ideal of a bird, as was previously thought, but because its ancestors had possessed wings which were used in flight.

Physiology also gained much especially the theory of reproduction of heredity of organs of the cell and especially of the cell nucleus I do not mean to say that all these were the direct result of the idea of evolution but they have an indirect connection with it

Anthropology gained quite a new interest after it was recognized that man too was a product of evolution A vast number of problems presented themselves It was necessary to investigate the gradual becoming not only of the body but of the mind, the evolution of the Psyche and all that flows from it. Before that time there had been a history of language of law of religion of art and so on but it now became necessary to carry these further back—beyond Adam and Eve to the animal ancestors Undoubtedly a study of the phychology of animals is one of the essential tasks of the future! I can here only give a few hints without elaborating them but I must emphasize the fact that the idea of evolution in the form in which Darwin presented it to us has given an impulse to new life and further development in every department of human knowledge and thought everywhere it acts as the yeast in cider—it sets up fermentation This has already borne rich fruit, and we may hope for much more in the future

Our greatest gain from the theory of evolution has however been the evidence it affords of the unity of nature the knowledge that the organic world must be referred back to the same great everlasting laws which govern the inorganic world and determine its course Even if formal proof of this be still wanting the probability is now so strong that we can no longer doubt it.

It is not only the theory of evolution as a whole but the active principle in it the principle of selection that is transforming and illuminating all our old conceptions It is teaching us to understand the struggle silent or clamant among human races their rivalry for the possession of the earth and to understand too the composition of human society the unconscious division of labor among the members and the formation of associations. The development of classes and their union in a State appears in a new light when looked at from this point of view In this department a good deal has been already accomplished

The study of human health must be particularly influenced by the theory of evolution and a beginning has already been made in this department also

But there is another and very important point in regard to which the theory of selection must be our guide If we take a survey of the evolution of the world of life as we know it we see that, on the whole it has been an ascending evolution, beginning with the lowest organisms and advancing through higher and higher to the highest of all, man himself. It must be admitted that at certain stages in this evolutionary series we find retrograde steps (as, for instance, parasites and sedentary animals), but on the whole the direction of evolution has been an ascending one

I see no ground for assuming that this will be otherwise in the future According to the principle of selection the best will survive in the future as in the past, and mankind will ascend I do not believe we are likely to undergo any essential changes in a crude physical sense, we are not likely to grow wings, and even our mental powers may not be capable of much further improvement, but ethical improvement seems to me not only possible, but probable on the principle of selection Mankind will never consist of wholly selfless saints but the number of those who act in accordance with the ideals of a purer, higher humanity in whom the care for others and for the whole will limit care for self will it is my belief, increase with time and lead to higher religions, higher ethical conceptions as it has already done within the period of human existence known to us. But here again I can only indicate without following out my ideas I wished to express them because the principle of selection has so often been applied in an inverted sense as if the brutal and animal must ultimately gain the ascendency in man The contrary seems to me to be true for it is the mind not the body that is decisive in the selection of the human race

Thus we see the principle of evolution intervening transforming re-creating in every department of human life and thought and endeavor We owe this principle which has been so fruitful in results mainly to Charles Darwin, though he was not the only one nor the first to think it out But it was he with Wallace who secured it its place in science and made it a common possession of mankind by working it out in all directions and supporting it with another principle that of selection which explains the riddle of the automatic origin of what is suited to its purpose in nature Thus he cleared away the obstacle which would otherwise have stood in the way of the acceptance of the theory of evolution

By all this he has earned enduring fame in the annals of science His own country has not been ungrateful to him A colossal statue of him in marble decorates the British Museum from the background of the entrance hall he looks down on the passers by with the calmness of the sage His mortal remains lie in Westminster Abbey beside those of Newton

Fate too was kind to him He could truly say that his life was a happy one for it was filled with a great idea and he was supported by the consciousness that Goethe expresses through his Faust Es kann die Spur von meinen Erdentagen nicht in Aeonen untergehen This is true of Darwin and we may think of him as one of the great immortals among men

The Modern Motor Car*

Ten Years' Progress

By W W Beaumont

Motor vehicle engineering as generally understood may be said to be all modern although in fact it was born in England about 85 years ago Taking however only the ten years of the present century a survey of the advances which have been made will show that as a branch of engineering its progress has been unprecedented that the industry it has established has reached the incredible and that the new knowledge it has acquired to the advantage of metallurgy and other arts and manufactures has placed it in the front rank as a philanthropist to science

Early in 1900 the inventions and patient investigations of Daimler Butler Maybach Benz and a few original contributors in a less degree fostered by the mechanical skill of Levassor Peugeot, Mors, Renault, and others had proved so full of practical and commercial value that a large number of motor vehicle manufacturers had become established in Germany and France together with a few in England including the Daimler Company the Lanchester the Wolseley the New Orleans Star and Napier Vehicles from all these makers and more were among the 65 which started from Hyde Park Corner in April, 1900, on the 1 000-mile endurance and hill-climbing trial of the Automobile Club and of them 49 with more or less complete records entered the Crystal Palace and were exhibited there in the following month With two exceptions the whole of the vehicles exhibited were fitted with engines of the types originated by the first named inventors and makers the exceptions being small steam cars one of a type now not seen in this country Most of those which had not the type of gear transmission of the Daimler Levassor origin and Daimler Panhard Levassor, and Mors construction were of the very small powers now out of date

THE ENGINE.

To start from this preliminary as to what the courts call the state of the art of ten years ago a few comparisons may be made with present conditions In the first place the power of the internal combustion engines used to-day is on an average at least three times that of 1900 In that year the 12 horse-power Panhard engine represented the most advanced form of construction A Mercedes (Cannstatt Daimler) car of nominally 24 horse-power ran in the Nice-Marseilles race of March that year but its average speed was from five to ten miles less than that of five Panhard cars in the same race. All these engines had hit-and-miss governing and valve-operating gear with exposed cam shaft gearing, but they for the first time used the magneto-ignition apparatus which had been for years used by the French gas engine makers. Up to that time the engines of this type had been fitted with the flame-heated ignition tubes, with consequent inferiority as to period of ignition and pressure effects. Mors had, however, used one complicated type of electrical ignition, and Benz had always used another and simpler form but confidence in electric ignition was not established until after the Bosch magneto had been in use some time To-day electric ignition is universally fitted and the cars run many thousands of miles with it without any uncertainty engines of the same diameter of cylinders giving very much higher actual power than they did formerly At noise trials in 1900 it was a question of which engine made least noise, now it is more nearly a question of which engine makes any, even though quadruple the power is developed.

These advances have been obtained by the employment of valves of dimensions, forms seating, and ports of now known proper forms together with inclosed valve-operating gear beautifully made, by precise construction of valve-operating mechanism and cam forms, by the use of modern tools and methods which insure accuracy equal or superior to standard gages of a generation ago, and by the utilization of high property metals which permit a lightness in the construction of parts not dreamed of but a few years ago Steels of from 40 to 100 tons tensile strength and considerable toughness have been made at the suggestion of the automobile builder and largely as a result of the strenuous competition for pre-eminence in the race and other trials organized by the French and by the Royal Automobile Club

Things and materials which were the best possible in 1900 might to-day be looked upon as makeshifts,

* Engineering Supplement of the London Times

and very possibly the same remark will be true in 1920; but it is safe to say that there is no more perfect piece of machinery in the world to-day than the engine and other mechanism of the well made motor vehicle, and there never has been such perfection in the material, workmanship and performance of the finished thing.

TRANSMISSION AND GEARS

In 1900 the transmission mechanism was only beginning to be so completely inclosed as to run immersed in the most suitable lubricant and the transmission was in nearly all cases by chains exposed to every cause of wear. To-day by the use of the excellent steels that have been brought into existence for the purpose the gear wheels are of half or less the weight possible in 1900 and they run in oil tight gear boxes so that the teeth have hardly time to squeeze the oil from between their contact surfaces before they have passed each other with the result that their wear is almost insensible after propelling a car thousands of miles at average speeds which in 1900 were racing speeds.

The change speed gear of nearly all the cars of to-day including the best is of the longitudinally sliding type, as it was in Levassor's cars of 1895. This was then to the mechanical engineer a makeshift, but he had not then made the experiments he has since made with every other type of gear he has been able to devise. He therefore did not know that ten years would only show him that what he thought a makeshift was a good devise because by careful attention to the relations between the different speeds of the gear by study of the number pitch, and form of the teeth by the removal of unnecessary inertia stresses by lightening parts the acceleration of which had to be suddenly varied and by the improvement of the transmission to the gear this type of gear change could be made the best possible when all practical requirements are considered with reference to both the hypothetically and the expediently best.

Transmission to the driving axle by exposed chain is now but little used and direct driving by either worm and wheel as first used in motor cars by Lanchester or by bevel pinion and wheel all parts being inclosed is to-day most in use. The whole of the parts are made of very high grade materials and in good cars, are fitted with a precision impossible in earlier years. The improvements in the change speed gear and final transmission gear make it possible in cars having the now usual flexible engine and good clutch to change from one speed ratio to another in such a way that there is neither jerk nor noise and the passenger in a car does not know a change has been made. Improvement in this respect however is much wanted in motor omnibuses though with the changes that are being made and are yet to be made it will be forthcoming.

In 1900 speeds were much lower than are common to-day and comparison of the gasoline consumption then and now is not likely to be very trustworthy because it is difficult to allow for road and air resistance at the speeds at which consumption trials were made in 1910. Without such allowances the comparison is in favor of the best 1900 car—which is obviously wrong especially when the smaller weight of car per horse-power to-day is taken into account. It is not however at all certain that the carbureter of to-day is better suited to the average engine of to-day than was the simple Maybach carbureter to its engine of 1900, and there is no reason why it should be. Misconception prevails even yet as to carbureters as is shown by the fact that the best surface evaporator carbureter even now does not give the engine a carbureted air by which it can use gasoline more economically than with the ordinarily good jet or multiple jet carbureter. The makers of motor vehicles on a large scale have devoted the most painstaking and unrestricted experimental attention to this detail of the motor car well knowing the differences between the thing that will perform best under the varying conditions and circumstances of a carbureter on a car and the perfect carbureter in a laboratory.

BODYWORK

The car of 1900 had driving wheels larger—and sometimes much larger—than the front wheels and the general dimensions were influenced by those of ordinary vehicles. *Conflicting requirements thus made* the motor carriage body uncomfortable as a consequence of height of floor and deficiency of leg room. Much was said about inartistic design of bodies—but no artist offered any solution complain as much as he would of what was made. Ultimately the motor vehicle has become the most comfortable and luxurious of all known vehicles at the same speed on the same road as a result of the efforts of the motor car builder. He has had to produce bodies which are not only accepted as having every evidence of fitness but which will also withstand the shocks strains and vibrations of high speed over bad roads and show less of depreciation than would any other body work with a tenth of the mileage and one third of the average speed. It is known that when cab and hansom owners had to adopt rubber tires they saved a large part of the whole cost by the difference between the cost of the body upkeep with and without such tires. What the cost of the old cab and hansom upkeep would have been at an average speed of say 25 miles an hour with a travel of 400 miles a week can be estimated by those who are informed on these matters and they will be able to affirm that the improvement during the last ten years in body building and finish as applied to motor vehicles is the difference between an admittedly temporary makeshift and a satisfactory stage toward perfection.

A very great part of the whole of the depreciation of a motor vehicle is caused by the severity of the jolting twisting and vibration resulting from modern speed on roads most of which are not modern. Much may be done by elaborate springing by shock absorbers which refer the shock to the wheels and axle and by other means but ingenuity of this kind is expended in fighting what must be hoped to be a declining enemy. It is not a sensible proceeding that insists on multifarious appliances which may enable a car to run at high speeds on badly paved roads when it is known that generally the car will in fact run on much better roads and that a slow speed on the bad ones will avoid most of the trouble and discomfort and thus make these appliances unnecessary. To a very great extent the motor problem is a road problem and although all horse pulled vehicle owners have always taken bad roads as they do thunderstorms there is no reason why engineers and motor car owners should do so especially as good roads well and continuously maintained are in the end cheap.

DURABILITY

The comfort of motor vehicle travel has increased in the last ten years to an extent that can only be known by those who traveled much by car in all seasons in 1900. Involuntary stoppages on the road except for tire punctures or the like are many hundreds of miles apart, and stoppages owing to mechanical defect in a good and well kept car are now causes of surprise. The 15 000-mile trial of the Rolls-Royce car by the Royal Automobile Club shows what is possible in this respect the wear at the end of that distance not being measurable in any but an unimportant detail and the whole cost of repair only a few shillings. On other cars the writer has run 7 000 miles without a single mechanical stop and over 4 000 miles without a single tire stop of any kind. This is mentioned because it has been suggested that things are not what they seem in motor vehicles and because it is said that durability and other trials are wanted. But durability trials are being carried on now by about 6 000 cabs and about 1 000 motor omnibuses in London alone and by many thousands of owners of other vehicles of various kinds. A great deal of this practical trial running may be said to be through the owners within the cognizance of the makers of the vehicles they and the omnibus and cab companies and their engineers are getting the experience the real knowledge of the weaknesses the defects and the good qualities and points. A motor omnibus runs from 25 000 to 30 000 miles a year and during that time its engine and gear will make many millions of revolutions and have to be equal to the arduous work of starting hauling and stopping a vehicle and load of over six tons every few minutes.

SIDE SLIP AND BRAKES

During the ten years many devices for preventing side slipping have been invented but they have not been free from the defects that (1) they involve inconvenient additions of appliances (2) they need prevision on the part of the driver alertness not being sufficient (3) they destroy the road surface or (4) they are ineffective. Good driving and cleanly roads are the true side slip preventers.

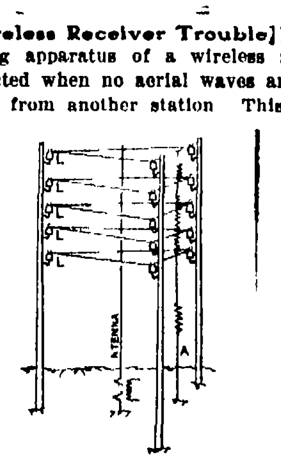
Brakes are now so generally well designed and well made that on the good cars of to-day if kept in adjustment they are quite trustworthy. A brake which is more than sufficient to skid the wheels is easily obtained but it is not a very desirable thing to put into the hands of most drivers and additional stopping appliances would probably be more expensive or troublesome than the wear of tires so long as tires are not skidded. A perfect brake such as an electro-magnetic brake without surface contact but depending only on cutting lines of force is hypothetically pretty but the ordinary brake which wears and causes some wear of the tires is in practice a better expedient—just as a leather boot sole which wears out is better than a copper sole which would last a lifetime. In conclusion then it may be said that the improvements made in the motor car during these ten years have been such as to earn universal appreciation even if not to remove all opportunity for the adverse and non constructive critic.

Poisoning by Gas from Heaters

A FACT which has a great practical bearing was brought out not long since by two French scientists relating to the slow poisoning of the system by gases given off from certain kinds of heaters used in private houses or hotels. Heating by hot air is not free from danger, according to their information and it appears that thirty-five persons who lived in a large hotel where hot air heating was used were subjected to a slow poisoning by gases and this gave some bad effects. It is carbon monoxide gas which causes the poisoning in this case and only a small quantity is needed such as 1 in 1 000 or in 10 000. In the present case some of the persons who lived in rooms which were free from this gas, did not show any bad symptoms. As to the others they showed troubles of different kinds nervous digestive or general. Among the nervous troubles were noticed vertigo fatigue insomnia or neuralgia. As to general symptoms we note that the persons lost flesh and became pale. These effects come from living for some time in the contaminated air but when the persons went to another place the symtoms disappeared or at least were lessened. Examination of the furnaces showed that they were very defective in their construction. It appears that some cities have the habit of mixing water gas with city gas, and for heating purposes this is a positive source of danger, and mortality from such causes is increased. We should remember that bad effects from the presence of gases are not easily detected at once, as the action is very slow, and thus the system may in time be very much affected when it is too late to take the needed precautions. Drs. Courmont and Mouriquand brought out these facts before the Paris Academy of Medicine.

Wireless Receiver Trouble

THE receiving apparatus of a wireless station is sometimes affected when no aerial waves are coming to the antenna from another station. This phenomenon is known as receiver trouble. It sometimes becomes very annoying and in the tropics often makes regular communication impossible during a period of twenty four hours. Investigations made at the Graefelfing station indicat that the trouble is due to atmospheric electrical disturbances caused by radioactivity.



ANTENNA SURROUNDED BY FARADAY'S CAGE

The earth is usually negative with respect to the air and the negative charge of the antenna favors the accumulation of radioactive deposits, which strongly ionize the air in the vicinity. Hence each wire of the antenna surrounded by a cylinder of air of abnormally high conductivity. The protrusion of the earth connected antenna into the atmosphere also distorts the equipotential surfaces and produces an abnormally high potential gradient over the antenna. The combination of high potential gradient and high atmospheric conductivity produces an abnormally great flow of electricity from the air to the earth through the antenna, and the variations of this flow set up electrical oscillations which affect the receiving apparatus.

These disturbances can be prevented by inclosing the antenna in a Faraday's cage with all of its wires placed horizontally so that they have no component in the direction of the electrical vector of the waves coming from other stations and consequently do not interfere with the reception of messages. These horizontal wires denoted by *LL* in the diagram are provided with an aperiodic or non oscillatory earth-connection *A*.

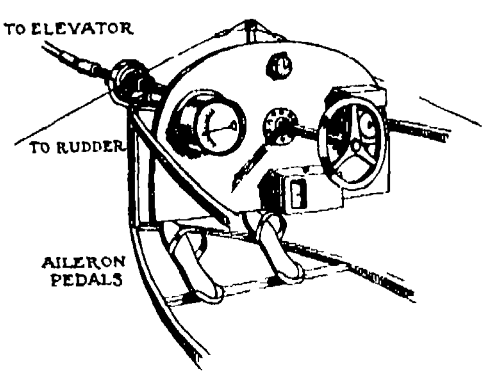
BEFORE a French scientific society M. Jouve has described the remarkable resistive property of ferro-silicon and other alloys of silicon. Nitric acid even as a vapor does not affect these alloys at all. Sulphuric and hydrochloric acid also have no effect. The same is true of acetic acid. The high price of platinum gives importance to ferro-silicon as a substitute to be used in the manufacture of acid resisting vessels but the alloy possesses a disadvantage in its brittleness and the thickness and weight of the vessels made of it.

The Maurice Farman Biplane

Scale Drawings of the Machine that Flew from Paris to the Puy de Dome

The Maurice Farman machine as first built, toward the end of 1909 was distinguished by the fact that it had vertical panels at the rounded extremities of the main planes and ailerons on the lower plane only The chassis was composed of skids and castor wheels Two smaller wheels supported the tail In 1910 after an alliance had been made between Henry and Maurice Farman the side panels were discarded and four ailerons were used The two small wheels supporting the tail were replaced by a skid From this period also dates the adoption of a rear elevator acting in conjunction with the front elevator Later in the military model the upper plane was extended In the Puy de Dôme model the castor wheels have been exchanged for those of the Henry Farman type and the leading edge of the main planes is now in line with the front uprights instead of being a foot in advance of them

The surface of the main planes which are covered with Continental fabric is 635 square feet, and the aspect ratio is 8 to 1 The weight of the machine is about 1 210 pounds and the speed 48 miles per hour A 60 horse power Renault air cooled 8-cylinder, V type motor has always been employed The Chauvière propeller is driven off the half time cam shaft



so that at a normal engine speed of 1 800 revolutions per minute the propeller makes 900

Maurice Farman was the first to use a covered body inclosing the seats and engine Some such construction is now recognized as essential for the comfort of the pilot and passenger In the accompanying sketch of the control the fabric inclosing the body is not shown for the sake of clearness On the dash board are placed a gradient indicator a timepiece an aneroid barometer and a recording barograph The handwheel is mounted on a square shaft which slides on rollers at the forward end Forward and backward motion of the shaft alters the angle of the elevator and rotation of the handwheel controls the rudders The pedals work the ailerons

On October 28th 1910 Maurice Tabuteau on a Maurice Farman machine broke the world's record (244 miles in 5 hours 3 minutes 5 seconds) by a flight of 290 miles in 6 hours 1 minute 35 seconds Later Henry Farman captured the duration record (making it 8 hours 12 minutes) and Legagneaux the distance record Tabuteau recaptured the distance record on December 30th by a magnificent flight at Buc of 365 miles in 7 hours, 48 minutes 31 seconds

thereby winning the Michelin cup for the longest flight of the year

The greatest triumph of the Maurice Farman machine is the winning of the prize of 100 000 francs offered exactly three years before by the Michelin brothers On the morning of the 7th of March Renaux and Senouque left Paris for the summit of the Puy de Dôme mountain 235 miles distant. They reached their destination in 5 hours, 10 minutes 46 seconds including a stop of 14 minutes at Nevers. This achievement marks an epoch in the history of aviation, as it is the first successful long cross-country flight with a passenger made in less than six hours It demonstrated the possibilities of the aeroplane for the rapid transportation of passengers from point to point, and without doubt before the summer is over we shall see aeroplanes regularly used for this purpose

On the need of the aviation world of a grand prize for a stupendous feat, the Michelin brothers—France's great tire manufacturers—based their $20,000 prize three years ago. The great flight they proposed was one of 223 miles from Paris to the Puy de Dôme mountain, a 4,812-foot peak located near their works at Clermont Ferrand The aviator must carry a passenger and make the flight within the elapsed time of six hours, circling the Arc de Triomphe at Paris at the

and turning about the steeples of the cathedral of Clermont-Ferrand before the finish As the summit of the mountain afforded a very constricted landing place, it was generally supposed that an aviator attempting to land upon it would demolish his machine and perhaps be killed or seriously injured and consequently a month or two ago the Michelins attempted to modify the rules to read that a safe landing must be made without breakage of the machine This modification was not allowed but Renaux fulfilled it nevertheless.

At the time the Michelin prize was offered the best records abroad were for height 12 meters (39 4 feet) made by Blériot in August, 1907 and for distance and duration 2 004 meters (6 575 feet) and 3 minutes and 39 seconds respectively (made on March 21st, 1908—two weeks after the trophy was offered—by Henry Farman) As for carrying a passenger this had never been done, even by the Wrights in America So improbable did it seem to the donors that the feat their prize called for could be accomplished that they allowed a period of ten years in which it could be won

The marked advance in aviation in 1909 and the far greater and more rapid progress made last year caused two attempts to be made last summer One of these —that of the Morane brothers in their Blériot monoplane—resulted in an accident soon after the start owing to a reserve can of gasoline breaking loose and interfering seriously with the steering gear The monoplane plunged to the ground and the two brothers were both badly injured The other attempt by Weyman a young Haitian in his Henry Farman biplane was much more successful Weyman getting within fifteen or twenty miles of his destination but being compelled to descend on account of night setting in after he had lost his way and made several descents *en route* in the fog

The first of last month Weyman with his Henry Farman biplane and Renaux with a similar Maurice Farman machine began practising making long glides from heights of 1 000 feet or so and alighting upon a small marked-off spot Next they perfected themselves in alighting upon such a spot with a passenger

On Monday March 6th Renaux was ready to attempt the great flight, but weather conditions at the P y de Dôme were not favorable The next morning however word was received that the air was clear with no wind As there was only a light and favorable northeast breeze blowing at the aerodrome at Buc Renaux got out his machine and climbed aboard with his passenger M. Senouque He left the ground after a short run at 8 50 A. M and flew to the Aero Club park at St Cloud where he crossed the starting line at 9 12 34 2/5 Heading straight southward he flew above the aerodrome of Juvisy at 9 28 Fifty minutes later he passed over the railway station at Montargis and flew down the line at an elevation of 1 000 feet overtaking and beating an express train. In another hour he crossed Cosne at high speed and at 11 30 La Charitié at a height of 600 feet. A quarter of an hour later the machine was sighted by the great crowd that awaited it at Nevers, where Renaux had planned to alight and take on fuel After circling gracefully about the cathedral of St Cyr the aviator alighted upon the aerodrome of the Lone Poplar at 11 53 30 His time for this first stage of the journey (141 5 miles) was 2 hours 40 minutes 55 3/5 seconds and his average speed about 52¾ miles an hour He reported heavy wind gusts near Briare, but the favorable wind had enabled him to maintain a high speed

After a stop of about a quarter of an hour for luncheon, Renaux re-started at 12 07 37 P M In an hour and a quarter he reached Moulins. An immense crowd awaited him in the country thereabout. He flew over the city at a height of 1,800 feet and M Senouque waved to the people that all was well. Following the valley of the Allier he soon reached Gannat (1.37 P M.), and at 1:53 the biplane was above Riom and almost at its destination.

At Clermont-Ferrand when the town clock struck 2 the great crowd assembled about the cathedral and up in its spires gave a cheer as those at points of vantage were able to discern a gray speck on the horizon Plainer and more distinct it grew and larger and larger as it approached at a height of 1 600 feet or more Fourteen minutes lat r the biplane passed over the cathedral spires amid tumult ous applause and turning sharply headed for the Puy de Dôme which was dimmed by a light fog In 13 min tes ore it ascended some 3 500 feet cir led about and descended easily upon the spot prepar d for it whi h was only a few square yards in size and was marked by wide red bands on the rocky ground Af er a n ag ifice t *vol plané* the biplane alighted easily and Renaux stiff with the cold was helped from his seat.

In describing his trip M Re aux said that soon after the start from Paris he suffered with cold and with cramps in his stomach So hard did he have to work at his controls to maintain equilibrium and so badly did he feel that when he reached Montargis he almost made up his mind to descend. Luckily however the fog dissipated and the weather improved giving him new courage and causing him to keep on his way His companion, who was busily engaged studying the map encouraged him by nods of his head Near Cosne they came upon the riv r Loire and for the rest of the journey they followed this and the Allier and had no difficulty in finding their way Nevers was reached and the stop made for replenishment of fuel and for luncheon as told above On e nore on his way Rena x had s m d bts of l is a o sl g l j r ey l 5¼ hours time as he lad b t h s f iends h wo ld do if he had good lu k a d g o l w a h H wonder d if the Puy de Dôme wo d ever show i self on the hori zon He was look ng anx o s y for the m ntain and finally at Gannat 28 mi s away he dis overed t He then began to l l f o 2 0 to 5 900 fee estimating hat this h ght wo d be necessary i order to les e d u the su nn it of he mo ntain At Rio h saw loo u t e dis a he spi s of the c thedr l whi h were his last t rn g poi t In less than t n n inu es th n a l was above Clermont a d he was withn t n min tes of his goal He wondered if l ke the unfortuna e Chavez he wo ld pay with his life for the g gantl l ory he had all but ac omplished He had been c imbing ti uously and now found himself at too high an elevation At this mon ent he was at Braq e at the fork of the roads which lead t Moreno and to Ceyssat He de sc ded again little by l ttle as he approached the sum n it Finally at just the right distance he cut off the spark and g ded n agnifice ly to the summit of the fa no s P y de Dôme

The distance c vered i the first stage of this flight that is from St C o d to Nevers was about 141½ miles whil he balan e of he journey to Clermont Ferrand and the P y de Dô ne was 93½ miles The first half of the jo rney was overed at a higher speed on ac ou t of the wind w h h was favorable The last half was overed a an average speed of 41 1/3 miles an ho r the time in flight bei g 2¼ hours The total e aps d t me was 5 hours 1 min tes 4 ½ se onds Deducting the stop at Nevers the total time in flight was 4 hours 56 minutes 38 3/5 seconds which corresponds to an average speed of 49¾ miles an hour—a remarkably high average considering the amount of climbing' that was done during the trip It will thus be seen that the journey was accomplished with 50 minutes to spare as the time allowed for the flight was 6 hours.

The Chemistry of Inks in Handwriting*

Things the Expert Must Know

By C Ainsworth Mitchell, B A (Oxon), F I C

Before giving an account of some applications of chemistry in the direction of the general principles underlying the chemical methods of distinguishing between different kinds of ink in handwriting I may perhaps be allowed briefly to recapitulate the main outlines of the theory and to add some details by way of illustration

Ordinary writing ink is essentially a mixture of a decoction of galls with a solution of copperas (ferrous sulphate) which slowly interact to form an iron tannate that gradually becomes oxidized by exposure to the air and gives the black pigment of handwriting

Characters written with a pure iron gall ink are nearly colorless when first put upon paper and a considerable time is needed for the insoluble black tannate to be formed within the fibers

Prior to about the end of the eighteenth century inks were exposed to the air or boiled so that a partial oxidation might take place within the fluid and thus give some depth of tint to the product before it was used for writing The chief objections to such partial oxidation are that deposits are formed in the bottle and prevent the ink flowing smoothly from the pen and that the fluid has not the penetrating power of an unoxidized ink Such inks however are still on the market under the name of Japan inks but they are but little used their place having been taken by unoxidized inks in which the black pigment is as it were in a latent condition and a second pigment such as indigo logwood or an aniline dye-stuff is added to give a color to the writing pending the formation of the iron tannate

The dye-stuffs employed in the commercial inks of to-day vary in color from pale greenish blue to indigo and deep violet and no two give identical reactions—at all events when mixed with iron tannate to form the pigment in writing It is mainly owing to the differences in these provisional coloring matters that it is possible to distinguish between handwriting written with different kinds of ink

In the old type of iron gall ink in which no such second pigment was used it would only have been possible to distinguish between different makes of ink in handwriting in exceptional cases such as when a large excess or a great deficiency of iron had been used Such irregularities in composition might readily occur however for in the days before the ink manufacturer could have made a living writing was a polite accomplishment restricted to those who could afford the time and the ink was made at home Each housewife had her recipe for making a good ink and its preparation was as much within her province as the making of cordials or the baking of bread

A particularly interesting example of a domestic recipe which was handed down as an heirloom is shown in the accompanying figure which Mr G Weddell has kindly allowed to be reproduced

This was taken from a manuscript collection of old family recipes dating back into the sixteenth century which Mr Weddell has published in facsimile (*Arcana Fairfaxiana Manuscripta* 1890) Directions are given for making everything needed for household use from apple pastes to cures for the kings evil and among its odd assortment of items are included several recipes for making ink of which the example (Fig 1) which was probably written toward the close of the sixteenth century is typical

The directions here given are to soak five ounces of galls in one quart of rain water (or claret or red vinegar) and to boil the decoction after five days standing with four ounces of copperas and three ounces of gum

Ink made under the rule-of-thumb methods of the housewife must inevitably have often varied widely in composition and it is to such variations from the right proportions of iron to galls that we must attribute the want of permanency of some relatively modern writings as compared with that upon manuscripts centuries older

No more interesting illustration of this effect of composition of ink upon the permanency of writing can be found than in the various names written on the first page of Miltons family Bible to be seen in the British Museum It will be noticed that all the entries of the births of himself and the members of his family are in the handwriting of Milton and that with one exception all the inks are of a good dark tone The exception is seen in the entry of the birth of his daughter Deborah on the 2nd of May being Sunday, somewhat before three of the clock in the morning 1652 Here the ink has faded to a faint brown color

Considerable variations are possible in the proportions of iron to gallotannic acid without changing the nature of the resulting black pigment but if there is a deficiency of tannin outside those limits insufficient

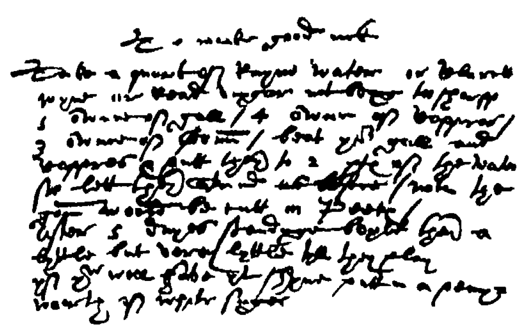

Fig 1—Elizabethan Domestic Recipe for Making Ink

pigment will be formed and the excess of iron will cause the writing to turn brown A lack of tannin to combine with all the iron in the ink is probably the explanation of this faded entry in Miltons Bible

The actual pigment formed when ink dries seems to be the same whether the proportion of tannin to iron be large or small The writer has made numerous analyses of the deposits produced when solutions of the two substances of varying strength were allowed to stand in contact with the air and has found them to contain from 5 4 to 6 2 per cent of iron

Of the known insoluble iron tannates the one that best corresponds with this proportion of iron is that described by Wittstein (*Jahresb der Chem* 1848 28

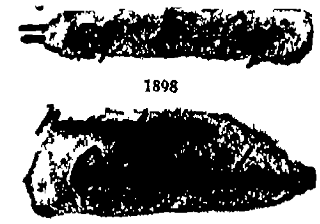

Fig 2—Showing the Action of Oxalic Acid on Inks Written in 1898 and 1908

221) and by Schiff (*Ann Chem Pharm* 187 175 176) which contains 5 3 per cent of iron and has the formula

$$Fe\,(C_{14}H_9O_9)_2$$
$$|$$
$$Fe\,(C_{14}H_9O_9)_2$$

It is probably this compound that is produced when ink dries on paper and that the more nearly the proportions of galls and iron sulphate are calculated to form this tannate without excess of either ingredient the more permanent will be the writing

Many of the commercial inks of the present day deviate widely from this standard and as everyone must have noticed the writing done with some of them

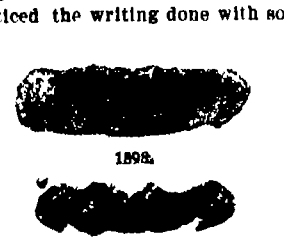

Fig 3—Showing the Action of Acetic Acid (50 per cent) on Inks Written in 1898 and 1908

will fade considerably even in the course of a year or two

Notwithstanding the probably closely similar methods of preparation the composition of different kinds of ink shows wide variations Thus, out of twenty four different varieties of writing ink sold in this country the writer has found the total amount of solid matter to vary from 1 89 to 7 94 per cent the ash from 0 42 to 2 52 per cent, and the iron from 0 18 to 1 09 per cent

Analyses made by the writer at intervals of three or four years have shown that the composition of the products of the same manufacturer shows but little variation This is only what was to be expected, since naturally when a satisfactory article has once been obtained great care is taken to keep it constant by using the same proportions of water, galls, dye-stuff and gum

In examining writing to ascertain whether it was done with a particular ink it is advisable to prepare a color scale with that ink consisting of four washes, ranging from the faintest to the darkest possible tone, and to leave this exposed to the air for at least twenty four hours The scale may then be compared under the microscope with different parts of the writing in question and is subsequently used for comparative chemical tests when such are permissible The broad surfaces of color are comparable with the surfaces of the written characters as seen under the microscope and there is thus obtained what practically amounts to a magnified record of the microscopical appearance

Lovibonds tintometer will also be found useful in comparing the colors of different specimens of handwriting and in matching the colors obtained in chemical reactions with those given by the color scales prepared from known or suspected inks

In some cases microscopical examination on these lines is sufficient to distinguish between the inks in different writings without the necessity of applying chemical tests The most striking instance of this kind within the writers experience was in the Brinkley poisoning case The will of an old lady named Blume had been forged by Brinkley who on the strength of being her heir took possession of all the property Mrs Blumes relatives contested the validity of the will and Brinkley had therefore to prove that it was genuine One of the witnesses whose signatures were on the will asserted that he had never signed a will at all but that he had only signed a folded sheet of paper in a public house As this witness Parker stood in the way Brinkley attempted to poison him by leaving a bottle of stout containing prussic acid at his lodgings but instead of Parker getting the stout it was drunk by his landlord and landlady both of whom died As a great deal depended upon whether Parker were speaking the truth or not the ink was obtained from the public house in question and was compared with the writing upon the will

As the ink happened to contain a particularly bright blue pigment as its provisional coloring matter there was no difficulty in proving its identity with the ink in the disputed signature on the will In fact three different inks were present on this will the body of the document being written in one kind of ink and the signatures of each of the witnesses in a different kind Brinkley cross examined upon this point stated that Mrs Blue had kept three different sorts of ink and that he had after her death given two of them to a little girl

After a trial lasting four days he was found guilty of murder and sentenced to death

For the differentiation of writing by chemical methods a wide choice of reagents is available but the following will usually be found sufficient (1) Hydrochloric acid (5 per cent solution) (2) oxalic acid (5 per cent solution) (3) stannous chloride (10 per cent solution) (4) nascent hydrogen (50 per cent HCl with zinc), (5) bromine (saturated aqueous solution) (6) bleaching powder (saturated solution), (7) titanous chloride, and (8) potassium ferro-cyanide (5 per cent solution containing 1 per cent of HCl)

Of these reagents the first two act mainly upon the iron tannate and leave the provisional coloring matter The third and fourth bleach the iron tannate and reduce the provisional pigment, changing its color The fifth and sixth reagents may act upon both pigments and cause more or less bleaching The titanous chloride acts as a powerful reducing agent on both pigments and the acidified ferro-cyanide solution acts mainly upon the iron liberated from the iron tannate

The reagents should be applied with a brush, and the writing examined under the microscope by reflected and transmitted light, firstly after five minutes', and then after twelve hours exposure to the air The colorations appearing on the wrong side of the paper are also characteristic in some cases In the tests with titanous chloride, blotting paper should be applied to the writing after the lapse of five minutes

The method may be illustrated by the following,

* Knowledge

results obtained with some of the best known commercial writing inks.

The question of determining the age of an ink in writing is much more difficult than that of deciding whether two writings are in the same or in a different kind of ink.

It is, as a rule, possible to distinguish colorimetrically between freshly written and old writing up to about the sixth day after which the iron tannate has become sufficiently oxidized to prevent further differentiation until after the lapse of two or three years or more when the provisional pigment will have faded or have become fixed by the iron tannate.

In most cases the provisional pigments employed offer greater resistance to the action of chemical reagents but are infinitely less stable than iron tannate when exposed to the action of light and of air and eloquent testimony to this difference is given by a comparison of certain manuscripts of the seventh and eighth centuries with typewritten documents in aniline ink which have been put aside for a few years.

Thus it happens that when writing done with blue black ink is kept the blue pigment will gradually fade out, leaving the black pigment, and when this stage is reached the ink in old writing is readily distinguished from ink that has recently been put on the paper.

Prior to this however the blue provisional coloring matter appears to become enveloped in particles of the oxidized iron tannate so that it no longer reacts rapidly with reagents.

Thus if a writing done within the last year or two be treated with a fifty per cent solution of acetic acid there is immediate diffusion of the blue pigment whereas in a writing a few years older diffusion if it takes place at all is very slow and limited in extent (see Fig 3).

A still more useful reagent is a saturated solution of oxalic acid which causes the pigment of relatively fresh writing to give an immediate smudge but has very little if any effect on writing six or eight years old. The differences between the behavior of old and relatively new writing in these tests is seen in Fig 2 in which the older writing of 1898 was scarcely affected whereas the writing done in 1908 gave the results shown. Both writings were in ink of the same kind and the tests were applied simultaneously.

Speaking generally a writing done with blue-black ink ceases to show such diffusion after about five to six years. When slight diffusion occurs in an older ink it is seen under the microscope, to differ in character and only to affect the surface of the letters whereas the diffusion in an ink written within the last two or three years affects the whole of the pigment in the letters.

The first occasion on which chemical evidence as to the age of an ink has been given in the law courts was in the recent forgery case in which Colonel Pilcher was accused of forging his cousin's will.

This will was alleged to have been written in 1898 and assuming this to have been the case the ink should have only reacted very slowly with the different reagents there should have been little or no diffusion with oxalic acid and if any slight diffusion occurred this should only have been upon the surface of the letters.

The ink on the will however gave an immediate reaction with the different reagents and diffused at once with oxalic acid and the diffusion extended throughout the whole of the letters. There was thus no doubt as to the ink upon the will having been written within the last year or two and certainly within the last six years.

Checks written by the deceased lady during the last thirteen years were also subjected simultaneously to the same tests and it was found that the ink upon those written in 1903 gave only a faint diffusion with oxalic acid in the heaviest writing while no diffusion at all was obtained upon the checks written in 1901.

The correctness of the conclusions drawn from these results was borne out by the confession of the prisoner who in the middle of his trial pleaded guilty to having uttered the will knowing it to be a forgery though he denied all knowledge of how it came to be forged.

Notes on the Economics of Locomotive Operation*

The Problems Presented by Increasing Size

By Prof Arthur J Wood

The locomotive is a power plant on wheels. Every year the demands on this plant are more exacting and as a result we find to-day the latest type developing over 2 000 horse-power weighing 445 000 pounds with all the weight on two sets of eight coupled drivers with a Walschaert valve gear compound cylinders superheaters and a hydro pneumatic reversing gear. Contrary to a somewhat common belief the modern locomotive if worked to advantage is an economical machine for what is demanded of it. But the demand for greater hauling capacity has emphasized and enforced the big problem in operation that of securing the most at the track out of a pound of the fuel burned. Let us briefly note some lines of progress leading to a better economy and to a higher efficiency.

THE THREE BALANCED FORCES

Let us be reminded that the locomotive is made up of three essential parts—the boiler the cylinder and the drivers. In this three-fold combination the boiler power is limited by the amount of steam that can be produced in a boiler of admissible size and weight. The cylinder power may be indefinitely great but not less than a certain amount the cylinder being a mere transmitting machine. The tractive power—or pull at the driving wheels—is limited by the total weight of the locomotive and the part of that weight which can be placed on the driving wheels. We have then three co-ordinate balanced forces. In practical working a lack of proper proportion in any one of these three co-ordinate forces which when combined make the completed machine will be shown in the following way. If the boiler power is smallest the steam pressure will fall and the wheels will stop. If the cylinder power is smallest the engine will be stalled when using full steam pressure and unable to slip the drivers. If the tractive power is smallest of the three the engine will slip the drivers. We come to see then that the locomotive is a balanced machine and in any attempt to increase its economy that balance should be preserved. Thus if we increase the boiler pressure and capacity say thirty per cent everything else remaining the same the drivers would be slipping some of the time if they were correctly proportioned before.

THE SCOPE OF THE PROBLEM

It is estimated that 125 000 000 tons of coal (one fifth of the coal production of the entire country) were burned last year on the 60 600 locomotives in the United States. This coal costs the railroads over $360,000,000. If a net saving of five per cent otherwise lost can be secured this item will be reduced by no less than $15 000 000 and will at the same time conserve one of the most valued natural resources of the country. If further this saving can be effected by the utilization of low grade fuels otherwise discarded and burned with more nearly smokeless combustion the results will be far reaching. Possibilities lie along many lines among which are the following. More perfect combustion better smoke box and front end construction by compounding superheating and from briquetted fuel. The first two of the above have general application while the others have given noteworthy results where the conditions were favorable. To these may be added the saving from the introduction of a perfected mechanical stoker eight or ten of which are being tried out. This saving—estimated on certain roads from ten to fifteen per cent—will come largely from the uncontrolled losses due to improper hand firing.

In a recent analysis of the heat losses in a simple locomotive with superheater running on the test plant at Purdue University Dr W F M Goss finds that a little over forty per cent of the heat in the fuel never has a chance to turn water into steam as shown in the table following.

TABLE I

AVERAGE HEAT BALANCE FOR TEST LOCOMOTIVE

(Percentages of total heat available)

Absorbed by the water in the boiler	52
Absorbed by the steam in the superheater	5
	—
Absorbed by steam in the boiler and the superheater	57
Lost in vaporizing moisture in the coal	5
Lost through the discharge of CO	1
Lost through the high temperature of escaping gases and in the products of combustion	14
Lost through unconsumed fuel in the form of front-end cinders	3
Lost through unconsumed fuel in the form of cinders or sparks passed out of the stack	9
Lost through unconsumed fuel in the ash	4
Lost through radiation leakage of steam and water etc	7
	100

The above suggests the grouping together of some of the various means of securing better results indicating under each what is being undertaken.

A.—More complete combustion and better firing	(1) Certain roads notably the Erie the C & N W and the B R & P have been giving regular instruction to firemen in the right methods of firing. (2) Adapting the coal to the best conditions of firing
B.—Saving in losses from stack and front end	Design of self-cleaning front ends and reduction of losses as a result partly of exhaustive tests at Altoona
C.—Adapting locomotive weight to required service and in compounding	Introduction of the Mallet articulated compound locomotives (with all the weight on drivers) and having two independent sets of coupled drivers for mountain grades where one locomotive can do the work of two smaller engines
D.—Reducing high temperature in exhaust gases	Adapting the Schmidt Baldwin Schenectady Jacobs Cole Vaughan Horsey and other superheaters

We may look a little further into these questions.

A COMBUSTION

Approximately 544 000 cubic feet of air are required to supply the necessary oxygen to completely burn one ton of coal; less than this means waste in the form of unburned carbon. Not only must the air be supplied but it must be supplied in the right quantity at the right place. The simple principles of combustion may be studied from the best theoretical furnace on the market, that of the common coal oil or kerosene lamp.

The upper part of the chimney of the lamp corresponds to the stack. The larger part of the chimney is in the analogy the combustion chamber including the front end of the locomotive. The small space just above the wick is the fuel bed and the air openings below are the openings through the grates for air supply.

First remove the chimney open the hood and light the wick which should be evenly trimmed. If turned low it does not smoke. Close the hood and the flame smokes because the hood has cut off the air about the flame thus illustrating a furnace with insufficient air where most needed a condition which occurs when we have too much fuel on the grate.

* Railway Indicator

Second, place the chimney in its right position on the lamp. The smoke ceases and the flame brightens, showing better combustion. This better condition is from the fact that the draft draws more fresh air about the wick just where demanded.

Third chill the flame by means of a piece of iron held in it, thus cooling the gases before combustion is complete illustrating the condition when too much cold air strikes the flame.

Fourth when burning brightly with the chimney on shut off the air supply by wrapping a cloth about the hood closing off the required air supply and the flame smokes as it does when the dampers in the fire box are closed too much.

Fifth break a hole into the side of the chimney or raise it from its seat and the flame is chilled and the lamp smokes as we are admitting air where it is not most needed. Open the fire door of the locomotive and the same thing happens the air being chilled before combustion has been completed.

From these simple experiments, which any reader can make we learn that the conditions for preventing smoke and securing better fuel economy are

1 That the fuel be supplied in small quantities and just enough air be passed up through the grates to burn it

2 That the gases be distilled from the coal at a uniform rate

3 That the air be heated by passing through the bed of hot coals

4 That the volatile gases given off shall mix with the fresh supply of air so that each particle of the carbon elements gets its necessary supply of air

It is understood that smoke comes chiefly in the burning of bituminous coal. The losses in black smoke are not large scarcely ever exceeding one per cent of the heat in the fuel. A furnace working with a minimum air supply may give out dense clouds of smoke but still give a higher evaporation than one made smokeless by an excess of air. Consequently smokeless combustion is only an indication of conditions in the fuel bed and is a very small part of the question of fuel economy. The simple principles of combustion should be well understood by every fireman, and their application be enforced by more systematic instruction. While it is true that locomotives in poor condition are often turned over to the engine crew and they are expected to get results with poor fuel yet the evil from improper handling of the fuel is by far the greater of the two.

Special Fuels.—The kind of fuel—its chemical composition its size friability ash and moisture—also influence economy. In one of many results using Lloydell raw coal and the same coal pressed into briquets being held firmly intact by aid of a binder (see Bulletins 412 and 363 U S Geological Survey), it will be seen that the briquets gave ten to fifteen per cent higher evaporation than with run-of mine coal from which the briquets were made. It has been shown that steam can be kept up easier with the briquets but the disadvantage comes from decreased storage capacity in the tender difficulty in shoveling and last but not least difficulty in firing.

Road Tests of Briquets.—In co-operation with the Missouri Pacific the Lake Shore and Michigan Central the Chicago Rock Island and Pacific the Chicago Burlington and Quincy and the Chicago and Eastern Illinois railroads 100 locomotive tests have been made for the United States Geological Survey to determine the value as a locomotive fuel of briquets made from a large number of western coals. All tests were made on locomotives in actual service on the road. In some tests there was small opportunity for procuring elaborate data, but in others, where dynamometer cars were employed it was possible to obtain more detailed results. In nearly every test, the results reported show that the coal when burned in the form of briquets gives a higher evaporative efficiency than when burned in the natural state. For example, Indian territory screenings gave a boiler efficiency of 59 per cent, whereas briquets made from the same coal gave an efficiency of 65 to 67 per cent. Decrease in smoke density and in the quantity of cinders and sparks are named as the chief reasons for increased efficiency.

Similar comparative tests in 1907 on the Atlantic Coast Line showed a saving of 20 per cent in the pounds consumed per car mile and with the elimination of black smoke and clinkers. On the W and L E a gain of 16 per cent was secured in ton miles hauled by using three-fourths coal instead of run of mine the former costing 8 per cent more at the mine. Development lies in the direction of making it possible to use to advantage the low grade fuels and in this the briquets have just begun to open up a new field. The cost of briquetting is roughly $1.25 per long ton.

B FRONT END LOSSES

Referring to the table by Prof Goss, we find that in his tests 12 per cent of the heat of the coal is lost in the front end cinders, and in cinders and sparks passing out of the stack. To correctly design the smoke box, a long series of tests were made three years ago on the Altoona plant with an Atlantic type locomotive of the Pennsylvania Railroad. Approved forms of a self-cleaning front-end arrangement were designed as an outcome of this series of tests. A study of this result compared with the Master Mechanic's front-end design shows a change in the relative proportions of the stack, the exhaust nozzle and the diaphragm plate, the result being much better evaporation in the class of locomotive tested over the same class with the old arrangement in the front end.

C ADAPTING LOCOMOTIVES TO SERVICE.

Another way of effecting economy in operation lies in adapting the train load and speed to the particular engine best suited to meet the conditions. The most marked advance attracting attention and interest in this particular is in the adoption of the Mallet articulated compound locomotives. An articulated locomotive is one composed of independent cylinder and driving wheel units "tied together at a joint." One example of economy by using an engine of this type is on the Delaware and Hudson Railroad. Four runs were made the past summer with two pushers of the E-5 class, 2-8 0 type with a total weight 246,500 pounds, 217 500 pounds of which is on the drivers then four runs with one of the Mallet locomotives having 445 000 pounds on the drivers followed by four more with another Mallet. The tonnage of all trains were practically the same. The result showed that the Mallet locomotives did almost exactly the same work as the two E-5 engines with a saving of 40 per cent in coal and 27 per cent in water.

D. LOCOMOTIVE SUPERHEATERS

A superheater is a device whereby additional heat may be applied to the steam after it has been evaporated by the boiler. The advantage comes in (1) reducing or eliminating cylinder condensation, (2) increase of available temperature range of expansion without increase in pressure and (3) the large increase in steam volume with a comparatively small increase in heat to superheat.

In 1901 the Canadian Pacific introduced the use of superheated steam on locomotives in America and nearly 500 Vaughan Horsey superheaters are now in service on that road. The Atchison Topeka and Santa Fe with 168 locomotives thus equipped, comes second in the list of twenty roads in this country now trying out a total of eight types of superheaters. The Schmidt superheater is used on 130 railroads in Europe applied to over 5 000 engines. The adoption of superheaters in this country has on the other hand been along more conservative lines notwithstanding the fact that nearly all the roads using them report a material saving in coal and at least half the number find no increase cost in running repairs. The most serious trouble experienced has been in leaky gaskets and filling of front end and flues with cinders.

The question of the amount of superheat is a most important one. The Purdue tests have shown that the first 80 to 100 degrees superheat do not make the same proportional decrease in coal consumption as do the second 80 or 100 degrees. European practice is to superheat until the temperature is 500 to 600 deg F or over in fact, as high as possible and still maintain good lubrication with forced lubrication for the balanced piston valves. This general practice applies to simple and to compound locomotives in both cases the attempt appears to be to prevent condensation in the cylinder. This makes an expensive construction to maintain and it has not met with favor.

Recently tests were run on a tandem compound, 2-8-0 type of the Atchison Topeka and Sante Fé Railway equipped with high and low pressure superheaters versus the same class of engines without superheating. Both superheaters are in the front end the low pressure superheater being directly ahead of the front flue sheet and the high pressure in front of the low pressure superheater, both being designed so as not to obstruct the flow of the gases more than necessary. In the following summary the first column gives the results for the locomotive with the superheaters.

Mr H B MacFarland, engineer of tests of the Santa Fe Railroad, has drawn the following conclusions from those made.

1. "There is a marked decrease in coal consumption for a superheater engine. The decrease averages 20 8 per cent per thousand ton miles for up-grade runs, 11 5 per cent for down grade runs, and 19 6 per cent for constant hard working of engine on heavy grades."

2. "Superheater engine uses 10 per cent less water per hour, developing more drawbar horse-power on heavy working."

3. "Superheater engine with 16.6 per cent less heating surface gives equivalent evaporation of 10 6 per cent more water per square foot heating surface than non-superheater engine."

4. "Superheater engine developed 30 per cent more draw-bar horse-power per square foot of heating surface than non-superheater engine."

TABLE III.

	Superheater.	[illegible]

Boiler horse-power	1,1[illegible] 0	[illegible] 0
Boiler efficiency per cent	[illegible]	[illegible]

Mr MacFarland informs the writer that the cost of equipping engines with the superheaters used in the tests is $898 of which $750 is for the superheater, $75 for applying the same and $73 for cutting off the flues and setting the flue sheet back. If we assume the cost complete of a locomotive of this type and class as $15,000 the cost of applying superheaters is approximately one-seventeenth of the first cost. The Atchison Topeka and Santa Fé Railway is having certain engines equipped with low pressure superheaters only. These will be run in service to determine if this is the most satisfactory arrangement of installation in order to get for this and others the net economy with front-end superheaters for many conditions.

The study of this question on the Santa Fé is the most important investigation of the superheater equipment for compound locomotives undertaken in this country. Assuming 450 deg F as the maximum temperature allowable in the steam chest, the present development as being worked out is much more attractive than any of the methods requiring excessively high temperatures.

From the data given the writer has plotted a temperature-entropy diagram. To any not familiar with this diagram it may be stated the areas represent heat units expressed in B t u. In the original of this particular diagram 1 square inch equals 10 B t u. Knowing the number of B. t. u. in a unit area we may readily determine the heat change represented along any line. This is all we need to know to understand its application to the problem in hand.

Fifty-eight and sixty-one-hundredths B t. u. per pound of steam equals work done in high-pressure cylinder which is less than one-half of the amount of work done in the low pressure cylinder. The same fact is shown from the horse-power results given in Table II. The work could have been more equally divided by changing the cut-off in the low pressure cylinder. In stationary practice it is common to divide the temperature range equally between the high and the low. This would have given a better distribution in the case at hand.

We conclude (1) that a small amount of superheating in the high pressure cylinder is of little or no advantage, (2) when the pressure drop is large between the cylinders large gain is effected by a considerable superheat in the low pressure cylinder, (3) for the same amount of heat in the superheat (in the case considered) we could theoretically gain less in heat transformed into work by using the two superheaters than we could by the same amount of heat in one high pressure superheater, but this requires the objectionable high superheat, and (4) superheating to 100 degrees or over for the low pressure cylinder is, theoretically an attractive proposition, the practical results of which will be learned later with interest.

It must be understood that actual conditions on a locomotive will not correspond exactly with the conditions which have been taken in this study. For example, the writer has assumed adiabatic expansion. Actually, it is modified by cylinder condensation, but since it was considered the same in all cases the results may fairly be compared in the way outlined.

Mastering the Alaskan Glacier Barriers

By LAWRENCE MARTIN
Professor of Geology University of Wisconsin

GLACIERS have both helped and hindered exploration and settlement in Alaska which we purchased from Russia forty three years ago for a little less than seven and a quarter million dollars We have since removed over seventy million dollars worth of furs especially the seal one hundred and nine million dollars worth of fish especially salmon and one hundred and sixty two million dollars worth of minerals especially gold In accomplishing this men have had to cope with conditions of mountain glaciation to a greater extent than any where else in the world The following paragraphs will narrate some of these difficulties and the ways they have been met

NECESSITY FOR TRAVELING OVER GLACIERS

The Klondike district and the adjacent gold fields in Alaska were separated from the coast by a lofty mountain barrier This could be crossed at Chilkoot and White Passes or the lower Yukon could be ascended The latter route was long and difficult and unexplored the former was also hard and led through Canadian territory Accordingly the prospectors sought a short all American route and found that the head of ocean navigation at the east entrance of Prince William Sound near the mouth of Copper River was nearer the gold fields than Skagway the beginning of the White Pass route They did not count on the range being double however or on the higher passes or the glaciers The lower Copper River valley is barred by three great glaciers projecting from either side and making river navigation impossible Most of the prospectors therefore turned their attention to Port Valdez the northeastern extremity of Prince William Sound Here rumor said that the Russians had a route to the upper valley of the Copper River where gold was also reported Here however canyons and unexplored high passes made a pass in which there was a glacier barrier the only highway to the interior If the Valdez Glacier were not there this pass would furnish the shortest road or railway route to the copper mines of the Wrangell Mountains the coal fields of the Matanuska River and the interior of Alaska. The harbor is the best and takes ocean steamships farthest back into the land In the valley and pass however is a glacier barrier

THE GLACIER BARRIERS OF LOWER COPPER RIVER

As already stated the Copper River is apparently the logical highway to interior Alaska Only a few prospectors entered this way in 1898 and 1899 however and army officers had previously shown in 1884 and 1885 that this route was difficult dangerous and impracticable

The specific difficulties and dangers occur in connection with the three great glaciers of the lower Copper River There is now no great trunk glacier occupying the main valley as in the case of the valley at Valdez Instead we have three glaciers projecting into the valley of Copper River two from the west and one from the east. These are about 3 miles from the Pacific Ocean They were long known to the natives and to the Russians and were seen and named by Abercrombie and Allen of the United States army in 1884 and 1885 and revisited by the former in 1898 after his trip across the Valdez Glacier highway

Childs Glacier three miles wide projects into the valley from the west ending in a magnificent cliff shown in one of the photographs reproduced here It constricts the river and forms dangerous rapids up which boats can be lined with great labor and danger because of the swift current and the great waves from falling ice masses The river is so retarded that a lake is formed above Childs Glacier in which Miles Glacier terminates

Miles Glacier enters the valley from the east, as shown on the map Part of it projects only slightly from its valley and terminates in a beautiful ice cliff 200 feet or more in height and with a frontage of two and a half miles in the lake into which it discharges many icebergs The remainder of the Miles Glacier terminus which expanded into a bulb in the main valley is a low dark surface five or six miles wide projecting clear across the valley from the east to the west wall and forcing the Copper River into a narrow channel called Abercrombie Rapids At Abercrombie Rapids this dirty part of Miles Glacier has been in

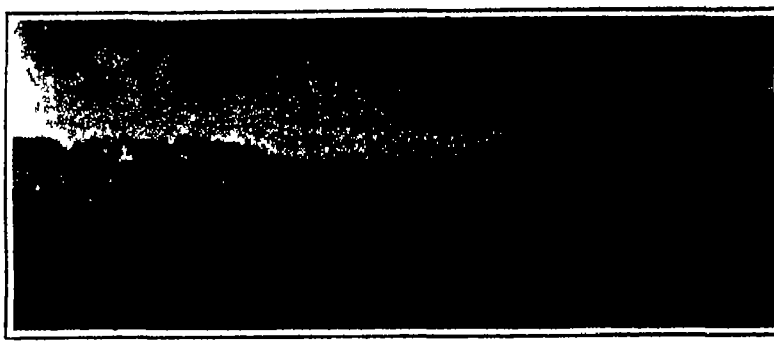
MASTERING THE ALASKAN GLACIER BARRIERS

active since some time during the Russian occupation of Alaska and does not look like a glacier at all for its ice is veneered with dirt stones and soil in which a thicket of shrubs has grown At Abercrombie Rapids the river is so narrow and swift that it plunges down in a series of boiling rapids not inferior to those below Niagara It is unnavigable for steamers and small boats are taken through with the utmost labor and hazard



THE MILES GLACIER AS SEEN FROM THE COPPER RIVER THE MOUNTAINS IN THE BACKGROUND ARE 8 000 TO 10 000 FEET HIGH

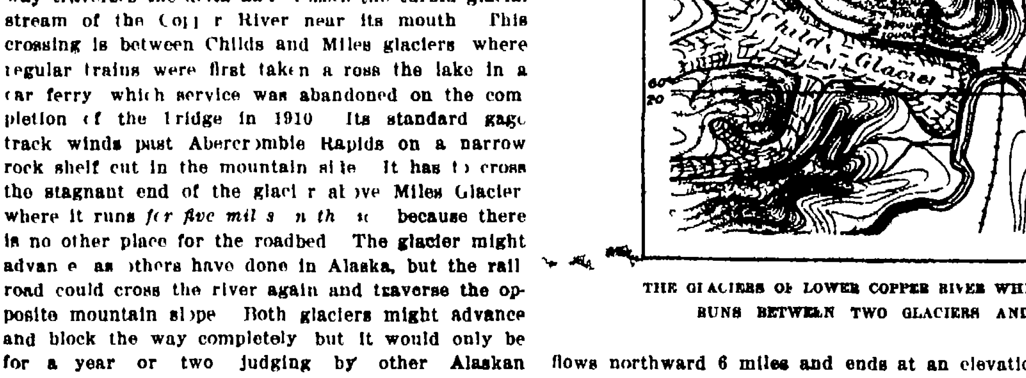
Above Miles Glacier where a third great glacier the Allen projects into the valley this time from the west the Copper River is forced over against the east bank in Baird Canyon by the glacier bulb terminus of which has been stagnant but veneered and tree covered since before 1898 and probably longer

Above Miles Glacier steamers ply on Copper River below the river is unnavigable The glacier barrier is of another sort from that at Valdez but it has effectively prevented the gold seeking prospectors and others since from utilizing the Copper River highway to the interior of Alaska

MASTERING THE GLACIER BARRIERS ON COPPER RIVER

The need of transportation in productive Alaska particularly of transportation for copper ore for coal and of cheaper and quicker access to the interior has interested large capital and one of the first of the great trunk railways in Alaska is being built up the Copper River and at the end of 1909 had successfully mastered the glacier barrier of the lower river reaching the copper mines near Mt Wrangell in the winter of 1911 It cannot start from the mouth of the river which is too shallow for ocean steamships but begins at Cordova at the east entrance of Prince William Sound where one of the future metropolises of Alaska is growing rapidly in a beautiful location The railway traverses the delta and crosses the turbid glacial stream of the Copper River near its mouth This crossing is between Childs and Miles glaciers where regular trains were first taken across the lake in a car ferry which service was abandoned on the completion of the bridge in 1910 Its standard gage track winds past Abercrombie Rapids on a narrow rock shelf cut in the mountain side It has to cross the stagnant end of the glacier above Miles Glacier where it runs *for five miles on the ice* because there is no other place for the roadbed The glacier might advance as others have done in Alaska, but the railroad could cross the river again and traverse the opposite mountain slope Both glaciers might advance and block the way completely but it would only be for a year or two judging by other Alaskan glaciers

The glaciers have been mastered and a permanent highway across the mountains has been obtained It took daring skilful engineering large capital and



PROSPECTORS AT THE SUMMIT OF VALDEZ GLACIER 4 800 FEET ABOVE SEA LEVEL, CARRYING THEIR OUTFITS

MASTERING THE ALASKAN GLACIER BARRIERS

it should be said no cent of government subsidy or land grant We have another scenic route destined to rank with the great American wonderspots of the Grand Canyon of the Colorado the Yellowstone Park and Niagara Falls for nowhere else the world over can one pass between two such glaciers and over the ice of a third in a Pullman car The Valdez Glacier barrier was crossed temporarily, as described below

That of the lower Copper River has been mastered and made a permanent highway to the interior of Alaska until the glaciers advance and destroy it, as several of them might do Such an advance however should be short-lived, and the section of track affected could be rebuilt

THE VALDEZ GLACIER HIGHWAY

From the head of a beautiful fiord Port Valdez a gradually sloping gravel plain leads three and a quarter miles to the terminus of Valdez Glacier 210 feet above the fiord The glacier is 18 miles long and 1 to 2 miles wide and rises in terraces or benches to a height of 4 800 feet where there is a snowy pass from which another ice tongue the Klutena Glacier

THE GLACIERS OF LOWER COPPER RIVER WHICH FORM A BARRIER TO NAVIGATION THE RAILROAD RUNS BETWEEN TWO GLACIERS AND FIVE MILES OVER THE ICE OF THE THIRD GLACIER

flows northward 6 miles and ends at an elevation of 2 020 feet From here a stream flows into Klutena Lake which drains to the upper Copper River In recent years the Valdez Klutena Glacier has been inactive and little broken by crevasses and could be used as a highway by man and horses The end receded 630 feet from 1898 to 1909

THE STAMPEDE TO VALDEZ

In the late winter and early spring of 1898 the prospectors stampeded to Valdez The gold seekers of 1897 had had a hard time crossing Chilkoot and White Passes and this new route which avoided these passes and the rules and regulations of the Royal Northwest mounted police, was eagerly followed, although in complete ignorance of what it promised. It has been estimated that over 3,000 men were landed at the head of Port Valdez in February, March and April, 1898, and one or two thousand in the ensuing months Beside these prospectors there was a United States government party under command of Capt. W. R Abercrombie. It is chiefly from the accounts by Abercrombie and his lieutenants and the geologist F. C. Schrader of the United States Geological Survey that the facts stated below are gathered There has never been in the world s history so wholesale a utilization of an ice-filled pass as a highway as that in connection with the stampede of 1898

TRAVEL ACROSS VALDEZ GLACIER.

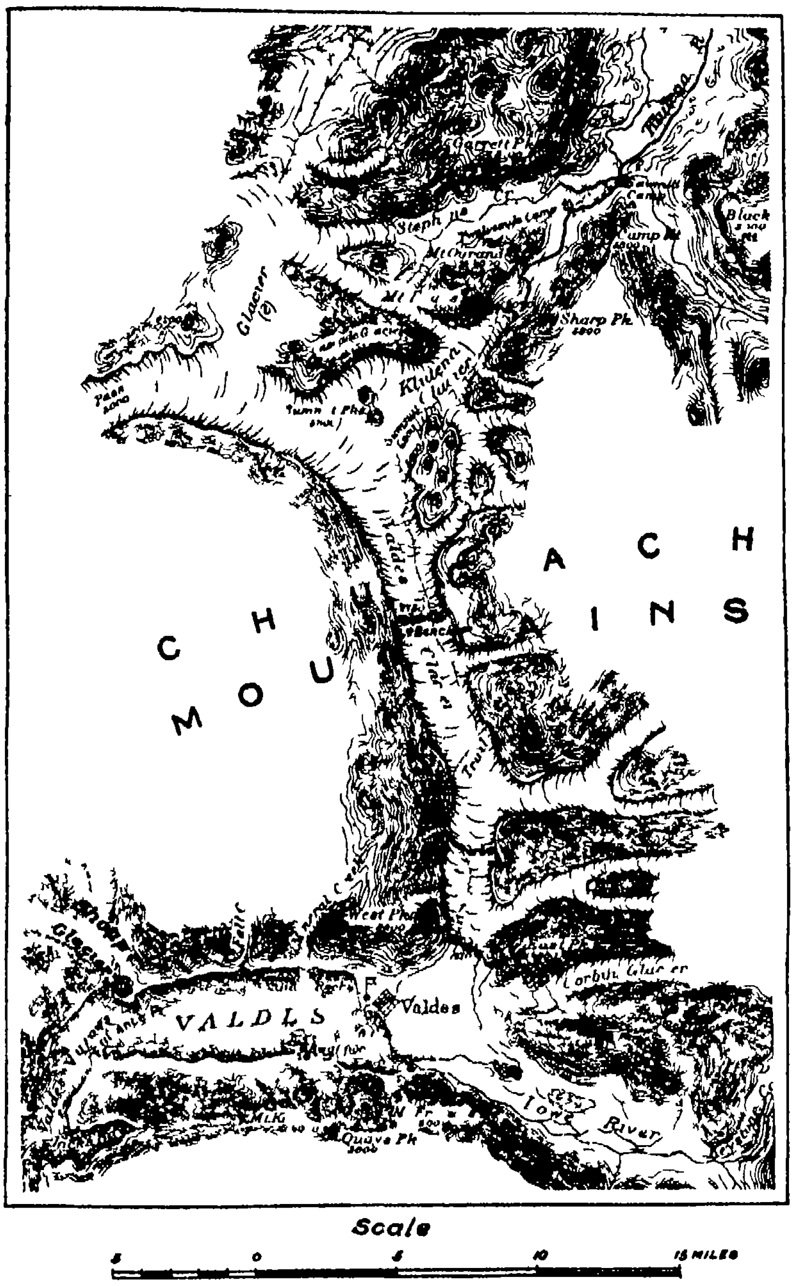
These prospectors were wholly unprepared for travel over ice And when most of them landed at Valdez, they saw a glacier for the first time They had sleds, but almost no other glacial equipment and suffered particularly for lack of fuel and water until experience taught them that wood must be carried or better oil stoves to make fires for cooking and melt snow or ice to get water Few had snow shoes and none had ice axes or glacier ropes especially necessary for rescuing those who fell into crevasses

The trail was crooked for while the glacier was not severely crevassed it was so riven by chasms that the parties had to weave back and forth between crevasses sometimes going three or four miles to advance one mile This was also the case when the writer traversed the lower portions of the glacier in 1904 and 1909 The way was easily lost in a fog or a snowstorm and the many days necessary for traversing this glacier with a heavy outfit of equipment and provisions were attended by great fatigue, discomfort and some loss of life.

Men lived for days upon the glacier chiefly in tents Schrader mentions one trip when he counted camps as follows 300 people at the foot of the glacier near Valdez 100 tents at Five Mile Cache, and 300 or 400 people at Twelve Mile Camp The so-called benches were places of temporary settlement, for here there were steep ascents of one hundred feet or more up some of which the loaded sleds could not be drawn Near the summit there was a rise of 1,000 feet at an angle of nearly 15 degrees or 20 degrees. At such places provisions had to be hauled up by block and tackle or carried on men s backs Glacier villages occupied by the succession of parties and large temporary deposits of provisions and outfit called caches were at the base and the top of this ascent. At such places of delay fuel was in especial demand, and wood brought a dollar a pound

Sometimes it snowed continuously for 120 hours, and tents would be crushed unless shoveled off These caches buried beneath eight to twelve feet of snow could sometimes be found again only by probing with long poles. Large snow slides came down the steep walls of the valley and out upon the glacier continually An avalanche of this kind buried eight or ten people, all but two of whom, however, were dug out alive Another slide buried ten horses and mules, several dogs, and a number of caches. The travelers on the glacier highway soon learned to avoid such

[illegible] danger near the valley walls, especially for [illegible] caches. The accompanying map shows the [illegible] over the glacier in 1898 and how it avoids the [illegible] walls except when forced over to them by the [illegible] near the center of the glacier. The pre[illegible] of avalanches in the daytime, the softness of the trail, and the danger of snow blindness soon [illegible] these men to work and travel at night, there



THE VALDES GLACIER, SHOWING THE TRAIL BY WHICH THE PROSPECTORS TRAVELED IN 1898, AND THE TOWN OF VALDES

being ample light for this purpose between 10 P. M. and morning in this northerly latitude.

A FRUITLESS MASTERY OF A GLACIER BARRIER

Despite all these difficulties the hardy prospectors mastered the glacier barrier on the coast range of Chugach Mountains. By the first of May 2,000 gold seekers had traversed the highway of ice and 1,500 more were on the way across. Many took horses, mules and burros over successfully, two army detachments crossing with 14 and 23 pack animals respectively.

The trip down the shorter Klutena Glacier from the Valdes Glacier summit was easy and rapid, a man being able to draw as much as five or six hundred pounds in a sled. Beyond this there were rapids to be shot, there was a long lake to be crossed, and for this many of the adventurers were unprepared. But, worse of all, there was little or no gold at hand, but there was a long, hard, largely unexplored 250 miles of road over the second mountain range, the Alaska Range, to the Yukon Valley. It was upstream toiling, not downstream floating as in the case of the route from the lakes beyond White Pass to the Eldorado.

The mastery of the glacier barrier had been fruitless. The exodus began early in the summer and prospectors streamed across the Valdes Glacier highway to take ship for home, if they had money, or to stow away or work passage, if penniless, as a great majority were. A few stayed in the Copper River valley and founded the town of Copper Center, some going out during the winter and not a few losing their lives on the glacier. Of those remaining many died during the epidemic of scurvy that scourged Copper Center and Valdes. A very few went on and found fortune the following year.

A few prospectors went across the Valdes Glacier highway early in the spring of 1899, but during the summer and since then the military trail, now a wagon road built by the army over a lower non-glacial pass, has been the highway of entry to the Copper River valley. A telegraph line goes this way now to Eagle and Fairbanks on the Yukon and Tanana. The glacier barrier at Valdez, mastered by thousands of poor, inadequately equipped prospectors who toiled prodigiously and profited nothing, is still a barrier. It can be traversed, but the trail to the east is easier. Men go short distances upon its surface to prospect, one party being seen by the writer in 1904. In 1909 we found a sledge that had been abandoned by another short distance prospecting party. Though temporarily a crowded highway, the Valdez Glacier is no longer traversed, though tourists now go to its front in an automobile.

The Making of Mountains

Even a casual observer as he proceeds along a country road will sometimes notice curiously bent and twisted rocks, some of which strikingly resemble layers of crumpled cloth. The evidence that the forms of these rocks furnish of the action of some tremendous pressure in long past times, which was able to bend and fold the layers of the earth's crust, is of a kind to appeal to the eye and mind of all.

The geologist sees in the mountains themselves far greater proofs of the might of those forces of disturbance that have broken and corrugated the rocky shell of the globe.

The effectiveness of the slow contraction which the earth has undergone as its interior has gradually cooled off in upheaving and deforming its surface has been beautifully illustrated by the experiments of a French geologist.

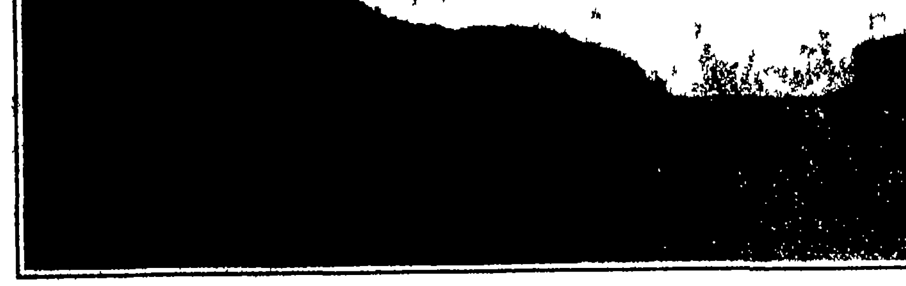
He employed a distended ball of caoutchouc made to imitate the form of the earth, slightly flattened at the poles, and covered it with a layer of beeswax. Then the ball was allowed to contract a little. Immediately the beeswax surface was thrown into folds and fractured and upheaved in some places and depressed in others, the effect being to produce a striking resemblance to the surface of the earth with its mountains and valleys and vast beds of broken and tilted rocks.

So in a few minutes by this ingenious experiment a geological history of the earth in miniature can be enacted, and while watching it with the aid of a little imagination we may behold some of those mighty processes which, acting through millions of years, have gradually brought our planet into the condition in which we see it to-day.

Wireless on Aeroplane

Experiments with wireless telegraphy from aeroplanes are being carried out in France, and one of the first to be successful was made at the Buc aeronautic grounds on an aeroplane piloted by Maurice Farman, using wireless apparatus of the Ancel type. In the first experiments there was used a 4-inch spark coil supplied by four storage battery cells. One pole of the spark gap was connected to the steel brace wires and all the metallic mass of the aeroplane, and the second pole to an aerial wire which was well insulated. This aerial was composed of two 0.04-inch copper wires hanging down parallel to each other and 130 feet long, suspended in the rear of the aeroplane. During the flight the wires took an almost horizontal position. The total weight of the wireless outfit is 45 pounds. In the present tests M. Farman did not carry a passenger, but worked the apparatus himself. Signals were received in the aerodrome shed, using an aerial stretch along horizontally for 600 feet length and mounted on 25-foot poles. The aeroplane flew at 8 miles from the shed and the signals were always well received, using a Ferrié electrolytic detector. New experiments are being made so as to increase the range, using an 8-inch spark and a 300-foot aerial. A passenger mounted on board works the apparatus.

Grapevine Diseases.—Treating of grapevine maladies before the French Agricultural Society, M. Frilleux spoke of the great harm done by cryptogamic maladies by the cochylis and eudemis. For these latter salts of arsenic have been used of late by sprinkling. It was desired to know whether the deposits left on the grapes had any bad effect on the wine or again upon the fresh grapes. On these two points the opinion of experimenters seems to be conclusive, and practically all admit that sprinkling with arseniates or even with arseniate of lead, which is the most dangerous, has no bad effect on the wine or the grapes. M. Gervais confirms these statements and found that no harmful ingredients could be detected in the wine. Upon the grapes it was impossible to find any but the merest traces of arseniates. The society is soon to report upon the use of arsenic salts and also nicotine.



THE RAILWAY OVER THE ALLEN GLACIER, THE TERMINUS OF WHICH IS COMPLETELY MANTLED WITH DEBRIS AND COVERED WITH SHRUBS. GLACIER ON LEFT, COPPER RIVER ON RIGHT. ICE WAS BLASTED OUT IN LAYING THE ROADBED AND COULD BE SEEN IN THE CUTS IN 1909 AND 1910

MASTERING THE ALASKAN GLACIER BARRIERS

Fire and Burglar-Proof Safes—II*

Recent Advances in their Construction

By E E Watson

Concluded from Supplement No. 1845, page 295

THE fire proof safe which will protect its contents from destruction and bring them safely through such fires as that following the San Francisco earthquake the Baltimore fire and the Parker Building fire is of very modern origin

No historical evidence exists of the use of safes for protection against fire earlier than about the year 1820 at which time a portable fire-proof safe was constructed in France This safe consisted of an outer and an inner metal box with a space between filled with some form of non conductor No information is obtainable regarding the details of construction or the materials used Previous to this the only form of fire protection afforded consisted in vaults built of masonry which owing to their cost were limited in use

In the year 1826 a fire proof safe was invented by J Delano This safe was made of oaken planks 3 or 4 inches in thickness which were saturated with salt brine to render them to some degree fire proof and were covered on the outside with bands of iron held in place by wrought iron nails This safe afforded only a moderate amount of fire protection Many of them were destroyed in the great fire in New York in 1845 A safe of this type is now in the possession of the Herring Hall Marvin Safe Company at its Hamilton factory

Some time between the years 1829 and 1832 James Connor of New York City constructed an iron box with a filling between the walls composed of plaster of Paris He used this safe in his own office but made no attempt to patent or manufacture it In 1834 William Marr of England patented a safe the peculiar feature of which consisted of sheets of mica pasted on paper the space between the mica sheets being filled with burnt clay and powdered charcoal mixed

In 1838 Chubb of London produced a safe in which a series of iron plates were used with intermediate spaces packed with wood ashes

Coincident with these various other freak safes were patented and placed upon the market but none of them seem to have left any impress of their individuality on the development of the safe industry

The first real safe patented manufactured and put upon the market as a commodity was introduced by Daniel Fitzgerald of New York city in 1834 In this safe the fire-proof composition consisted of plaster of Paris which was first baked and then reduced to a powder after which it was mixed with water and mica to the consistency of paste and was poured between the outer and inner walls This filling was a good fire resistant but its chemical action upon the iron plates composing the walls of the safe was such that it weakened the construction and rendered the safe entirely worthless in a short space of time

Mr Fitzgerald early associated himself with Azor Marvin who founded the Marvin Safe Company and was long considered one of the heads of the safe industry This Fitzgerald safe was known as the Salamander safe to distinguish it from the wood lined chest built by Delano

In 1843 Tann Brothers invented and patented a safe which depended for its fire proofness upon a filling consisting of ground alum mixed with powdered gypsum These elements were thoroughly mixed and melted together after which the mixture was pulverized and converted into a coarse powder and used in this form for the filling of the safe The mixture when subjected to extreme heat would give off water This safe was known as the Marvin Alum and Plaster Patent and was exploited for many years

During this time numerous other dry filled safes were invented and placed upon the market Various kinds of heat resisting elements were used in the filler, but the safes were not a success on account of the fact that in some instances the steel walls of the safe were corroded by the filler and in other instances the heat resisting qualities of the material used was low and many of these safes—in fact the majority of them failed to preserve their contents when subjected to the test of great fires.

The industry was not placed upon a solid and substantial basis until after the modern concrete filling came into use In 1865 when Joseph L Hall of Cincinnati, Ohio the (at that time) president of the Hall's Safe & Lock Company patented what was known as Hall's Matchless Concrete Filler a safe was made that would withstand severe fire tests and would actually improve with age This filler was composed of cements mixed with certain liquids and contained a large proportion of steam producing elements in solid form In addition to its non-combustible and non-conductive qualities it has the other important advantage of materially strengthening the entire structure It also improves with age instead of disintegrating in the manner of all other fillers that had previously been used

The claim is made that when heat is applied to a mixture such as this the liquid element that is contained within it not in a liquid form however but in what has been characterized as water of crystallization is upon the application of this heat converted into steam thereby changing the heat into work and rendering it latent

The most successful dry fillings previously used depended for their heat resisting qualities upon this same principle but were a failure on account of their destructive action on the steel walls of the safes and for the further reason that they did not add any strength to the structure

In the event of a fire a safe is apt to be subjected to a fall sometimes from the upper floor of a building to the basement Its construction must be such that it will withstand this fall without exposing its interior to the destructive action of the flames In the case of a dry filled safe the exterior shell of metal is apt to be punctured and the dry filling sift out leaving some part of the safe entirely unprotected

The concrete filling above mentioned strengthens the entire safe and by the test of great fires has proven that this added strength is one of the greatest points in its favor The concrete filling invented by Joseph L Hall has been improved upon and is now used exclusively by the Herring Hall Marvin Safe Company in the filling of its entire line of fire proof safes

During the development of the industry much thought was expended upon the construction of the framework and jambs of the safe itself A good grade of cast iron is used in the jambs of the door and the body of the safe This is used for the reason that cast iron will withstand greater heat without warping than bars or plates of steel or iron The framework of the outer box is made of angles securely welded at the corners These angles add strength to the jamb casting and prevent its breakage in case of a fall The outer door plate performs the same function for the casting which serves as the jambs of the door Particular attention is directed to this combination of metals

The cast iron which will not warp under great heat but which is apt to break as the result of a fall

The steel angle frames and the door plate which add the necessary strength to the castings so that they will be able to withstand the shock of a fall

The fire proof safe made fifty years ago and filled with the concrete filling was a creditable article considering the advances made in related industries It was not fitted however with an angle-hoop and the outer body of the safe was necessarily much weaker than in the safes made to-day The fit of the doors was less accurate and the workmanship in general as might be expected not approaching to any degree that of to-day

The safe had many defects The castings mentioned above were cut away on the hinge side of the door for the lodgment of the hinges The hinges were made with an interlocking lug or boss that closed in back of the frame The construction was bad on account of the added metal which tended to conduct heat into the interior of the safe and the weakening effect which it had on the frame on account of the metal that had to be cut out in order to provide space for the hinge.

The recent advances in the construction of fire proof safes consist

First in the Matter of Patterns for Door and Frame Castings—These patterns have been revised and reconstructed at large expense with a view to securing a better fit between the door and its frame Foundry practice has improved to such an extent that castings can now be secured with much less variation in size than formerly To keep pace with, and to take advantage of, this advance in the art of making castings, it was necessary to reconstruct the patterns When this was done seven years ago the tenon and groove and the interlocking-jamb features were incorporated in all of them that had not previously been so constructed We are now using molding machines in the making of many of our door and frame castings, which has enabled us to further reduce the limit of variation in the size of the castings themselves and to fit together a door and frame with the smallest possible allowance for variation in size of castings

Gray iron castings can now be made that will withstand a high degree of heat without warping In the production of our castings we use those materials *which have been determined by experiment to be the* best adapted to the production of a casting of uniform size strength and rigidity

The effect of the close-fitting door together with the features of the tenon and groove and interlocking flange upon the relative fire proofness of the safe is great A closely fitted door braces and reinforces the strength of the frame while a loose fitting door adds the weight of its overhang to the frame and weakens it in direct proportion to the looseness of the fit

Second the Framework—The old style band hoop or frame has been superseded by the solid welded angle-frame The front frame supports the jamb casting and provides a fastening for the hinges This angle is a vast improvement over the old style band or bar frame

The manner of welding the corners is of the greatest importance We have found by experiment that the best and strongest results can be obtained only by the hand method of welding After the angles have been mitered at the corners the edges to be joined are hammered out hot by hand, so that they will over lap each other when bent The actual welding operation is then performed by hand and the strength of a corner so produced has been found by test to equal in nearly all cases the strength of a solid section of the angle itself—a result which we have found impossible to arrive at by any other method

The outer section of the safe has been strengthened by reinforcing wherever experience has shown such reinforcement to be necessary At the same time no unnecessary weight has been added In fact, any weight that does not add proportionately to the strength of the whole structure is a serious detriment in case of a fall In the modern safe we provide angles and bars between the front and rear frames The angles are placed at the corners and the bars midway between These are securely tied to the frames of the safe and provide additional means for fastening and supporting the outer steel wall This outer steel wall as well as the inner steel wall is made heavy enough to properly support and retain the fire-proof composition and light enough so as not to add any superfluous weight to the safe

The proper proportioning of the parts relative to each other and to their various functions is a matter that has been given the most careful consideration in the development of the modern fire proof safe

The doors are hung on malleable iron ball bearing hinges These hinges are fastened on the outside The introduction of the interlocking flange in the rear of the door has made it no longer necessary to mortise them into the door and jambs The burglar would gain nothing by knocking them off The ball bearings by their resistance to wear maintain the door in its proper relation to the frame and provide the additional feature of ease of operation The outside hinge as now used makes it unnecessary to cut away part of the strength of the frame as was formerly done while the inside hinge was used

The operation of the bolting mechanism has been simplified by being made more direct. The locks now used on the outer doors are of the combination type They are protected by steel plates to prevent drilling and the arbors or spindles are shouldered to prevent driving in or pulling out.

An additional device is also provided that will automatically hold the bolts in the locked position in case the lock is in any manner rendered inoperative

Those features in their best form are all of comparatively recent origin, and have added much to the value of the protection afforded by the modern safe

The inner steel doors of fire-proof safes have heretofore been guarded by ordinary key locks The same is true of the small cash boxes usually found as a part of the cabinet equipment. In the very near future the Herring Hall-Marvin Safe Company will equip all of its inner doors and cash boxes with changeable key locks, thereby adding greatly to their security by the facility with which keys may be changed by the user.

* *Journal* of the Franklin Institute

A complete line of steel interiors fitted with the most improved modern filing devices will shortly be completed and placed upon the market by this same company This will be a great advance over the type of interiors now in general use.

To the above-mentioned improvements have been added numerous other minor refinements that result from better mechanical methods modern factory organization, and thorough inspection

There has lately been placed upon the market by the Herring Hall Marvin Safe Company a modern safe fitted with a built-in system of electrical protection This safe may be connected to a central station system or may be fitted with a local alarm In appearance it resembles closely the ordinary fire-proof safe and is a marked improvement over the types of electrically protected safes now in use which depend for their security upon a separate electrical cabinet encasing the safe

In this new safe the electrical circuits are built into the safe itself The circuits are so arranged that any attempt to wrongfully gain entrance to the safe by the manipulation of the locks by drilling or by any other method will cause an alarm to ring

The circuit connecting the safe with the alarm is a closed one and is so arranged that it cannot be tampered with without causing an alarm to ring The Herring Hall Marvin Safe Company owns and controls the patents covering this type of construction

The so-called burglar proof safe or vault has been improved and perfected in many ways in the last ten years.

The development of the burglar proof safe depended in a large measure upon the development of the steel industry and to a great extent also upon the development of locks Until such time as really burglar proof locks had been perfected no great advance could be made in the development of the burglar proof safe or vault

The burglar proof safe of to-day must be drill proof It must be fitted with a door that seats so closely into the opening provided for it that no liquid explosives of any kind can be forced between the door and the jamb

Its bolting mechanism must be of sufficient strength to retain the door in its seat and it must be controlled by locks the operation of which will leave no opening through the door for the introduction of explosives

The modern method of arriving at these conditions differs greatly from the attempts that were made years ago Drill proof steel as formerly used consisted either of Franklinite which was cast or poured between two solid metal walls and allowed to harden in place or strips of so-called spring steel laid between two retaining plates of soft steel

The drill proof steel used in the construction of the modern burglar proof safe or vault is what is known as five-ply steel It consists of alternate layers of hard and soft steel rolled and welded together the result being a plate that will when tempered successfully withstand the hardest drill and will yet retain enough tensile strength to resist the crushing and rending effect of modern explosives This steel was not available in the older types of construction It is now in general use

The most recent improvement in burglar proof construction is the round-door safe and the round-door bank vault The increased closeness of fit can be made in a round door between the door and jamb and the possibility of actually grinding the door to its seat makes this type of construction the highest in existence to-day

The amount of protection afforded by the lighter forms of construction that were in use fifteen or twenty years ago is in the light of present day developments very inadequate It is only in recent years that the jambs or the union between the door and the frame have been polished Earlier than this the machining was roughly done and if too much opening was left a free use of putty and paint at least made an appearance of a fit.

All this has been changed and for the past eight or ten years no burglar proof door has been made by a reputable builder that does not show the polished metal on the edge of the door and jambs.

There are two general types of construction in use to-day, one being characterized as laminated construction, consisting usually of alternate layers of open hearth steel and five-ply steel and the other being what is known as insulated constructions This latter contains an outer section of cast steel containing in its construction insulating materials in which are imbedded drill proof rods or bars, and an inner section of laminated construction

The intention in this latter construction is to eliminate the danger of burning by the electric arc by Thermite or the oxy-acetylene flame

There has been much discussion as to the possible use of these agents by the burglar It is a fact however that long before they were considered in this connection the modern builder of bank vaults had made many experiments and had devised ways and means of overcoming practically all the danger from these sources Many of the older types of bank vaults however are not as well protected in this way as are the recent ones

The general tendency was up until recent years to built vaults very light in construction An 8-inch door was considered a very heavy one Now doors are built as thick as 28 inches and one is now in course of construction in the factory of the Herring Hall Marvin Safe Company that will be when completed 38 inches thick from the outer face of the door to the inner face of the bolt frame plate The total thickness over all from the surface of the operating mechanism of the door to the extreme inner surface of the glass door covering the bolt work will be 61 inches

The greatest advances however in recent years in burglar proof construction have been the result of the application of up-to-date mechanical methods in their production

Modern drill proof steel gives absolutely adequate protection against the use of the drill Steels formerly used and incorporated in the construction of bank vaults were not, however drill proof to the extent that this quality exists in the present day steels These older types of vaults therefore are not as thoroughly burglar proof in this sense as are the more modern ones.

When the vault manufacturer succeeded in producing a bank vault that would successfully withstand the use of a drill he found that his vaults were subjected to attack by the use of the wedge in the crack of the door itself The closeness of the fit of the door did not in any way interfere with the successful use of the wedge

A system of interlocking jambs was devised which in a measure would prevent the springing of the frame away from the door and this reinforced by the more recent overlapping flange of these modern doors has eliminated entirely this source of danger No owner of a modern bank vault need fear either the drill or the wedge

The same security exists in reference to lock spindles that are used at the present time Formerly these were carelessly fitted and openings could be found around them for the introduction of liquid explosives Now they are so carefully ground into the doors that it is impossible even with pressure to force around them any known liquid explosive

The same close fit is now also made of the door in its seat. Every modern bank vault entrance is subjected to what is known as the water test and the door must fit so closely into the jambs that it will resist the passage of water between the door and frame

The operating mechanism of the bolt work has been greatly improved Formerly the bolts were operated through a system of levers and bell cranks that were indirect in their action and were frequently the source of great inconvenience to the user The modern bolt work is operated through gears and racks and is so balanced in its action that very little effort is required in locking and unlocking

The hinges are better adapted to the service expected of them In all modern vaults the doors swing on hinges fitted with ball and roller bearings of the very best design workmanship and materials making a door of many tons weight so easy to operate that a child can swing it in and out, yet so perfectly balanced that it will stand at any point These bearings are fitted with means of adjustment to compensate for wear

The pressure mechanism for seating the door into the jambs has been improved in design and construction

The inner surfaces of the front jambs on all of the best examples of the modern doors are brought to a uniform plane to provide a perfect seat for the locking bolt wedges These wedges have an inclined inner face parallel to the beveled bearing face of the bolts themselves These bearing faces are made as broad and large as possible and the wedges are separately adjusted and fitted under the bolts so that when the door is seated and the locking bolts thrown the holding and retaining power is uniformly distributed throughout the entire system

The modern means employed for binding the locking bolt mechanism to the body of the door consists in tapering or conical bolts running well into the body of the door each bolt separately fit to its seat and all binding the bars through which the locking bolts operate firmly and securely to the door This method of fastening and fitting makes the door with its bolting mechanism an indivisible unit the holding and retaining power equaling the great strength of the solid section of the door itself

In the older types of construction revolving bolts were used The fit of the doors was so imperfect that it was feared that the burglar might pass a saw through the crack of the door and saw off the locking bolts

The structure guarded by the door or entrance which in common practice is called the lining has been strengthened and improved upon in many ways The modern lining is built up of alternate layers of steel plates A combination is made of plates of unusual toughness and high tensile strength with drill proof plates of five-ply welded iron and steel all bound together and protected at the outer and inner corners by massive steel angles The plates of adjoining layers are laid at right angles to each other and the size of the various plates are calculated so as to break the joints The surfaces of all plates are rolled to perfect planes and the edges of plates and angles are ground to a liquid proof fit The angles at the corners are welded into three-way members that effectually bind the vertical and the top and bottom faces of the lining together

The steel plates used in the construction of the modern vault will resist the penetration of the best drills The high tensile plates will successfully resist all explosives and the ground joints prevent the introduction of liquids

Steels of the quality in use to-day were not obtainable in the earlier years of the industry Machinery and machining methods were crude and factory organization as it exists to-day with its team work and all of its multitudinous aids to rapid and perfect production was undreamed of

All the foregoing that relates to improvements in bank vaults applies with equal force to burglar proof safes The same high grade materials are used and the same careful methods applied in the construction of even the smallest burglar proof chest

Burglar proof safes are now made both of the laminated and also of the later solid manganese steel variety that are absolutely impervious to any known method of attack

Coincident with the modern development of the safe and bank vault industry was that of the profession of the bank vault engineer The industry owes much of its progress to the work done by the pioneers of this profession William H Hollar John M Mossman George L Daman E A Strauss Frederick W Holmes Benjamin F Tripp and George I Remington

The days when might was right have given place to the later days when right is mighty The safe industry stands ready to protect your valuables not only against fire and the burglar but against organized mob violence as well

The Cultivation of Cotton in Egypt

DURING the last few years there has been carried out important hydraulic work in Egypt in order to provide a remedy for the great dryness of the climate and to give a great fertility to the soil by irrigation In this way the level of the Nile is now raised considerably and irrigation canals could be run at greater heights than before However this influenced the height of the underground water and in Lower Egypt this now comes very near the surface of the ground At the same time there was observed a lessening in the yield of cotton In the Delta this is especially remarked, and the crop for 1909 was almost a failure Accordingly, the State administration took measures to find out the cause of the trouble. As the only change appeared to be due to the carrying out of the hydraulic work it was thought that the rise in the level of the watersoaked part of the soil was the direct cause of the falling off of the cotton production and to verify this the commission made a series of tests by growing cotton plants under conditions which were the same as usual except that artificial means were provided for keeping certain soils at ranges of 2 to 10 feet depth for the watersoaked layer For each portion the depth was kept constant The results of the tests clearly showed the great influence which the water depth had upon the cotton crop The yield of cotton in each piece of ground is constantly proportional to the depth of the underground water and is better as the watersoaked layer lies farther below the surface. At present the commission is engaged on tests in order to show what are the best conditions for cultivating cotton as well as other Egyptian plants These results will be of value in many other cotton producing countries

In Europe there has been employed a novel method of exploding mines based upon the action of sound waves It is known from laboratory experiments that if a disk which is free to turn about its diameter is placed inside a cylindrical resonator and the fundamental note is sounded the disk will place itself in a plane perpendicular to the cylinder By causing such a turning disk governed by sound waves to complete an electric circuit it would be possible for a warship to explode a mine by giving a certain signal on a siren tuned to the same note as that of the resonator

The Progressive Disclosure of the Entire Atmosphere of the Sun*

By Prof H Deslandres of the Meudon Observatory

The sun to which this paper is devoted is a magnificent subject of study All men feel more or less clearly that terrestrial destinies are closely bound up with those of the sun and that it is necessary to investigate its particular nature its total radiation its variations and in a word its exact and complete effect upon our globe Our dependence upon the sun is absolute and recently this has been summed up in a very simple manner by a French politician now minister of finance To him is due especial credit for the Meudon Observatory which I direct and for the solar researches there pursued At first he refused to consider the matter pleading in excuse the continued increase of the public expenses Then as I became more urgent he exclaimed You are right the sun is *notre maître* the master of us all It is impossible that we should not do something It is thus that the Meudon Observatory has been able to add to its ordinary budget a supplementary sum not large to be sure but coming at an opportune moment and rendering great assistance in the researches which I am now able to present

The modern study of the sun requires a costly equipment complicated apparatus and an observer especially fitted for physical as well as astronomical observations Now the sun shines for all the world and ripens all the crops *à priori* it seems natural that all the men of this planet should co-operate in solar research In accordance with this idea I proposed some years ago to the Astronomical Society of France a very small special and general tax for the sun If each Frenchman said I would give one sou one single sou for the sun the sum total would be large It would be sufficient to guarantee the maintenance of a continuous record of the sun and its variations—a record not yet realized—and therefore a more profound knowledge of this star But now taxes are ever being added on to us and this one although very light and perfectly legitimate would probably be repudiated Moreover it may be said that the individuals of civilized nations especially those who live in towns concern themselves very little with the sun They have less regard for it than the primitive man and the savage who have neither watch nor almanac The realization of this plan is reserved for the future city and for a social state more perfect than ours

Recourse to the government to the people as a whole is a French custom It would be better as in England to appeal to a private initiative to the initiative of enlightened and generous men It is thus that the Royal Institute was founded an institution which has witnessed the development of so many beautiful discoveries and the rise of so many illustrious savants This fine example ought to be cited to all and we may say that it has been largely followed in America where the greatest of observatories and especially those devoted to the sun have been founded by private individuals

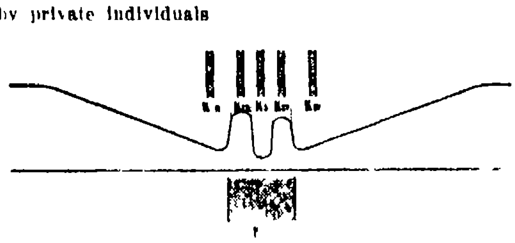


Fig 1—Curve of the Intensity of the Solar Spectrum in the Region of the Broad Band K The Shaded Areas Represent the Different Positions of the Slit of the Spectroheliograph

In fact in the last fifty years thanks to the help of governments and of men of wealth the study of the sun has made considerable progress Astronomers have devoted to it a serious and permanent organization and have even extended it to the entire atmosphere of the star a region hitherto inaccessible

The principal discovery which has been made in regard to the sun is the periodic variation of its black spots a variation which is manifested also by the brilliant faculæ of the sun's surface and by the entire atmosphere which extends out to a great distance The sun as a whole has one great general oscillation and what is even more remarkable this oscillation extends to the earth at least to its magnetic elements

The extension of this solar phenomenon to the earth is of great importance It implies almost necessarily a hitherto unknown special action exercised by the sun upon our globe This is the first cause of the great favor in which solar research is now held Since the discovery by Sabine and Lamont of the connection between terrestrial magnetic variations and

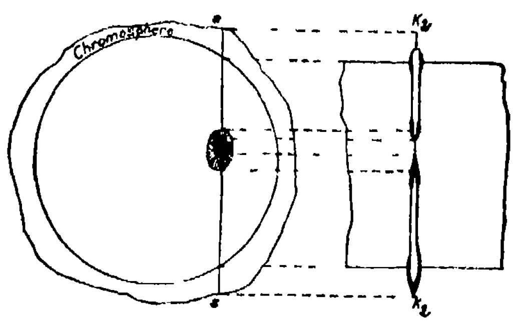

Fig 2—(Diagrammatic) 85 Section Through the Sun in the Plane of the Spectroheliograph Slit The Chromosphere and Spot are Greatly Magnified K Brilliant Line Attributed to Calcium Vapors and Appearing at the Center of the Dark Band K of the Normal Spectrum This Line is Single and Sharp Over the Spots and in the Upper Parts of the Chromosphere and is Double at Other Points Being Divided in Two by the Central Dark Line K₃

solar phenomena English science has paid great attention to sun spots and England was the first to organize systematic photographic observations of the sun spots and magnetic elements at several different points on the earth and to concentrate all of these observations at one observatory which has discussed them with great precision The labors of Ellis and of Maunder in this field are well known and it is well also to recall the works of Lockyer and of S[illegible] who have recently recognized in the variations [illegible] spots periods both larger and shorter than the [illegible]cipal eleven year period

The action exercised by the sun upon the ea[rth is] generally attributed to the spots but it may ha[ve its] origin in the solar atmosphere which has the [same] period of variation hence the necessity of stu[dying] and investigating this atmosphere with care

Now for almost twenty years I have devoted m[yself] to the investigation of the entire atmosphere of [the] sun and I shall present to you herewith the most [re]cent results in connection with the higher layers [of] this atmosphere hitherto unexplored

ATMOSPHERE OBSERVED DURING ECLIPSES AT THE EDGE [OF] THE SUN

The atmosphere of the sun revealed itself to m[en] for the first time during total eclipses at the ed[ge] of the sun's disk It forms at that time a luminou[s] ring bounded on the outer side by the black sky an[d] surrounding the disk of the moon equally black It comprises two distinct parts starting from the moon or the edge of the sun the *chromosphere* thin and brilliant of a rose color from which arise the *prominences* likewise rose colored and then the *corona* much paler but of great extent In what follows the attention will be confined to the chromosphere and prominences In ordinary times the luminous ring seen during eclipses is concealed by the more intense illumination of our sky The screen which hides it is luminous In order to remove this screen the English astronomer Sir Norman Lockyer in 1866 conceived the idea of making use of the spectrum, adopting the quite probable assumption that the solar atmosphere was gaseous That was the idea of a genius who has since made his mark

The eclipse of 1868 showed in fact that the red prominences are composed chiefly of incandescent hydrogen which emits the radiations already recog

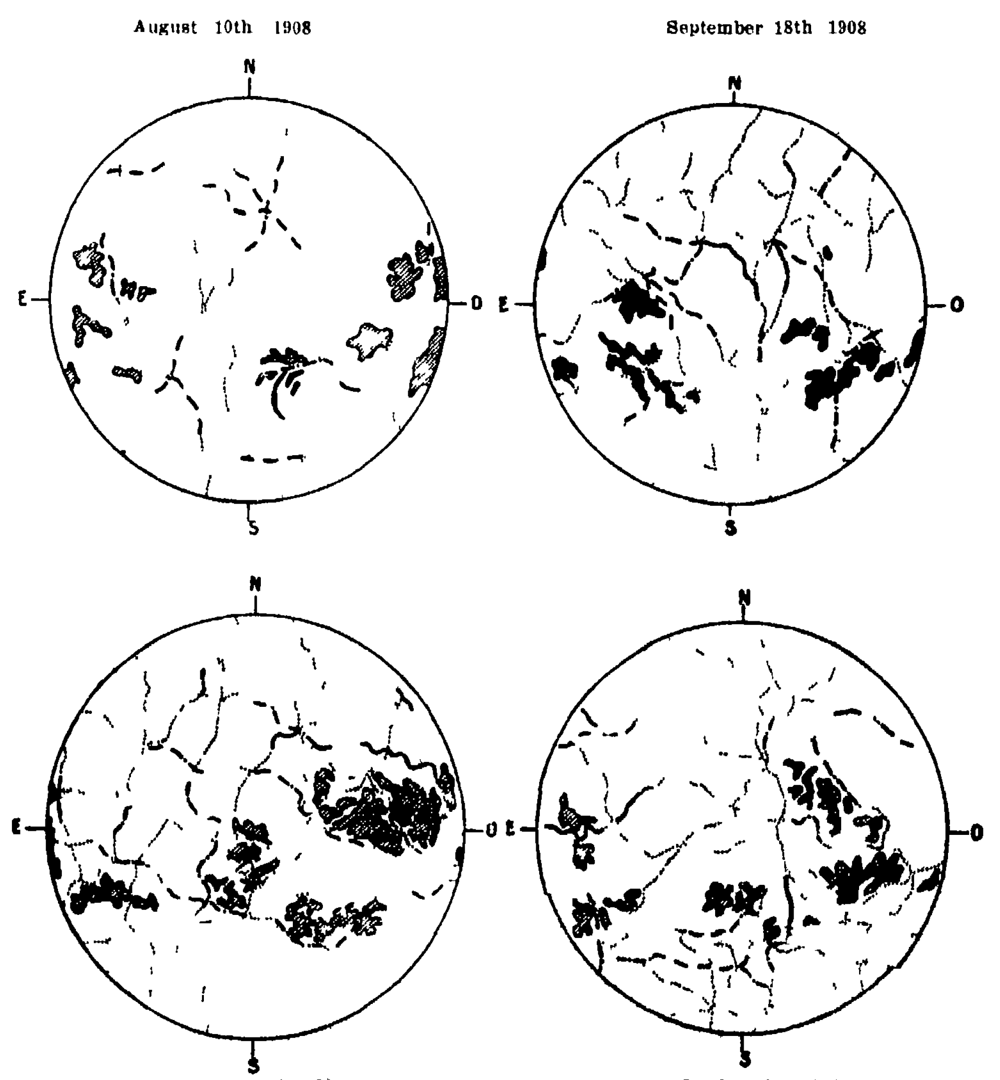

Fig 3—Net Work of Line Markings Observed in the Upper Layer of the Solar Atmosphere The Full Black Lines Correspond to the Sharp Continuous Markings, Known as *Filaments* The Broken Lines Represent Similar but Less Sharp Markings, and the Dotted Lines Correspond to Still Fainter, and Partly Discontinuous Markings. The Shaded Areas Show the Location of the Largest Bright Faculæ

* Discourse delivered at the Royal Institution of Great Britain June 10th 1910 Translated for the SCIENTIFIC AMERICAN SUPPLEMENT from *Nature* with illustrations from the Annals of the Paris Observatory

in the laboratory under the influence of the electric spark, and in particular an intense red ray $H\alpha$. After the eclipse, Janssen, in India, and Lockyer, in England with the spectroscope and the red hydrogen ray, again found the prominences and the chromosphere seen during the eclipse. This result excited a legitimate enthusiasm for the method so simple yet so fruitful has been used for the past forty years in the daily study of the chromosphere and of the positions and forms of the prominences This study is even more fascinating than that of the spots for the prominences have the most varied forms and exhibit the most rapid changes They appear in all latitudes and also follow the eleven year period of the spots the duration of the maximum being it is true somewhat longer

The spectral study of the edge of the sun carried out in ordinary times or better during eclipses has also revealed the chemical composition of the chromosphere and the height of each vapor determined by the lengths of the corresponding lines in the spectrum

In a general way the vapors of elements of small atomic weight and of the light gases rise to the greatest height Such is the case with hydrogen and helium The spectral line of these two gases which rises to the greatest height is the red $H\alpha$ ray of hydrogen The other hydrogen lines diminish both in length and intensity from the red to the ultra violet

But the highest of all are the brilliant violet H and K lines which are emitted by the compounds of calcium As the atomic weight and the density of calcium vapor are both relatively high this would appear strange, but it is easily explained according to Lockyer by a dissociation of calcium in the sun and in the electric spark of our laboratories The H and K lines (in all respects exceptional) are very brilliant at the edge of the sun and thus render easy the photography of prominences with ordinary plates

On the other hand, the heavy vapors which are by far the more numerous, rise only to a small height in the atmosphere, and are easily visible only during eclipses They form the relatively brilliant lower layer of the chromosphere called the *reversing layer*.

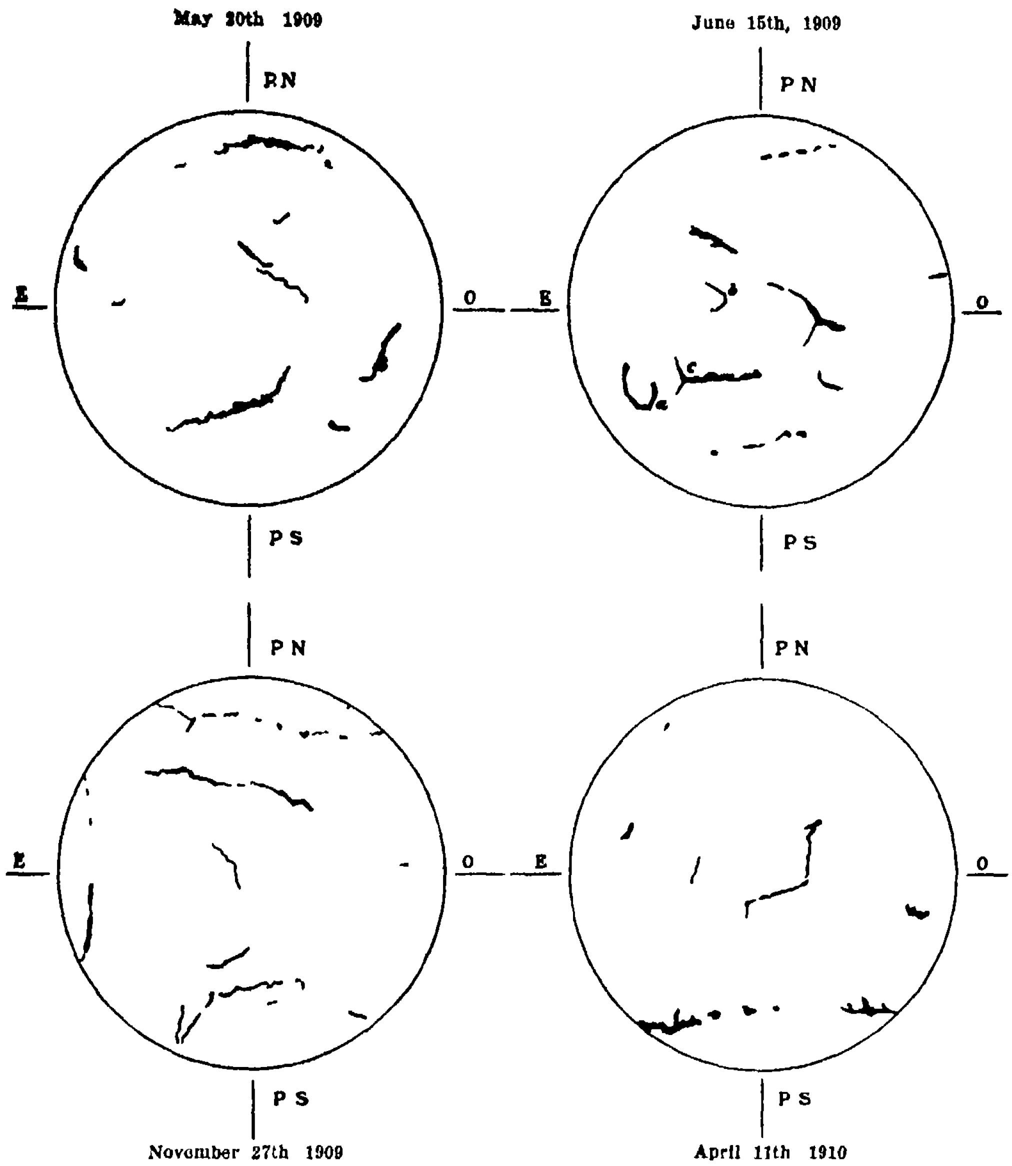

Fig 4—Image of the Highest Layer of the Solar Atmosphere Showing the Characteristic Black Filaments and Especially the Polar Filaments Taken in the Central Part of the Hydrogen H Line or in the Calcium K These Views Show Only the Filaments Without the Alignments

CHROMOSPHERES PROJECTED UPON THE DISK, MIDDLE LAYER

Such are the principal results of the Lockyer Janssen method They are surely remarkable but in certain respects incomplete They apply only to that part of the chromosphere outside the edge of the sun and only to the light vapors which rise from the edge The part within the edge that is projected upon the disk fully fifty times greater in extent escaped them

Now this gap was filled in from 1892 to 1894 by a perfectly general method which disclosed all the vapors high and low and their successive layers in the entire hemisphere turned toward the earth

At the edge of the sun the rays of these vapors stand out bright against the continuous spectrum of our sky but upon the disk these lines appear as dark bands as is well known and the continuous spectrum which serves as a background is the spectrum of the sun itself which is much more intense *A priori* the difficulty appears very great

The calcium lines H and K however form an exception to this rule and this fact was announced simultaneously in February 1892 by Hale and Deslandres These lines are very broad indeed the broadest in the solar spectrum but at points on the surface where there are faculæ they are reversed that is to say they show in their centers a double bright line which in fact appears double not only in the dark band but also in the bright line of the prominences outside the edge of the sun (See Fig 1 which shows the ray K and its components K_{1}, K_{2}, K_{3}, K, K)

The result has been obtained by Hale with a spectroheliograph a new and very complicated apparatus which isolates a radiation by means of a second slit and by the movement of this luminous slit produces a monochromatic image of the sun For my part I used an ordinary simple spectrograph and successive sections of the sun thus paving the way for the use of the spectroheliograph

In the mean time the two observers were disagreed as to one important point Hale located the vapors thus revealed in the faculæ upon the surface I on the contrary located them outside in the atmosphere

Now the ordinary spectrograph which combines all the elements in question furnishes a general solution of the problem It is from this point of view superior to the spectroheliograph

The double line K_2 is brilliant not only upon the faculæ but also upon all other points of the disk where it is to be sure somewhat weaker and more difficult to distinguish Moreover the bright double K is always sharp just inside the edge of the disk and is prolonged outside the edge by a bright double line (See Fig 2 which shows diagrammatically the aspect of the double line K at the edge of the sun and upon a spot)

As the K line outside the edge of the sun represents by definition the chromosphere it follows that a picture in the light of the K line with the spectroheliograph represents the entire chromosphere projected against the disk

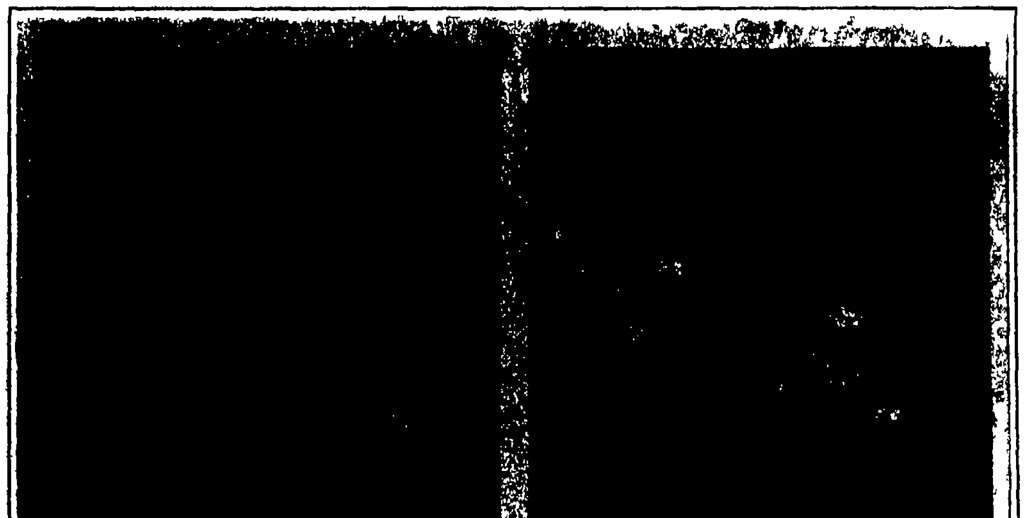
Moreover the calcium pictures made at Paris in 1894 which were the first complete pictures show the bright faculæ larger than upon the ordinary surface photographs and they also show the smaller bright areas now called flocculi which are seen at the poles as well as at the equator I have verified the presence of flocculi at the poles in the years of the sun spot *minimum* and during the whole of the eleven year period

The bright K line remains double outside the edge up to a height of 4 or 5 seconds and as the chromosphere at the edge has a height of 10 seconds we may say that the image in the light of the K line represents the mean chromosphere

To sum up the first spectroheliograph to give results was constructed in America but it was in France that the entire chromosphere of the sun was first recognized

THE SHALLOW CHROMOSPHERE

But we may go still farther In 1893 I announced that the isolation of an ordinary dark line with the spectroheliograph would give an image of the corresponding vapor and in 1894 with a small spectroheliograph of weak dispersion I isolated the low edges of the K ray called K_1 and K and the neighboring dark lines of aluminium iron and carbon The images obtained differed from that of K_2 The



Exposure in the K_3 Line Exposure in the K Line

Fig. 5—Views of the Sun Taken on September 18th, 1908 The View in K, Shows at the Center a Fine Example of a Filament

spots which are at times partly obscured when photographed in the light of K_2 always have their umbræ and penumbræ very sharp when photographed in these other rays The faculæ are bright at the center as at the edge but smaller than in the K_3 images In fact this new image given by the K ray or the rays of aluminium iron carbon etc is intermediate between the image of the surface and that of the mean chromospheric K_2 layer It represents the entire reversing layer which was thus obtained for the first time

A greater dispersion would permit the isolation of the fine lines which are so numerous and especially of the narrow central dark line K_3 between the two components of K_2 This line corresponds to the highest layer of the atmosphere This method is therefore absolutely general It furnishes the images of all the solar vapors and also the images of their successive superposed layers at least when the line is divisible into distinct parts as in the case of the large K ray

Now the number of lines in the solar spectrum amounts to about 20 000 and according to Jewell all the lines present in some degree the same special constitution as this typical calcium line This opens to investigation a new field of vast extent

FURTHER RESEARCHES GREAT SPECTROHELIOGRAPH OF A NEW TYPE

The programme of research marked out in 1894 was therefore most elaborate It has been carried out in part in the ensuing years and the progress has been real if not very rapid

In 1903 Hale and Ellerman at the Yerkes Observatory took up again the study of the dark lines with a spectroheliograph of greater dispersion and since 1906 they have continued this study with still more powerful instruments at Mount Wilson They have obtained magnificent pictures and a large series of new facts With the lines of the reversing layer the results are about the same as those obtained in 1894 but the hydrogen lines and very recently the $H\alpha$ line have shown some new and very curious phenomena which we shall discuss more in detail

Although they have used only moderate dispersion they have isolated a somewhat greater number of lines than were isolated in 1894 but none of the very fine lines And even in the cases in which they have been successful they have isolated the line as a whole They have not separated the line into its distinct parts and obtained images of the successive layers of the vapor Their image is a composite of several distinct images corresponding to different layers

I propose to fill in this gap in the investigation and carry out the programme of 1894 and isolate completely the highest layers which have not yet been revealed Since becoming director of the Meudon Observatory in 1907 I have been able to direct the resources of the Observatory and we have been fortunate in obtaining extensive credit which has rendered it possible to construct a great spectroheliograph as dispersive as the great spectrograph of Rowland and a large special building to contain it

The building covers an area 22 meters by 6 meters Its roof is of stone and earth which assures a constant temperature in the interior It receives the light of the sun from a coelostat at the south constructed from the old transit of Venus apparatus and an old objective of 25 centimeters aperture and four meters focal length These pieces of apparatus which are only mediocre in quality have been used for the sake of economy The spectroheliograph on the other hand is of a new type and possesses several interesting characteristics It is somewhat complicated at least in design for it comprises four spectroheliographs combined with one collimator The first is an instrument with three prisms and two slits, with a length of three meters, giving an image of the sun 85 millimeters in diameter, the second has a grating and two slits, and is of the same length. The third has an entirely different arrangement from the two preceding and the fourth the most powerful of all has three slits and may be used with prisms or gratings It comprises first a spectrograph of seven meters length as in the classic apparatus of Rowland which permits the isolation of very fine lines But

Exposure in the K_3 Line Exposure in the $H\alpha$ Line

Fig 7—Views of the Sun Taken on March 21st 1910 Showing Filament Faculæ and Solar Vortices in the Faculæ

the solar image requires too long an exposure we therefore insert a second spectrograph which diminishes the size of the image to any desired degree and at the same time eliminates the interior diffuse illumination The final image of the sun has a diameter which can be anything whatsoever and thanks to a certain special arrangement of the apparatus the image is complete a result which is not realized in the other spectroheliographs of high dispersion The diameters ordinarily used are six centimeters and our centimeters.

The apparatus with the two spectrographs has a total length of 14 meters and in this arrangement remains immovable It is the first spectroheliograph to be constructed all of whose parts are fixed except the plate The movable parts are the photographic plate and the astronomical objective which are moved at any desired rate by synchronized electric motors and transformers for special speeds The agreement of the motions is assured by electric means independent of distance and this arrangement is presented as a general solution of the spectroheliograph Each of the four spectroheliographs has its especial advantages and the passage from one to the other can be made in a very few minutes The observer thus has at his command the means of carrying out various investigations In a general way the three meter spectroheliograph with two slits gives a larger image richer in detail The great 14 meter apparatus with three slits gives with a longer exposure a much smaller but much purer image and it permits the isolation of the very fine lines

The researches with this apparatus have been carried out with the assistance of a young astronomer of the observatory—M. d'Azambuja, whose name is associated with mine.

DISCOVERY OF THE K_3 HIGHEST LAYER OF CALCIUM

In 1908 we were able to isolate the small central dark band, K_3 of calcium, and thus photographed the highest layer of calcium Fig 1, which shows the K ray and its components will enable one to judge of the progress realized.

Up to that time the spectroheliographs employed isolated only the combination of the two bright K_2 components which inclose the K_3 ray For this a slit wide enough to include 90/100 Angström units of the spectrum was used The resulting image called by us the K_{2} image was a composite of the K_2 and K_3 layers with a predominance of the brighter K_2 by which the highest K_3 layer was rendered inconspicuous Now with the great spectroheliograph with a slit width of only 3/100 Angström units we have been able to isolate easily not only the K_2 ray but also the K_3 and to have the image of each layer perfectly pure and free from all extraneous light The corresponding positions of the slit are indicated in Fig 1 by the shaded bands

The vapor of calcium which at the edge of the sun rises higher than any of the other vapors presents as we have seen three distinct superposed layers If we add the surface we have four layers which it will be interesting to compare

Starting from the surface and going up the faculæ or bright areas increase in extent and in relative brightness The middle-sized flocculi also increase while the small ones disappear or become scarcely visible The result is a characteristic appearance of the K_3 layer which at a glance distinguishes it from the K_2 layer photographed since 1892 (See the two K_2 and K_3 photographs of September 18 1908 Fig 5) I may add that the peculiar network of flocculi called by me in 1894 the *chromospheric réseau* which often covers a considerable area with polygons having their sides and vertices in juxtaposition is in general sharper in the highest layer

On the other hand the black spots which are the chief characteristic of the surface diminish as one goes up and may even disappear

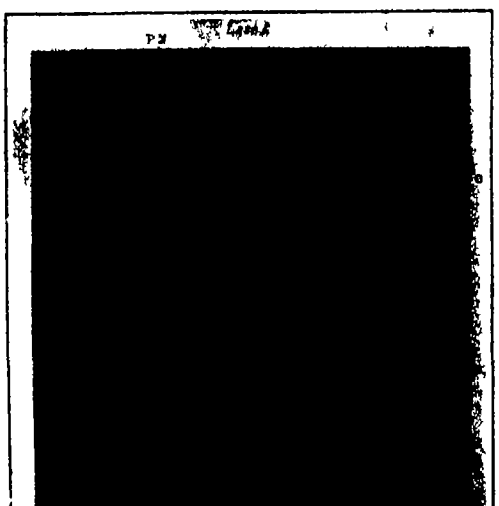
There appear in the highest layer some black lines which are invisible in the lower layers They are often very long and have been called by me filaments In general the filament is continued in both directions out to the edge by other lines less black and less sharp called alignments The combination of the filaments and alignments forms a regular network over the disk of the sun The filaments and alignments are a new phenomenon characteristic of the highest layers

The filament has the same importance as the spot on the surface It persists like the spot through several rotations and like the spot also it is the seat of special disturbances and is accompanied by prominences

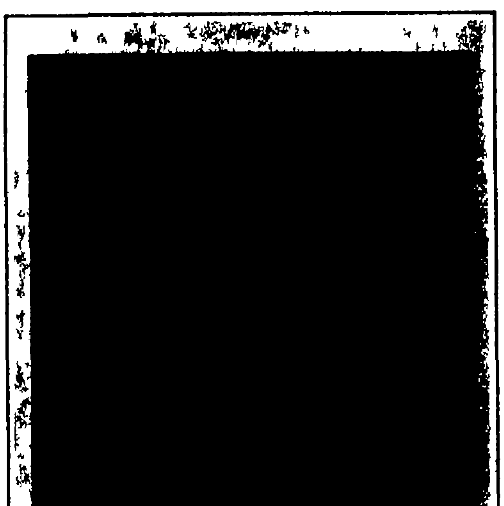
In my first studies I have likened the spots to the barometric depressions or cyclones of our atmosphere, and the filaments to the anti-cyclones. I shall return again to this comparison and develop it more fully

DISCOVERY OF THE HIGHEST LAYER OF HYDROGEN

The following year 1909, d'Azambuja and I with the same apparatus studied the hydrogen lines, and especially the red $H\alpha$ These lines had already been isolated by Hale and Ellerman, who obtained very curious results. In 1908 they discovered that with



Exposure on the Violet Side of the $H\alpha$ Line



Exposure in the Central Part of the $H\alpha$ Line

Fig 6 Views of the Sun Taken September 11th 1909 These Two Views Clearly Show the Difference in the Two Hydrogen Line Images the One Corresponding to the Middle Layer, the Other to the Upper Layer

and H_2 the faculæ are not brighter as in the case of the calcium lines, but on the contrary they are often dark. With the $H\alpha$, isolated in 1908 one generally finds all around the spots a series of fine lines which generally give a distinct impression of a vortex. Most of these $H\alpha$ images are beautiful and very rich in fine detail.

However these American $H\alpha$ photographs were obtained by isolating the spectral band as a whole and I announced in 1908 that they ought to be a composite of two or three images of distinct layers. In fact according to Rowland the $H\alpha$ band is doubly reversed just like the calcium K but much weaker. The width of the $H\alpha$ line including its lower parts is 1 24 Angström units without these parts 0 90 Angstrom units. We ought therefore to expect some slight differences in the images when the different parts of the line are isolated.

Now we have verified completely this fact and indeed contrary to our expectation the differences between the hydrogen images are relatively greater than with the calcium.

The exact results are as follows. If one isolates in $H\alpha$ the lower part near the edge corresponding to the K of calcium for a distance from the center comprised between 0 47 and 0 62 Augström units the result of 1909 will be obtained that is to say the faculæ will be dark with respect to the background.

With the middle of each part between the distances 0 10 and 0 42 Augström units from the center the image is quite different. It presents the chief characteristics of the American photographs of 1908 and especially the groupings of fine lines which Hale has called the solar vortices.

Finally with the center of the band we have a third type of image different from the other two much weaker and less complex an image which corresponds to the highest layer of hydrogen.

Now and this point is important this new image shows the same black filaments as the K_3 layer of calcium. As for the faculæ in this image they are never black but are bright. They are less extensive than with K_3 and correspond to the brightest portions of the bright areas in the K_3 portions which differ from those of the K_1 and K layers. The darkest parts and the brightest parts coincide in position. (See the corresponding K_3 and $H\alpha$ photographs obtained September 11th 1909 March 21st and April 11th 1910 Figs 6 7 8.)

Moreover we have isolated also the different parts of the blue $H\gamma$ line of hydrogen which rises to a much less height in the solar atmosphere than the $H\alpha$ ray and we have obtained images which show the faculæ almost exclusively in black just as in the lower part of the red $H\alpha$ and which therefore correspond to a low level.

Finally we are forced to conclude that the hydrogen as well as the calcium presents three distinct superposed layers which have now for the first time been clearly separated.

Moreover in what precedes I have explained the different parts of the same band and the different images by the ordinary action of emission and absorption in the gas assuming as is natural that the density of the gas and the width of the band diminish as the height in the solar atmosphere increases. But it has been objected that anomalous dispersion can also have some effect and can explain at least in part the peculiarities of the images. Now in my opinion anomalous dispersion certainly ought to enter but to a very slight degree and is neglible in a preliminary investigation. The arguments in support of this assertion would require too much space to develop here. Moreover even if anomalous dispersion has been discovered in the laboratory in the $H\alpha$ line of hydrogen it has not as yet been proved in the case of calcium. Further as the center of the band does not undergo anomalous dispersion the objection does not apply to the highest layers with which we are especially concerning ourselves here.

The black filaments which appear both with the calcium and the hydrogen form a characteristic element of the highest layers. Some of these were suspected by us and some mentioned by Hale in connection with the early complex images of K and $H\alpha$ under the name of long black flocculi and were considered as probably to be associated with the higher layers. In fact under these conditions the most important filaments which correspond to the broad dark bands are generally obtained but the complete investigation of the filaments and their characteristics can be carried out only in connection with the images of the highest layers.

Another important element in these latter layers is the bright faculæ which are found in the same positions as those upon the surface but of different shape.

To sum up then if we consider the four layers formed by the surface and the atmosphere the bright parts are found over the faculæ. The darkest features, however have quite different positions upon the surface and in the highest layer. Below are the spots; above are the filaments which have a black surface area greater than that of the spots. The area of the filaments can easily be measured just as accurately as that of the spots.

RESEARCHES UPON THE MOVEMENTS OF THE ATMOSPHERE SPECTRO-RECORDER OF VELOCITIES

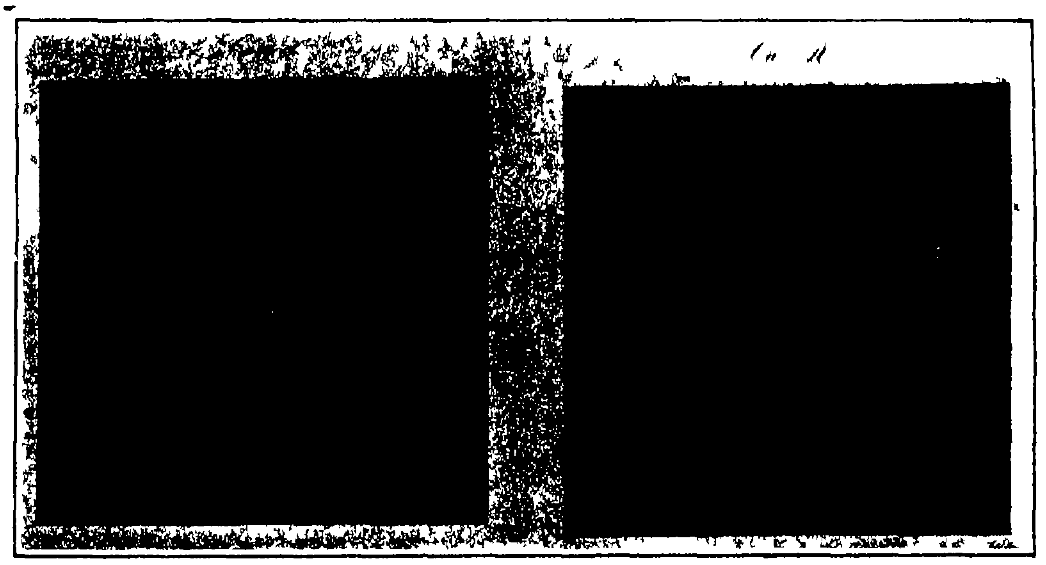
The dark filament attracts especial attention and as has been said above it has an importance at least equal to that of the spots. What is then the origin what is the nature of these long black lines? An exact answer is indeed difficult and in this connection we may recall our lack of precise knowledge of the sun spots which have been studied for three hundred years. However in the case of the filament, the investigation may be easier. The surface in which the spots are located is included between the interior of the sun which is entirely unknown to us and the lower complex layers of the atmosphere. But the highest layer in which the filaments are located is more free and open and may have a structure less complex, and simpler movements.

In Meudon we have recently obtained some most interesting results in regard to the filaments by means of a special apparatus the *only one of its kind* thus far constructed which might be called the spectro recorder of velocities. This instrument which I have used since 1892 was greatly improved in 1907. It reveals as its name implies the radial movements of the solar vapors by juxtaposing small portions of the spectra of successive equidistant sections of the solar disk. This is accomplished by using a wide second slit and an automatic discontinuous movement. This speed meter is a necessary complement of the spectroheliograph and is at least as useful. It reveals in addition to the radial velocities the general forms of the K_3 image of the highest layer the vapor is descending where the image is relatively dark the vapor is ascending. This is perfectly logical for the descending vapor is becoming compressed and heated while the ascending vapor is expanding and cooling.

This phenomenon already detected upon a great many plates is important for it explains the special structure of the atmospheric layers which appear as if divided by convectional currents just like liquids in the laboratory when heated uniformly at the bottom. The bright flocculi often form over a wide area distinctly outlined polygons joined at their vertices and very similar to the polygons which form the vortex cells in liquids so well studied in France by Benard.*

As the vapor descends upon the bright flocculi and rises in the spaces in between each solar polygon thus becomes a vortex cell. As to the other flocculi on the same image they show less marked polygonal shapes or even though more rarely have forms which are wholly irregular.

On the other hand the filaments and alignments probably form the boundary of larger cellular vortices superposed upon those previously formed in the upper layer which have *the spots for their centers*. This conception is in accord with the notion of this layer in the vicinity of spots discovered by the English astronomer Evershed. We can thus easily explain why the spots are points and the filaments lines sometimes very long. The question involved in these researches is therefore already partly answered. The problem will be completely solved I believe by the systematic measurement of radial velocities extending these measurements to the entire disk of the sun a process of great difficulty involving long and tedious labor.



Exposure in the K_3 Line | Exposure in the $H\alpha$ Line

Fig 8.—Views of the Sun Taken on April 11th 1910 Showing Filaments and Polar Curves

of the vapors the details of the entire line and especially the width of the line isolated a width very variable from one point to another on the sun. It reveals points not shown by the spectroheliograph for the latter cannot with a slit of constant width isolate exactly a line of variable width. In a word it registers all the elements which escape the spectroheliograph and permits a sure interpretation of its results.

Upon the plates obtained with the K ray an examination with the naked eye shows at once that the radial movements are in general more noticeable upon *the filaments than upon neighboring points*. Frequently all the K_3 rays of a filament are inclined in the same direction. This indicates a vortex with an axis horizontal as opposed to the vortex with vertical axis which is acknowledged to exist in connection with spots. Moreover this agitation is followed by a relative calm just as in the case of the spots. If we measure with care the displacements and radial velocity of K_3 near the center of the sun we find that the vapor is ascending with a velocity often greater than the equatorial velocity of rotation (say 2 kilometers per second). This fact has been verified upon several filaments. In regions away from spots and filaments the vertical velocities in the highest layer are conspicuous and often of the same order as the equatorial velocity of rotation. The magnitude of this vertical movement is less astonishing when it is noted that the *mass of gas which forms* the atmosphere rests upon an intensely hot surface.

Analogous measurements have been carefully made at the center of the sun upon faculæ and flocculi and the result has been just the reverse. The bright vapor has a descending motion while the relative dark areas near by are ascending. In general at bright points

INVESTIGATION OF POLAR FILAMENTS

I will close by mentioning a new property of filaments recently discovered at Meudon. The observatory already has plates of the upper layer of the atmosphere for more than twenty completed rotations of the sun and from these it is possible to study the distribution of the filaments. They appear in all latitudes but especially around the poles. they are grouped upon a curve more or less circular surrounding the pole but often not concentric with a parallel. This polar curve of filaments is at times sharply defined at both poles but in general it appears only at *one pole and changes from one pole to the other*. This polar curve was particularly strong around the south pole last April. (See the two photographs of April 11th, 1910 Fig. 8 and Fig 4 which represents the filaments on four different days.)

The polar filaments are accompanied by prominences and agree in position with the secondary maxima of prominences which have already been noted near the poles. They may also have some relation to the peculiar form of the solar corona near a sun spot minimum and to the fact often noted that the axis of the corona is inclined to the axis of rotation.

At times the polar curve is accompanied on the side towards the equator by a line of parallel filaments which is joined to the curve by inclined filaments or alignments. We have thus an arrangement analogous to the belts of the planet Jupiter.

Finally the polar zone of filaments where the vapor

* This arrangement of adjoining polygons is at times very distinct over the entire disk of the sun. The K_3 plate of September 18th 1908 shows in the southern hemisphere near the center some of these polygons united at their sides and vertices but a sharper and larger image is necessary in order to see them well.

as we have seen above is ascending may be connected with the zone of spots and faculæ in the vicinity of the equator where the vapor is descending. We are led to infer in the upper region of the atmosphere a great meridianal circulation a great general convectional current, analogous to that which exists upon the earth in each hemisphere between latitude 35 degrees and the pole

The time unfortunately is too short to develop all the consequences of these first observations. The facts presented will suffice to show the great interest in the study of the upper regions of the solar atmosphere and the great necessity of continuing them

The solar atmosphere is the only atmosphere we can study as a whole, and in its successive layers Our recording apparatus will give in a few minutes its general aspect and its principal movements. From this point of view the solar atmosphere is better known to us than the atmosphere of the earth [illegible] we can observe only the lower regions of the [illegible] and those only over a limited area even with the [illegible] of the telegraph.

The network of convectional currents and cur[illegible] filaments discovered in the upper regions of the s[illegible] atmosphere may exist also on the earth, and it is t[illegible] that the study of the sun may teach us to understand better our own atmosphere.

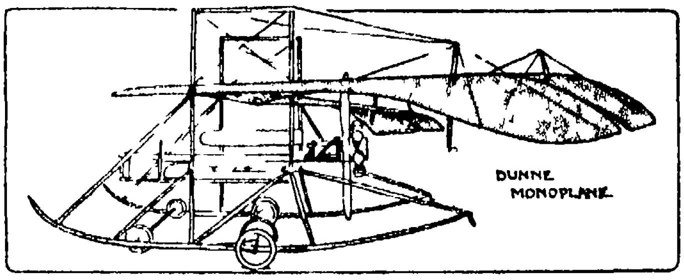
More Aeroplanes at Olympia*

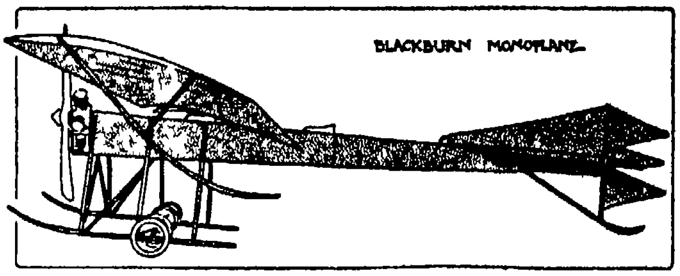
With Special Reference to the Dunne Monoplane

We publish herewith details of the Maurice Farman and Humber biplanes and the Blackburn Piggott Dunne and Nieuport monoplanes

The two biplanes as may be observed afford rather an interesting comparison because they both embody in their construction the characteristic Sommer type forward outrigger in which the skids are carried up for the support of the elevator The Humber machine is also shown with the side pan is designed by A H Bailey for the purposes of stability and control who also exhibited this system in the model section The object of these pan is is to confer the principle of the dihedral angle and to act partially as rudders and partially as screens as was done on the Neale biplane which we recently described and the details of which will be fresh in the minds of our readers The panels, it will be observed are attached at their lower corners by cords to the lower main plane while a single cord attaches the center of the upper edge of the panel to the upper main plane By this means the panels can be skewed or warped into any desired position and the control attachments are such that similar or opposite movements may be made simultaneously in the two panels according to the effect required

Among the monoplanes that which will probably attract the greatest interest among our readers is the Dunne The Dunne monoplane like its prototype biplane is designed to possesses natural stability and is tailless in the ordinary sense of the term In principle however the V plan form of its wings gives it two tails instead of one and the hinged flaps in the trailing extremities of the wings provide it with two elevators instead of one The se flaps are under





independent control and serve the purpose of steering the machine horizontally and vertically The principle of stability associated with the Dunne monoplane is somewhat complicated and has to do entirely with the special formation of the wings which are generated on the surface of a cone This is not the place in which to go into the details of this method but it will be interesting to learn that the apex of the cone is altogether in a different place being situated on the monoplane a little way behind the trailing extremity of the wing and more or less directly in line with the outside edge This formation of the wing gives a variable angle of incidence from shoulder to tip which in conjunction with the V plan form confers on the machine the principle of the fore and aft dihedral angle which is one of the accepted methods of obtaining natural stability and is a characteristic feature in the design of all successful aeroplanes Owing to the wing extremities being situated in an exposed region and not sheltered behind the middle portion of the plane as is more or less the case with the tail of an ordinary aeroplane Mr Dunne claims that their tail effect is enhanced Also the same argument applies to the efficacy of the dihedral angle because owing to the formation and continuity of the wings it is impossible to define what part constitutes main plane and what part tail That in fact the relative functions of these members are performed by different parts of the wings in accordance with the requirements of the moment

Lateral stability in the Dunne monoplane is somewhat more difficult to explain but that which is the most significant feature in the design is unquestionably the fact that the wing formation provides down turned wing tips as distinct from the upturned wing tips on such monoplanes as the Handley Page and Weiss which are also designed more or less with a view to natural stability It will be noticed of course that it is the leading edge of the Dunne monoplane that is turned down whereas in the Handley Page and Weiss monoplanes it is the trailing edge that is turned up so that the relative positions of the leading and trailing edges in all three machines are identical On the other hand it will be observed that there is a very material and fundamental difference in principle between the two methods for whereas in principle the upturned trailing edge represents the lateral dihedral angle the down turned leading edge represents the gull's wing which is an accepted method of obtaining lateral stability in side gusts. The general action is as follows A side gust ordinarily lifts that side of the machine against which it first strikes, because of the aeroplane action of the planes considered in their attitude toward the gust and the consequent travel of the center of pressure toward the virtual leading edge facing the gust, which involves an actual travel of the center of pressure laterally from the real center of gravity of the machine Thus the machine cants over and the upset is emphasized with the dihedral angle because the upturned wing offers an increasing surface for normal pressure In the gull's wing method the remoter down turned wing tip presents the more effective surface to the gust and tends to counteract the lift due to the travel of the center of pressure on the remainder of the plane It is, in principle little more or less than this idea which was tried by the Wright Brothers in some of their early gliding experiments Like most things of this kind however there is all the difference between the broad principle and the detail of carrying it into effect on a practical machine It is the detail that makes the Dunne monoplane such an original design

Among the other machines illustrated herewith the Piggott monoplane is a remarkable example of the ultra stream line body for in it the engine pilot and passenger are completely inclosed The Nieuport monoplane is an example of the surfaced frame, which may be described as the practical stream line body of the moment and the Blackburn monoplane which is an interesting British built machine is another example in the same category

The Grade of Iron Ores in Relation to the Question of Available Ore Reserves

In his recent paper on Geology and Economics" Prof J A Kemp discusses the grade (richness) of the several domestic and foreign iron ores in its relation to the question of the world's available ore reserves We quote here the pertinent passages from the source mentioned

"In early days and in remote situations only the richest iron ores could be mined. Magnetites for example in the lump from the Adirondacks afforded over 60 per cent metallic iron Specular hematites from the Lake Superior districts necessarily yielded 65. For some years no one regarded them with respect if they contained less. Red hematites from Alabama at

45 to 50. The minor ores near the furnaces often much lower—but they may be passed over the moment in emphasizing the larger features. Magnetites in the Adirondacks are now concentrated before shipping, and in instances two and one-half to three tons are condensed to one of 65 per cent tenure The crude ore carries 33-35 per cent During the early years of the present decade the general average yield of Lake Superior shipments fell off about one per cent per year—so that now the soft ores so called in contrast with the hard lump specular of earlier days, range somewhat above 50 per cent Alabama ores, once 45 to 50 now are very uniform at 36 to 37 So far as the brown hematites are concerned which in the form of lumps crusts pipes etc are distributed throughout ochres and clays the percentage of available iron in the crude ore is lowest of all We wash from eight to ten tons of crude in order to get one ton of concentrates of say 40-45 per cent in iron and under favorable circumstances may treat much lower raw materials. Soft magnetites in Pennsylvania, which on the richer outcrops gave 45 to 50 per cent, are now dug in very large amounts with a yield of 43 If we take the total production of ore in the United States and the total production of pig iron we find the yield in the large way to be about 50 per cent

In order to gain some idea of the comparative merits of these figures when set alongside the per centages in the ores produced in other lands a few cases may be cited Germany in 1907 produced 27 700 000 tons of ore exported nearly 4 000 000 and imported 8 500 000 Of the local production three-quarters were obtained from Elsass Lothringen and Luxemburg whose percentage in iron ranges between 30 and 40 and is on the whole not very different from Alabama s present percentages of 36-37 Germany s imports of course range much above these figures else the ore could not stand the freight charges from mines in such countries as Sweden Spain and Algiers

Great Britain produced in 1907 approximately 15 000 000 tons, of which about three-quarters were the so-called impure carbonates yielding 30-35 per cent iron One-ninth of the total was red hematite at 50-55 The general average would be somewhat less than that of Alabama Importations of richer ores especially from Spain helped to raise the furnace yield

France in 1908 produced 10 087 000 tons of which 88 per cent was mined in French Lorraine of the same type as the main German supplies The ore ranged from 33 to 40 per cent—again not far from the Clinton ores of Alabama. We are justified therefore in saying that the largest part of the output of the next three producing countries of the world is about the same as the lowest grade of lump ore which can be profitably mined under present conditions in the United States When we estimate comparative reserves we must realize that in the Lake Superior region—our greatest producer—we pay no attention to day to ores which are nevertheless much richer than those of Great Britain and continental Europe

A New Life Saving Buoy

The Miller Luminous Buoy

THE frightful loss of human life caused by collisions and other accidents at sea demonstrates the insufficiency of the apparatus provided for the prevention of death by drowning The lack of proper means of illuminating or even of indicating the scene of accident increases the difficulty of giving aid at night The recent sinking of the fishing steamer Adolf in the Baltic illustrates the consequences of the lack of proper life-saving appliances. Eleven of the crew escaped in a boat and were picked up by a Swedish steamer but the remaining ten men although they were pro-

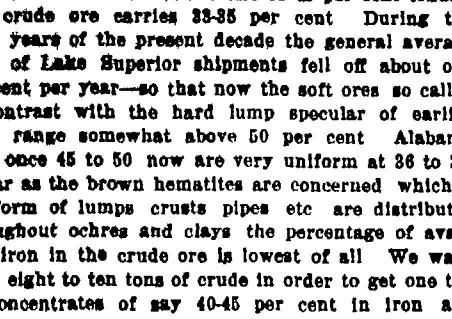

FIG 1 —A NEW LIFE SAVING BUOY HANGING ON THE RAIL OF THE SHIP

vided with cork jackets and floated so near the Swedish vessel that their cries could be heard on board were doomed to slow death by drowning because they could not be found in the darkness

How often the cry Man overboard' is heard and how rarely the poor fellow is rescued At night, especially it is almost impossible for the ship to return exactly to the spot where the accident occurred Life buoys thrown overboard in such cases are seldom picked up although the ship has apparently not moved during the night Even if the victim secures a buoy the boats sent to rescue him may cruise for hours in vain and finally leave him to perish as it is impossible to determine his location especially in a heavy sea

Hence a means of indicating the position of a drowning person at night is required The luminous buoys which are now in use and which usually consist of a cork ring carrying a cartridge filled with a mixture that becomes luminous on contact with water have many defects It is difficult and even dangerous to store and handle the highly inflammable cartridges which often fail at the critical moment In a rough sea the flame cannot be seen by the drowning man to whom the buoy is thrown or by the crew of the rescuing boat If the cartridge is attached directly to the buoy the latter may be burned or injured by corrosive gases and if it is attached by a line of any considerable length the victim may be unable to reach the buoy after finding the cartridge

Capt Miller a retired German naval officer has devised a greatly improved luminous buoy the following description and illustrations of which we reproduce from *Die Umschau* The essential features which assure the efficiency of the device are these The flame is raised nearly three feet above the surface of the water so that it is visible even in a heavy sea. The flame is 12 inches high and produces a light of 700 to 800 candle power which can be seen from a great distance and which burns three hours The burner is attached directly to the buoy

The new life-saving apparatus (Fig 1) consists of a cork ring of 17 inches interior diameter to which the burner is attached by a cardan suspension so that it maintains a vertical position despite the varying inclination of the ring tossed by the waves The lower end of the burner carries a water tight and air tight cartridge filled with calcium phosphide When the buoy is thrown this cartridge is slightly torn with the fingers or automatically by a short chain attached to the cartridge and the ship s rail (Fig 1) A few seconds after the buoy has struck the water the hydrogen phosphide which is generated by the action of the entering water on the calcium phosphide in the carton bursts spontaneously into flame at the top of the burner (Fig 2)

FIG 2—THE BUOY AFLOAT AND LIGHTED

The flame produces dense smoke as well as an intense light so that the new luminous buoy may be used to advantage in the daytime when it is much more easily located than an ordinary buoy The flame is so high above the water that the heat and smoke do not endanger the user of the buoy The efficiency and convenience of the apparatus have been demonstrated by numerous practical experiments

RULES GOVERNING THE COMPETITION FOR THE $15,000 FLYING MACHINE PRIZE OFFERED BY MR EDWIN GOULD

1 A prize of $15 000 has been offered by Mr Edwin Gould for the most perfect and practicable heavier than-air flying machine designed and demonstrated in this country and equipped with two or more complete power plants (separate motors and propellers) so connected that any power plant may be operated independently or that they may be used together

CONDITIONS OF ENTRY

2 Competitors for the prize must file with the Contest Committee complete drawings and specifications of their machines, in which the arrangement of the engines and propellers is clearly shown with the mechanism for throwing into or out of gear one or all of the engines and propellers Such entry should be addressed to the Contest Committee of the Gould-Scientific American Prize 361 Broadway New York city Each contestant, in formally entering his machine must specify its type (monoplane biplane helicopter etc), give its principal dimensions the number and sizes of its motors and propellers its horse-power fuel-carrying capacity and the nature of its steering and controlling devices

3. Entries must be received at the office of the SCIENTIFIC AMERICAN on or before June 1st, 1911 Contests will take place July 4th, 1911, and following days At least two machines must be entered in the contest or the prize will not be awarded

CONTEST COMMITTEE

4 The committee will consist of a representative of the SCIENTIFIC AMERICAN a representative of the Aero Club of America and the representative of some technical institute This committee shall pass upon the practicability and efficiency of all the machines entered in competition and they shall also act as judges in determining which machine has made the best flights and complied with the tests upon which the winning of the prize is conditional The decision of this committee shall be final

CONDITIONS OF THE TEST

5 Before making a flight each contestant or his agent must prove to the satisfaction of the Contest Committee that he is able to drive each engine and propeller independently of the other or others and that he is able to couple up all engines and propellers and drive them in unison No machine will be allowed to compete unless it can fulfill these requirements to the satisfaction of the Contest Committee The prize shall not be awarded unless the competitor can demonstrate that he is able to drive his machine in a continuous flight over a designated course and for a period of at least one hour he must run with one of his power plants disconnected also he must drive his engines during said flight alternately and together Recording tachometers attached to the motors can probably be used to prove such performance.

In the judging of the performances of the various machines the questions of stability ease of control and safety will also be taken into consideration by the judges The machine best fulfilling these conditions shall be awarded the prize

6 All heavier than air machines of any type whatever—aeroplanes helicopters ornithopters etc — shall be entitled to compete for the prize but all machines carrying a balloon or gas-containing envelope for purposes of support are excluded from the competition.

7 The flights will be made under reasonable conditions of weather The judges will at their discretion order the flights to begin at any time they may see fit provided they consider the weather conditions sufficiently favorable

8 No entry fee will be charged but the contestant must pay for the transportation of his machine to and from the field of trial

9 The place of holding the trial shall be determined by the Contest Committee and the location of such place of trial shall be announced on or about June 1st 1911

Stone Composition for architectural ornaments—Dissolve 8 parts of glue and 1 part of gum arabic in 12 parts of water and heat the solution to the boiling point During boiling stir in 12 parts of paper pulp Mix the whole with washed chalk Press the paste into well-oiled molds allow it to dry When hard soak it with hot linseed oil

Diesel Marine Engines*

A Resume of Recent Performances

By Herr Th Saeuberlich of Osterholz-Scharmbeck

S N E th days of the old ow press re steam en gines le e has been no time when marine propul sion attra ted more atte tion than to day In the pla e f the highly devel ped steam engine the ef ficiency f whi h it appears impossible further to in reas he D es engine is now making its way for ma i r pos s It is at the present moment the os perfe t ol e gine According to recent experi will like that of the large gas engine follow the ex ample set in steam engine construction

The prejudice against Diesel motors which still exists in shipb ilding circles has to a great extent broken down and recently it has become clear that various shipyards are in the position to build Diesel engines free from faults and reliable in working even with their present equipment

the rough requirements of a ship s auxiliaries

The advantages of the Diesel engine for mari purposes as compared with the steam engine diff according to the type of ship and the size of t equipment but in general the following are amo the most notable The gain in useful space by th reduction of boiler plant and small size of the fue

F G 2 ENGINES OF THE FRERICHS

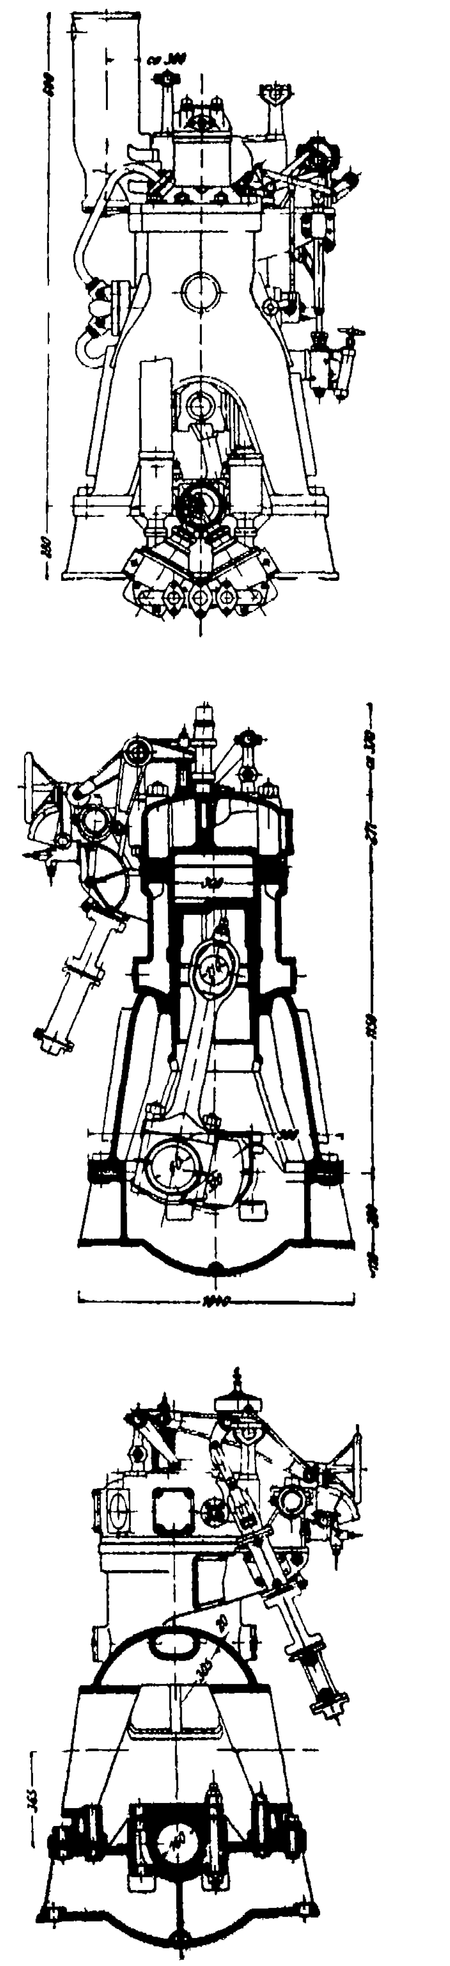

FIG. 3.—END ELEVATION AND SECTIONS

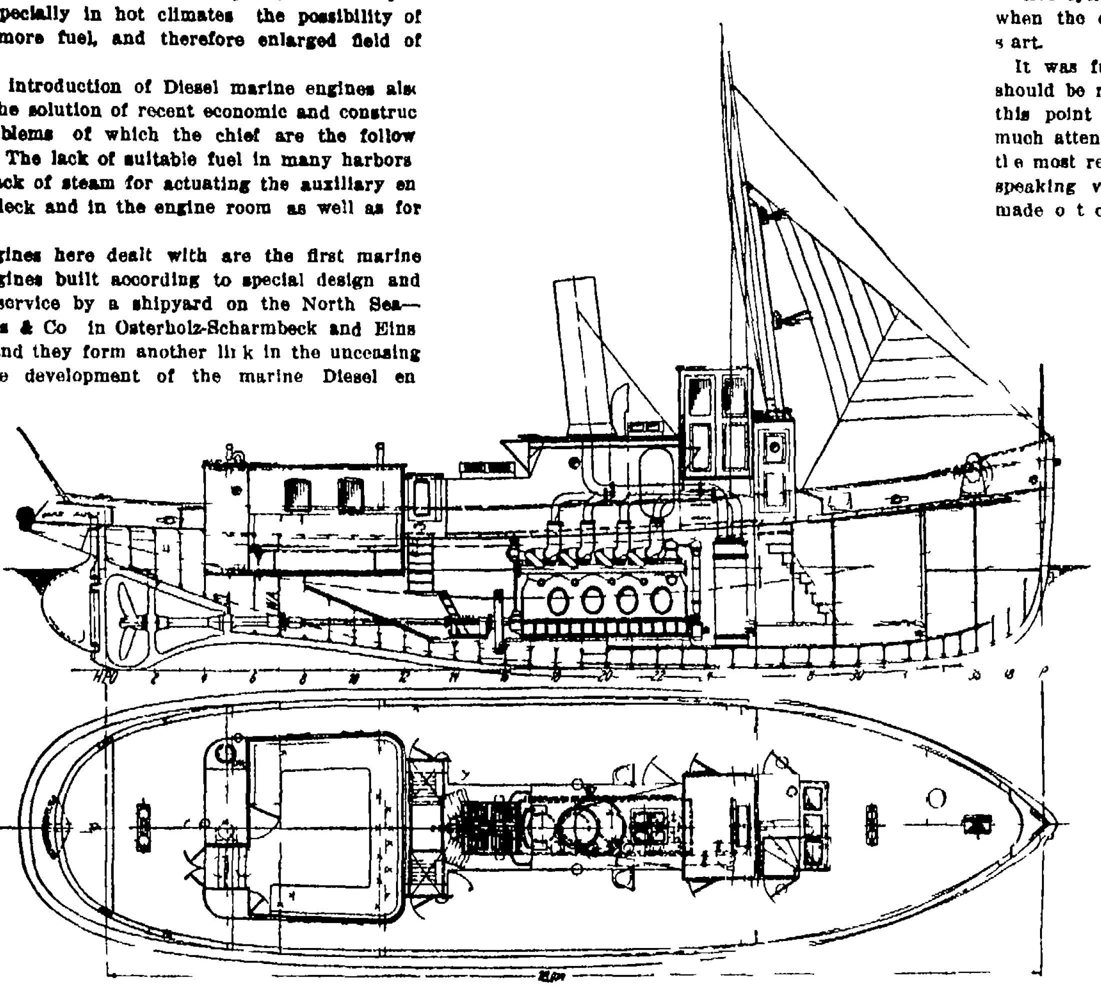
bunkers; increased capacity due to the small weight of the engine plant and the fuel utmost utilization of the otherwise limited useful space taken for fuel bunkers gain in time and economy of wages due to quicker and easier bunkering and also to decrease in coal trimming quicker starting of the engine reduced and easier management personal and space economy by reduction of the number of the stokers reduced cost of fuel cooler engine rooms resulting in the increased mechanical capacity of the personnel especially in hot climates the possibility of carrying more fuel, and therefore enlarged field of action

But the introduction of Diesel marine engines also involves the solution of recent economic and constructional problems of which the chief are the following (1) The lack of suitable fuel in many harbors (2) the lack of steam for actuating the auxiliary engines on deck and in the engine room as well as for heating

The engines here dealt with are the first marine Diesel engines built according to special design and put into service by a shipyard on the North Sea—J. Frerichs & Co in Osterholz-Scharmbeck and Einswarden—and they form another link in the unceasing progressive development of the marine Diesel engine They are (1) the direct reversing four cylinder Diesel engine of a maximum effective 200 horse-power with 360 revolutions per minute fitted to the service boat "Frerichs" built by the above-named firm (2) the 90 effective horse-power two-cylinder marine Diesel engine and reversing gear for driving the herring lugger "Ewersand" which is employed by the Brake Herring Fishing Company in Brake

The Service Boat Frerichs This service boat is a single-screw vessel built according to the rules of the German Lloyd for small coasting traders and has been in use since the spring of 1910 She serves for the special purpose of communication between the shipyard in Einswarden and the opposite bank of the Weser but especially for towing For this purpose she is equipped with a strong towing gear The towing power amounts to about 2 000 kilogrammes measured on the rope. The fuel employed is the so-called gas-oil 1 000 kilogrammes of which are provided in two tanks under the cabin double this quantity could however, have been conveniently carried These 1,000 kilogrammes permit of a voyage of 240 sea miles at 9½ knots, a distance which corresponds to about the voyage from Bremerhaven to Hamburg and back



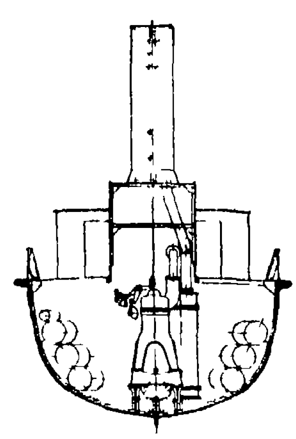


Fig 4—THE SERVICE BOAT "FRERICHS"

The vessel in external appearance is like a steam tug since she has a funnel for carrying off the gases With a length of 18 meters she has a very spacious engine room On deck near the pilot house and other deck erections is a large cabin affording room for twenty people The existence of this roomy accommodation is due to the omission of boiler and coal bunker space The motor Fig 1 is a reversing four-cylinder four cycle engine direct coupled to the propeller shaft at 360 revolutions it develops 200 effective horse power measured on the fly wheel and gives the ship a maximum speed of about 10 knots Its weight is about 10 000 kilogrammes

The reversing gear is actuated by compressed air abundance of which is available which moves the horizontal cam shaft endwise thus bringing a second set of cams into action Starting can be made quickly and safely and can even be effected in one second By a special arrangement of the compressor perfect certainty is guaranteed with regard to the starting of the engine in either direction even in the event of the motor stopping on the dead center The valve gear of the motor is the simplest imaginable All the necessary movements and arrangements are combined in a single mechanism For the entire manipulation including the regulation of the motor for high or slow speed all that is required is a single lever which for convenience is designed as a hand wheel

The cooling water pumps and Lenz pumps are driven by the engine crank shaft by an overhung crank and are—see Fig 3—fixed to the common base plate

The hot exhaust gases are cooled with water on their discharge from the cylinder in a double walled chamber After their union in a collecting pipe they are conducted into a large condenser which acts as the part of a silencer From there the exhaust pipe leads into the funnel where the exhaust gases pass into the air

The Lenz pump provides cooling water for the exhaust The compressed air which is required for maneuvering is generated by the motor itself by means of a two stage compressor which constitutes as it were the fifth cylinder of the motor It is received in six large receivers—Fig 4—which are placed along the side of the engine room and made fast to the ships side where they take up little room Further a smaller air receiver is also arranged on the port side. From it the air for the injection of the fuel into the cylinder and for reversing is taken The six large receivers serve only for starting The air used for starting is during the voyage gradually restored again from the small supply tank In the construction of the motor the utmost simplicity was sought, and it was especially demanded that the number of the cylinders and the movable parts should be limited as far as possible

To start a four cycle motor in any position at least six cylinders are required if the usual method is adopted It was however desired to limit the number to four cylinders and a way was found by making use of the compressor direct coupled to the motor This compressor is of special design and is provided with a gear which makes it possible to use it as a motive cylinder driven by the air from the receivers when the engine cylinders are not in a position to start.

It was further required that the cost of the plant should be reduced to the lowest possible amount To this point of view the constructor cannot pay too much attention since the cost of Diesel engines until the most recent times has always been comparatively speaking very high The base plate of the motor is made out of cast iron and in one piece It is closed [illegible] and the separate crank pits are connected below by channels so that the lubricating oil can flow to one end The main bearings Fig [illegible]—are recognizable as on the whole similar to the usual type in ship construction the lower brass is rounded and therefore easy to remove the upper on the contrary is squared A plate of Siemens Martin steel takes the place of the bearing cap

The general form of the standards will be gathered from Fig 5 It will be seen that great care has been taken to avoid sharp corners and sudden changes of form The whole piece is a single iron casting The lower part is semi-cylindrical above and the ends of

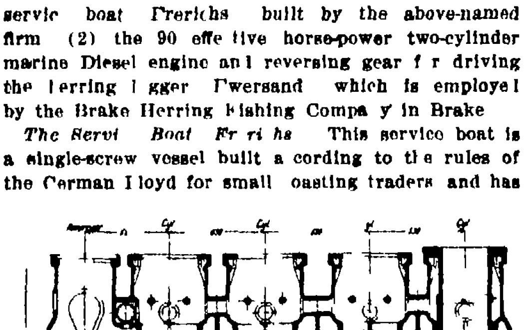

Fig 5—CAST IRON STANDARDS

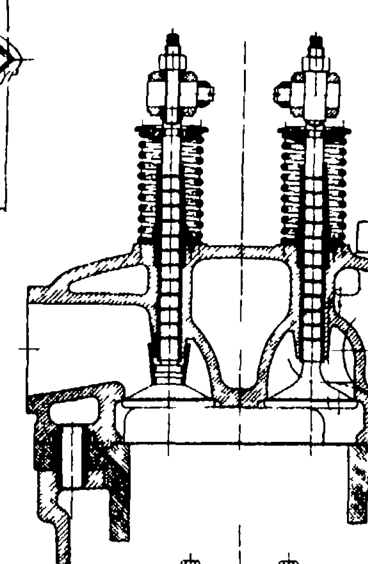

Fig [illegible]—CYLINDER COVER

it are domed The two walls are splayed outward to the base and pierced by large elliptical openings The cylinder liners fit the casting as shown and the water jacket is kept tight by a calked leaden ring All the jackets are in communication with each other by the passages shown in the drawing Round cleaning holes are provided in each jacket Between the compressor and the adjacent cylinder a square box is formed in the casting which constitutes an inter cooler for the compressor The brackets which support the valve shaft are also cast on The thickness of the casting is throughout about 20 millimeters

The cylinder cover is the largest and heaviest casting in the engine and on it are collected all the principal valves—the suction valve the exhaust valve the starting valve and the fuel valve All these parts have to be got into a constricted area little bigger than the piston diameter and yet to avoid unequal thicknesses of metal reasonable spaces must be left between the separate parts This arrangement is also necessary to insure equal cooling and to avoid stresses being set up by unequal heating. Furthermore an exceedingly sound casting is absolutely essential particularly at the joints and valve faces, and at those surfaces subjected to the high internal pressure in the cylinder or connected with the high pressure air supply

To carry out all these requirements however, presented little difficulty As may be seen from the engraving Fig 8 the suction and exhaust bends are separated from the two tubes or passages which take the starting and fuel valves The exhaust bend is entirely surrounded by water and is of such a shape as to give an easy flow to the gases The exhaust and admission valve seat direct on the cover for in no other way was it possible to bring them so close together It may be objected to this arrangement that dismantling is far more difficult than when separate valve cages are employed as it involves the removal of the whole cylinder cover but in an engine of this size no trouble in this direction has been experienced The only real objection is that the part of the valve spindle exposed to the hot gases may wear more rapidly than the remainder which is water cooled, but to reduce this objection the lower part of the spindle is protected by a cone from the direct impact of the hot gases. In the case of larger valves the employment of a liner is, of course, recommended. In order to make the cooling as effective as possible, the walls are made only 12 millimeters thick.

From the foundryman s point of view the casting of the cover presents now no difficulty but before the best mixture was found a considerable number were tried In the tests the fact that only the closest and densest blends should be employed was disregarded, and it was proved that the best results were obtained with the iron in ordinary use for steam engine cylinders All that is required is to use special care during casting and to keep the liquid iron after the mold is full in constant motion by means of a pump, to make sure that the mold is completely filled and the iron homogeneous

(To be continued)

The Two-point System Ignition

Merits of the Scheme Outlined

A talk on ignition and ignition methods given by Roger B Whitman of the Bosch Magneto Company not long since before the Long Island Automobile Club developed the merits claimed for the two point system Mr Whitman dealt with the details of ignition and its method His paper is given almost in its entirety below

The state of perfection of the present day internal combustion engine has not been reached without deep study and investigation in the course of which it has been realized that ignition has vastly more to do with efficiency than was at first believed

The early conception of ignition was the production of a spark some time toward the end of the compression stroke and if this spark was successful in igniting the mixture that was all that was desired The character of the spark the accuracy of its production or the exactness of its timing were points that were disregarded by the designer because he did not understand that these had any bearing on the power output or on the fuel consumption of the engine

The modern designer takes an entirely different view of the subject however and it may be of interest to outline the problem as it is now understood

To appreciate the fine points of ignition as they are understood to-day the engine must be considered in its true light as a heat engine pure and simple

The mixture that is drawn into the cylinder during the inlet stroke represents a certain heat value and the efficiency of the engine depends upon the manner in which this heat is applied to the expansion of the gases Any condition by which some of this heat is lost or by which it is not applied directly to the forcing of the piston outward on the power stroke will reduce engine efficiency

The first step in the securing of efficiency will be to study the points at which losses of heat may occur and to adopt means by which these losses may be prevented

The charge of mixture represents a certain heat value and has a certain maximum pressure To exert the greatest possible proportion of this pressure against the piston each particle of mixture should be made to give up its heat at the instant when the piston is at the end of the compression stroke and ready to move outward on the power stroke

To gain this result it would be necessary to ignite each particle of the mixture at the same instant, and thus to have ignition and combustion occur at top dead center The mixture would thus be compressed into a minimum space before ignition, and the rise in pressure due to combustion would then be most abrupt the piston being driven outward with maximum force

No existing ignition system will permit the ignition of all of the particles of mixture at the same instant The system in use therefore permits ignition of the mixture at one or two points from which the flame is expected to communicate itself to the remaining mixture particles

In a perfect mixture each particle of gasoline vapor will be surrounded by the particles of air necessary for combustion and to ignite the mixture it will be necessary to raise the temperature of these particles to the point at which the chemical change known as combustion will occur

Under usual motor conditions the heat developed by the electric spark is depended upon to raise the temperature of certain of these particles to the point at which they will ignite, and the flame thus started is communicated to the particles of the mixture immediately surrounding it this being propagated throughout the entire charge

To our senses the spread of the flame from the point of ignition is instantaneous but in comparison with the speed at which a gasoline engines operates the time required is very considerable and must be taken into consideration Thus there enters into our calculations the period of time that must elapse between the instant at which ignition occurs and the instant at which the entire charge will be inflamed

We desire to apply to the piston the greatest pressure possible and obviously the greatest possible pressure will be produced at the instant when combustion is complete At this instant therefore the piston should be at the top of its stroke We must not overlook the fact however that some pressure is produced at the instant when ignition occurs and that this pressure will be constantly increasing as combustion spreads If combustion is to be complete when the piston is at its top point it is clear that ignition must occur while the piston is still moving upward on the compression stroke For the last portion of its stroke the pison will therefore be subjected to this pressure which is rising to maximum and by which the piston will tend to be driven backward at the same time the momentum of the fly wheel is urging the piston upward Some of the power of the engine will thus be required to force the piston upward and in this is found one of the most serious of the losses in engine efficiency If the engine is going at a sufficient speed the momentum of the flywheel will force the piston against the pressure in the combustion space to top center but the result of the conflicting pressures will be shown in abnormal wear of the wrist pin crank pin and main bearings

You have all had experience with a back fire when cranking an engine and know that it is the production of maximum pressure in the combustion space before the piston reaches the top of its stroke the result being that the engine starts to run backward This same condition in a lesser degree exist in a running engine under the normal condition of ignition occurring before top center

The charge of mixture represents a certain heat value and can be made to exert a certain definite pressure upon the piston To get the best possible results all of this pressure should be exerted against the piston when the latter is at the top of its stroke If some of the pressure is exerted before the top center is reached less pressure will of course remain to act on the piston during the power stroke This entails a double loss for not only is the rotation of the crank shaft somewhat retarded but the maximum pressure developed at top center is reduced The effect is shown in an increase in the consumption of fuel and in a reduction of the power output

Another loss that results from ignition earlier in the stroke is due to the absorption of heat by the cylinder walls the surfaces being of metal are natural conductors of heat and of course the longer the period during which the flame is in contact with these surfaces the greater will be the heat absorbed and wasted in this manner

The obvious way to reduce loss of power from these causes is to produce ignition as late in the stroke as possible but in this we are limited by the necessity for having combustion complete at top center

The remedy will therefore be to hasten ignition as much as possible or in other words to reduce the time necessary for the propagation of the flame throughout the mixture

One of the most important factors in this is the location of the spark plug which should be so placed that the distances through which the flame must be spread are as short as possible If for instance the plug is located in the inlet valve cap the distance through which the flame must spread will be practically maximum and the operation will require more time than would be necessary if the spark plug were located in the cylinder head Furthermore the plug should be located that its points are actually plunged in the mixture and not set in a cavity or pocket Engines are occasionally seen with valve caps that are solid and possibly an inch thick If a standard plug is screwed into such a cap the spark points will be found some distance up the hole the spark will ignite the mixture which is in the hole and some little time will be required for the flame to spread down to the hole and to be communicated to the mixture

Such a construction will require considerably more advance of the spark than would be necessary if the spark points were in direct contact with the charge

The size of the ignition spark is also a factor that determines the time required for combustion The ideal ignition spark should be a mass of flame with as large a surface as possible for this will result in the ignition of a large number of mixture particles. It should be understood that the spark must come into actual contact with the mixture particles in order to ignite them and if the spark is thin it will be quite possible for it to pass through a throttled mixture without actually coming into contact with any of the particles With a spark that is in the nature of a flame this cannot take place A large spark not only insures ignition but makes combustion more rapid for combustion will certainly be more rapid if for instance a hundred mixture particles are ignited by the spark instead of but one

Following along this line brings us to the proposition that it might be better to ignite the mixture at two widely separated points instead of at but one on the theory that this will reduce the time necessary for the propagation of the flame

If a spark plug is placed in the inlet and a second one in the exhaust valve and sparks are caused to occur at these plugs at the same instant the time required for the spread of the flame throughout the whole charge will be much less than would be necessary were the flame to originate at one side and be required to spread across the entire width of the combustion space

This has been theoretically admitted for a long time but the difficulty in its practical application lay in the securing of apparatus that would permit the production of two sparks at absolutely the same instant

Ignition apparatus of this character has now been perfected however with results that are satisfactory from every point of view It may be said at the beginning that it is essential to locate the spark plugs properly If the two are set side by side in the inlet valve cap, for instance, there will be no gain through the use of two spark ignition over one spark. To secure proper results from this system it is necessary to separate the plugs and to locate them so that the flame will have an approximately equal distance to spread in all directions from each.

A series of comparative tests was recently made

…gine arranged for operation either with one … or with two The engine was a four-cylinder …-inch bore by 4¾-inch stroke and was con…ed to an electric dynamometer that made it pos…e to gage the power output very accurately

With single spark ignition the maximum output …6 horse-power was reached with an ignition ad…ce of 45 degrees, with two-spark ignition the …e output of 24 horse-power was obtained with …advance of but 18 degrees and a maximum output …8 horse-power was obtained with an advance of … 32 degrees. In other words the maximum power output possible with single spark ignition was equaled by two-spark ignition at considerably less than one-half the advance while with two-spark ignition it was possible to increase the maximum power output by 16 per cent

At first sight it seems somewhat extraordinary to claim that the power output of an engine will be increased 16 or more per cent by producing ignition at two points in the cylinder instead of at but one … the line of reasoning that we have followed makes it clear that the gain is due to the preventing of losses that follow early ignition

The two-spark ignition system has been used on racing cars since last fall the Vanderbilt race mark… its first appearance on American roads In that race Dawson s Marmon car was equipped with a Bosch magneto of the two-spark ignition type and no one who saw it run could fail to be impressed with its extreme speed and its extraordinary ability to pick up after a slowdown

All cars entered in races subsequent to the Vanderbilt have been equipped with two-spark ignition and to get down to actual results it may be said that the Marmon and Lozier cars showed an actual increase in speed of from four to five miles an hour on changing from single to two-spark igition (Bosch)

This system unquestionably marks the greatest improvement that has been made in engine operation for a number of years past The magneto itself is of great simplicity for it is identical with the ordinary magneto except that a second distributer is provided In the magneto of the independent type one end of the armature winding is grounded on the armature core and the current after passing through the spark plugs returns to the grounded end through the metal of the engine and magneto In the two spark magneto this end of the winding instead of being grounded on the armature core is carried out through the distributer and grounded on the engine through the second spark plug The circuit therefore consists of the armature winding one distributer one spark plug to engine ground to the metal of the engine and thence to the armature winding by the second spark plug and second distributer

Not the least advantage of this system is its great reliability for one plug may become fouled without interfering in the slightest with the operation of the other It has further been many times demonstrated that oil has far less effect on this system than it has on a single plug system and that overoiling that would put a single spark magneto completely out of business will not interfere in the slightest with the perfection of the operation of two-spark ignition

We have seen the necessity for causing ignition to occur as late as possible in the stroke and it follows that we must use ignition apparatus that will produce the spark at exactly this point and at no other

If the apparatus selected does not produce this result, and if it permits the spark to occur a little earlier on one stroke and a little later on another the result will be an unsteadiness in the operation of the engine a reduction in power output and an increase in gasoline consumption

Any one who has had experience with an automobile knows that the engine will run more steadily and more powerfully on a high tension magneto than it will on a battery and coil system but the reason for this is not always understood It lies largely in the fact that the magneto produces a spark absolutely accurately and without variation while with the coil and battery system the point at which the spark will occur will vary considerably

The battery timer will make contact definitely and at the proper instant but this does not mean that the spark is produced accordingly

Upon the closing of the battery circuit by the timer the battery current is permitted to flow through the primary winding of the coil with the result that the core becomes magnetized The effect of this is to draw the vibrator blade away from its contact and thus to break the battery circuit the consequent collapse of the magnetic field causing the induction of a high tension current in the secondary winding It is this current that furnishes the spark

It is seen that the electric current is required to do certain work between the closing of the circuit by the timer and the production of the spark at the plug and the lack of accuracy in the system lies in the fact that the current does not always consume the same time in performing those functions

This can be demonstrated on apparatus that consists of a shaft that may be driven at variable speed by an electric motor This shaft carries a pointer that travels around the inner side of a graduated ring One end of the shaft carries a battery timer while the other end drives a high tension magneto the magneto armature and the timer revolving at the same speed

The circuit is so arranged that the spark produced by the magneto or by the coil may be caused to pass between the moving pointer and the graduated ring

Turning the apparatus slowly by hand with the magneto thrown into the circuit will show that the spark is produced at the zero point of the graduation By throwing in the electric motor the speed may be increased to anything up to about 1 500 revolutions a minute and it will be seen that the magneto spark invariably occurs at the same point

In other words the point in the rotation of the shaft at which the magneto spark occurs is not affected by the speed

As the speed increases the igniting ability of the spark evidently increases for its size can be seen to increase until at 1 500 revolution a minute it endures for about 30 degrees of rotation

Throwing the magneto out of circuit and cutting in the battery we will again turn the apparatus slowly by hand The first battery spark will be seen to appear at the zero point and at low speed there is an apparent sheet of flame for the entire 40 degrees during which the timer is making contact

Running the speed up slightly we will see that this sheet of flame is broken up into a series of single sparks which occur very closely together Throwing in the electric motor we will see that at 500 revolutions a minute the distance between the successive sparks is increased very considerably

Each of these sparks corresponds to a single movement of the vibrator during which the battery circuit through the primary winding of the coil is broken

We will see another interesting thing which is that the first spark no longer occurs at the zero point but some degrees after it On increasing the speed to 1 000 and then to 1 500 revolutions we will finally find that during the 40 degrees when the timer is making contact only two sparks are produced which means of course that during that period of time the vibrator has had time to move but twice

The vibrator will make a certain number of vibrations a second say 300 If the timer holds its circuit closed for one second there will of course be 300 sparks produced at the pointer If on the other hand the timer holds the circuit closed for but 1/100 of a second there will be time for but three movements of the vibrator and in consequence only three sparks will be produced Furthermore the first spark instead of occurring at the zero point now app ars some 20 or 2 degrees afterward and we immediately recognize this lag as repr senting th time required for the electric current to perform its various functions between the instant when the timer closes the circuit and the instant when the spark appears

The delay in the production of the spark may be corrected by moving the timer so that contact is made some little time before the spark is actually required The lag due to the work that the electric current must perform is thus overcome mechanically by moving the timer

The moving of the timer however does not correct the shifting in the position of the spark and this cannot be corrected by any means that could be used on an automobile

If the spark is observed it will be seen that it does not always occur at the same point but varies considerably the total variation being 8 or 10 degrees

At the instant when the timer closes the circuit the vibrator contact may also be closed but on the other hand the vibrator contact may be open the blade not having come to rest from the movement caused by the previous closing of the circuit A slight variation in the voltage of the battery will also cause a difference for the lower the voltage the less able will the primary current be to force itself through the winding of the coil

The coil offers resistance of course and it takes certain electrical pressure to overcome it To overcome it more rapidly the pressure must be increased or in other words the voltage in the battery must be raised

If we could change the voltage of the battery to correspond with every change in the speed of the engine we might get better results but we would still need a vibrator blade that we could be sure would be in a true and good contact every time the timer closes the circuit Furthermore we would find it necessary to assure ourselves that the circuit was actually closed at the timer for when the timer contacts are covered with grease or dirt the circuit will not be actually clos d until the moving part of the timer is half way across the timer contacts

The timer that is used with the testing apparatus is operating under perfect conditions and the contacts are clean and uncorroded This is not often the case with the timers that are used on automobiles and consequently the results of the use of such apparatus on an automobile are far worse than are here indicated

Some Unsolved Problems in Electro-Plating*

By George B Hogaboom

As is well known electroplating was the beginning of the science of electrochemistry but it has lingered by the wayside and been neglected as a science and to-day the unsolved problems are many

Electroplating has been looked upon more as a trade than a science and it is only during recent years that much study has been given to it by scientists and that attention has been directed more to the electrolytic refining of metals than to the deposition of metal for decorative purposes The solutions published by Roseleur in 1854 have been improved upon but little and those who have published treatises upon the subject often give only a repetition of his formulæ Nickelplating, as invented by Dr I Adams is probably the only exception.

The field is broad, but its development has been left to the practical man, guided only by rule of the thumb An electrochemist in the plating room of a factory is so rare that it probably can be said without fear of contradiction that they can be counted on the fingers of one's hands The need to-day is mutual assistance in solving these problems and developing of new ideas. To a great extent they are useless each without the others—the plater producing results which he cannot duplicate—the electrochemist creating solutions that are not a commercial success

So many phenomena have been encountered that to include the perplexing problems would necessitate a history of nearly every known solution and finish The varying of the temperature and the electric current often proves a stumbling block and these conditions cannot always be controlled There is a vast difference between producing a homogeneous deposit at a minimum cost from a solution where th amount of cathode surface is being changed every twenty minutes and a solution in which the amount of cathode surface is always the same and the rapid deposit of the metal is more desired than a deposit that can be easily burnished Such would be the difference, for instance between the surface of a sheet of electrolytic copper and that of a cast lead and antimony electroller with its deep reliefs and where a coarse crystalline structure would destroy its beauty In the discussion of electroplating problems it must be borne in mind that a mere deposit of a metal is not all but that the deposit must be soft and smooth and lend itself to a decorative process, the anodes should be capable of being reduced easily, the electrolyte must offer little resistance to the electric current and last but not least to the plater, who hears it so often that it becomes a part of him. the cost must be nominal

DIFFICULTIES WITH SEVERAL METALS

The automobile industry has brought about more than anything else the need of a heavy deposit of brass At present this is done in a solution of cyanide of copper The deposit is not only slow but unsatisfactory, because of what is known as spotting out—a discoloration in spots which appears on the work after it has been polished and lacquered Deposits on cast metal give the most trouble It is probably caused by the acids or alkaline solutions being absorbed in the pores of the metal or in the small blow holes and the deposit covering these holes partially leaving minute holes through which the solution oozes out

Several promising remedies have been suggested and tried such as boiling out in some neutralizing chemical solution or placing in a drying oven for several days but a satisfactory remedy has not been found An acid brass solution would be a great advantage There is an acid copper and an acid zinc solution but no acid brass electrolyte The difference between the deposit from a cyanide and a sulphat of copper solution well illustrates the advantage of having an acid brass solution

The formula for a tin solution published by Roseleur is the most generally used to-day as little if any improvements has been made upon it, although a good solution, which would give a heavy deposit

* A paper presented before the American Electrochemical Society, New York.

is much d sired In Roseleau s solution the electro lyte is not replenished by the anode but by the con stant addition of a concentrated solution This should be overcome and would be appreciated by manufacturers of tin ware While several solutions have appeared from time to time for plating upon aluminium none of them is in general use and a good electrolyte that would deposit gold silver brass or copper so that it would stand burnishing and not peel off in time could be used The success ful removal of a deposit of nickel from another metal without affecting the latter has not been ac complished

UNSOLVED PROBLEMS

To give all the unsolved problems in detail would make a lengthy paper and a simple statement of those most desired will be given An electrolyte that will remove the fire-scale from brass also one that will produce a bright or a matte surface in place of using the present acid dips an electric cleaner that will saponify the grease and take it into solu tion instead of driving it to the top where it has to be constantly removed to prevent it adhering again to the work as the later is removed from the solu tion a heavy deposit of lead on the inside of iron pipes, to prevent rapid corrosion a method to coat electrogalvanized iron or steel with decorative metals without destroying the rust resisting proper ties of the zinc an alkaline nickel-silver solution that can be worked with a low voltage, a method of etching steel without destroying a resistance film of gelatine some alkaline substance that would replace cyanide of potassium This would be universally welcomed

For the above suggestions the writer is indebted to 100 different platers who were kind enough to answer a request for unsolved problems It may be interesting to note that 80 per cent of them requested an acid brass solution

Something About Writing Inks

Notes on Fluidity, Durability, Corrosion and Copying

A GERMAN firm has had the good sense to enlighten the public in general as well as its own customers in particular concerning the properties of writing inks and how to deal with these necessary fluids as follows

Fluidity- Every writing ink loses water by evapor ation and also becomes less fluid by the addition of dust. For this reason only such ink stands should be used as have small openings and these should be closed after use When the ink gets thick it should be replaced by fresh that which is spoiled by sedi ment should be thrown away- it costs only a very small fraction of a cent Ink bottles should be kept closed and in a cool place best inclosed in the ordin ary pasteboard package

Durability -If steel pens pieces of cork or other foreign bodies get into the ink stand they will spoil the best of ink For this reason the stand should be cleaned every time before being filled fresh ink should never be added to old and different kinds of ink should not be mixed Among other signs of spoiling may be mentioned change in color If ink which is kept in a closed bottle and a cool place is spoiled it is either originally bad or is very old and should not have been sold by the retail dealer

Corroding of Steel Pens—The points of the best steel pens would not last more than a week even if that when used with pure water by reason of the friction on the paper In addition to this about 80 per cent of writer hold their pen obliquely so that one point is more used than the other and for this reason the pen is sooner out of service than it other wise would be One should not blame the ink when the pen is used up Those who write all day should change the pen about every three days The expense is but slight in comparison with the convenience hardly a hundred pens a year—only about 50 cents For each kind of ink a special pen should be used

Dirty Pens—The oftener one breaks off his work and lays by his pen without wiping it, the sooner it will be covered with deposit If the ink is properly composed this deposit will however be but slight and cause but little inconvenience The amount of deposit will be influenced more or less by the degree of smoothness of the pen itself

Copies In choosing a copying ink one should consider the following questions

(a) The number of copies required (b) The amount of time available for making the copies (c) *The manner of copying* whether with a platen press or a roller machine (d) The kind of writing and copying papers

And even after paying attention to all these points in the choice of the ink one may get bad copies For this reason the following hints should be ob**served.**

(1) **Copying with the platen press. For this process both log wood and nut-gall inks are suitable The first have a great copying power and last very** long **the second last very long in the bottle, but will** not **copy when the writing is old**

Rough writing papers—not excepting the finest—give poorer copies than smooth ones that are well sized Cheap papers contain wood and most post cards absorb the ink and make copying impossible The thinner the copying paper the plainer and the more legible will the copies be Thick lines copy bet ter than thin ones Old writing must be pressed harder and longer than new Where copying must be done in a hurry (that is in large establishments with a very heavy mail) a copying ink is necessary which gives good copies even with rush work The best copying paper is the so-called pure silk paper for several copies the yellow so-called export paper or Japanese silk paper is preferable The copying paper should be made as wet as possible and super fluous water removed with blotting paper

To obtain several (four to six) copies as many sheets of copying paper should be moistened with out any paper between them as are desired, the extra water is removed by blotting paper and if the writing to be copied is fresh it should be pressed for a minute if old for five minutes At first the pressure should be but slight in order to give the ink time to free itself and enter the different sheets of copying paper Heavy pressure at first gives wide lines and blots on the copy

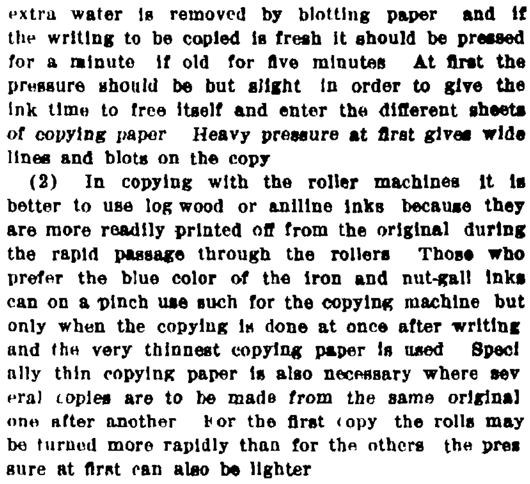
(2) In copying with the roller machines it is better to use log wood or aniline inks because they are more readily printed off from the original during the rapid passage through the rollers Those who prefer the blue color of the iron and nut-gall inks can on a pinch use such for the copying machine but only when the copying is done at once after writing and the very thinnest copying paper is used Speci ally thin copying paper is also necessary where sev eral copies are to be made from the same original one after another For the first copy the rolls may be turned more rapidly than for the others the pres sure at first can also be lighter

It is very important to adjust the machine properly for the ink used If several kinds of writing paper - rough and smooth—or different kinds of copying ink are used in the same office it is just as neces sary to adjust the machine for each as in the case of the platen press

In general the same principles apply to the choice of paper and the processes with the roller machine as for copying in a platen press

A Universal Tool

A NOVEL combination tool designed especially for a private garage has made its appearance Both sides of this tool are shown in the line-cut herewith At



A UNIVERSAL TOOL FOR GARAGES

A is located a forge that is given its blast through a tube leading to the central hole by a small fan in side the tool at *B* that is operated by the crank *C* On the opposite side is located an emery wheel *D* that is also operated by the crank *C* This same crank *C* through bevel gears also drives a chuck *E* that will hold drills or similar tools for machining work while the hand wheel *F* can be used to feed the work up to the tool The chuck can be taken out and the pipe grips *G* and *H* inserted in this hole and another one opposite and the tool used for a pipe vise while an ordinary machinist s vise is located at *I* The top and rear end of one vise jaw is formed into a black smith s anvil *J* while an anvil chisel *K* is supplied to fit the square hole for cutting off work —*American Machinist*

Lacto—A Scientific Summer Drink

THE popularity of summer drinks and ices is such as to make interesting any new addition in the na ture of a frozen product. **Many attempts have been made to present a drink from soured milk flavored with fruit juices with more or less success but in a recent bulletin the Agricultural Department tells of a new frozen product which is called lacto and has been developed toward perfection by the dairy section of the Iowa Experiment Station First buttermilk was used as the basis without entire success, and later skimmed milk which had been soured by a com mercial lactic acid culture was substituted for the buttermilk and combined with eggs, and various fruit flavors giving a product which possessed a deli cate flavor It was found that lacto which may be briefly described as a frozen product made of loppered, whole or skim milk with the addition of eggs sugar lemons and flavoring material has a more pleasing flavor than sherbets and ices and contains consider able more nutriment including as much protein as ice-cream less fat and more acid Out of 179 who sampled lacto 128 pronounced it very good 37 good, 6 fair, and 8 poor and as compared with common vanilla ice-cream 111 preferred lacto 9 considered it** equal to ice-cream and 59 preferred ice-cream Com paring lacto to sherbet, 123 preferred lacto 30 pre ferred sherbet and 26 considered lacto equal to sherbet

Artificial Fur

A NEW French process of making artificial fur which has been patented by its inventor M Marche merits description on account of its originality and ingenuity if not because of its practical importance Small pelts are sewn together stretched with the fur side up on the flat bottom of a large pan and covered with water which is then frozen The cake of ice is removed from the pan and a slice of the exact thickness of the skin is sawed off the bottom of the cake By melting this thin slice of ice the skins destitute of hair are recovered for use in the leather industry The upper part of the cake of ice con taining the hairs is placed with its base near a hot surface until a thin uniform layer of ice is melted and the lower ends of the hairs are exposed The base of the cake is then varnished with a solution of India rubber and after the varnish has become hard the ice is melted In this way is produced a large seamless artificial pelt composed of the natural hair of a number of small pelts or pieces attached to a sheet of India rubber These artificial furs are cheap as the natural skins are saved for other uses, and they are moth proof owing to the substitution of India rubber for animal tissues

Cement for Repairing Stone Slabs, etc —(a) Finely ground granite or standstone or burned magnesite in the absence of the latter ordinary magnesite is stirred with water glass into a paste and quickly worked For all cements it is best to use potash water glass (b) Granite heavy spar precipitated or ground fine as dust and hydrate of lime in equal parts are powdered into a paste with varnish Hy drate of lime with approximately 24 to 25 per cent of water is obtained by using equal parts by weight of hot water for slaking lime allowing it to stand for 24 hours and then straining it off

The Nature of Invention

How it is Governed by Evolution

By J. Lowy

I

The problem of fathoming the creative activity of the human mind of investigating the causes and the laws which determine the action of this mysterious agency has in all times engaged the attention of the thinkers of the civilized world. In spite of all efforts and astute analysis however no satisfactory conclusion has ever been reached. The reason for this is twofold.

In the first place the case has been regarded as standing more or less by itself and disconnected from other natural phenomena. A kind of sacred fear seems to be felt of attacking it from a purely objective point of view like any other subject of scientific inquiry. The analysis of creative mental activity was reserved to metaphysics and consequently failed to yield a clear result capable of rigid proof and fitting in without straining with the general plan of our knowledge of nature.

The second cause of the failure of the earlier attempts to solve the problem lay in the fact that the methods and results of scientific investigation had not yet reached that state of perfection which they possess at the present time.

We are to-day fully justified in assuming that all the phenomena of which we can become cognizant whether they belong to the domain of matter or to the world of ideas are subject to the universal process of evolution and its laws. If we take a survey of the world in the light of the laws of evolution all the boundaries which seem to divide the several domains of nature seem to be suddenly erased. There is no longer any deep cleft dividing the inorganic from the organic the living from the non living or plants from animals. Not only the concrete objects of nature are seen to be subject to the laws of evolution but also the realm of thought. Thus the great epistemologist E. Mach has said: Ideas are not individual organisms. They are however manifestations of organic life. If Darwin saw truly they too must display a succession of transformations and an evolution. The products of our mind represent special non material branches proceeding from a material trunk the brain and are therefore subject to the same laws as the material members in the chain of evolution.

II

It is proposed in the lines which follow to consider the phenomenon of invention from the point of view of epistemology. We shall see that this activity of the human mind mysterious and unfathomable as it appears proceeds strictly according to rule and obeys the laws of evolution.

The history of civilization shows that man originally was dependent for the performance of his various activities upon natural organs such as the hand the teeth etc. At a later stage man learned to employ articles which he picked up in nature such as branches of trees flints bones turning them into rude implements. Still later primitive man learned to modify articles accidentally found so as to better adapt them to his purposes. In doing this he as a rule copied some existing organic example. Thus for instance he made the ax in the image of the human arm and fist and the saw may be said to have been patterned after the human jaw with its teeth. The process of adapting the implements to their work went on vigorously until finally these artificial aids excelled in usefulness for their particular purpose the organic patterns after which they were fashioned.

The process of adaptation which we term invention takes its course under the guidance of the human will which itself is governed by law. The basis from which the operation necessarily starts is the stock of facts known to the inventor who as a rule proceeds in such logical manner that in most cases we have presented to us the appearance of a methodical process of invention seemingly quite independent of accident. The law and order which holds its sway over invention is not clearly realized by the inventor. A large part perhaps the most essential step in the mental process leading to invention takes place subconsciously. It appears as if some invisible power were guiding the process of thought.

That invention and technical developments follow a prescribed course is proved by many technical products which were not consciously evolved as copies from nature but which were subsequently found through the discoveries of physiology to be analogous in structure to human organs. Thus for example the piano represents a faithful copy of the ear though it was built without any knowledge whatever of the structure of that organ and similarly the camera is a close copy of the human eye. Human creative activity therefore begins with the unconscious copying of nature and unconsciously continues this copying process.

Similar requirements produce in the technical arts the same type of devices as they do in the organic world. The process of invention is a manifestation of natural forces just like all other processes of evolution—the inventor is merely a tool blindly following the law of nature. It is not the inventor who invents but as it were nature which invents in him and which through him and his technical achievements furthers the general process of evolution.

Animal technique also is a proof of the law which guides all technical products. Certain structures built by animals are so well calculated for the purposes for which they are intended and are in such excellent accord with the laws of mathematics and physics that even man could not with the same means produce anything more perfect. We need only call to mind the ant hills of the termites and the hive of the bee. The most important tool which human engineering commands over and above those at the disposal of animals is the weapon of mathematics by the aid of which he shortens the process of evolution. The laws formulated in mathematical guise are however nothing more than the epitome of experiences previously gained by man. Just as animals inherit the accumulated technical experience of their progenitors in their instincts so man hands down his acquisitions in the form of the natural laws and mathematical formulæ discovered by him.

III

We are provided by nature with organs of special sense which respond to a limited number of forms of energy such as for instance light and sound. For a number of other forms of energy we possess instruments the products of technical industry which enable us to detect the presence of these forms of energy. Thus for example the coherer serves to detect electric waves a bismuth spiral discloses magnetic radiation and the barium platinocyanide screen renders us conscious of the X rays. These instruments accordingly fulfill the functions of natural organs. They are like all other technical products nothing more than products of adaptation to nature auxiliaries in our struggle for existence. Where organic evolution ceases technical evolution sets in as its continuation. Instead of improving the eye nature created the telescope and the microscope, instead of strengthening our muscular powers it created working engines. Instead of adding new organs to those which we possess it created for us artificial organs.

Technical and organic evolution merge into each other both serve the same purpose both follow the same laws. The question then arises: Why and by what circumstances is organic evolution separated from technical evolution?

We have seen that technical creations represent products of adaptation of our being to nature just as is the case with our organs. The mode of origin of these products of adaptation we may according to modern scientific views picture to ourselves in this way that the stimuli exerted by external forces upon the existing organism have directly caused the development of such organs as are suited for the perception of the stimuli and the fulfillment of the requirements created by the stimulus. The products of adaptation thus formed serve in the first place the purpose of removing the cause of the stimulus which is usually felt as an irritation and often as a positively painful and dangerous condition. In the same measure as the process of adaptation advances the stimulating action is diminished when the body is perfectly adapted to its environment the stimulus which initiated the process has ceased to act altogether. In this way the stimulating action of light has produced the eye the stimulus of a toxine in the body produces the anti toxine, and similarly water under the influence of high temperature is converted into steam, which accordingly presents itself as a modified form of water adapted to those temperatures.

Every organism is subjected to a variety of forces and the organism is thereby compelled to adapt itself to stimuli. So long as adaptation was possibly only within the limits of organic processes, this adaptation went on excessively slowly, when however the organ of thought the brain had reached a certain stage of evolution these stimuli no longer acted merely upon the portion of the organism directly concerned but also upon the thinking organ. As the result of this any inability on the part of the body to react to the stimulus is unpleasantly felt by the brain which therefore seeks to discover some rapid method of adaptation and overtakes and therefore renders unnecessary organic adaptation. In this way the technical arts came into being as the continuation of organic evolution.

IV

On the basis of conclusions reached so far we shall now have no difficulty in satisfactorily answering a number of questions which arise in connection with the subject of invention. If in this process we divest the inventor of some of the glory in which he is ordinarily enveloped this will be in some measure compensated for by the fact that we shall gain a better understanding of his activity. The honor which we shall then pay him will it is true be far removed from a feeling of sacred fear or adoration but will nevertheless be a perfect and sufficient substitute in asmuch as we shall learn to appreciate the pains the labors and the disappointments of the inventor and shall thus be placed in more immediate human relation to him.

The first fact which strikes us is that no invention however epoch making was purely the product of the head of him to whose name the glory is attached. Every invention represents a temporary end point in a long series of technical perfecting steps which are all connected together like the links of a chain. In many cases the merit of the last inventor upon whom falls the reward and the applause of his fellows and of posterity is considerably smaller than that of many of his predecessors. He a favorite of fortune whose good luck it was to appear upon the scene at a later date has thrown into his lap often through some quite secondary performance on his part the mature fruit the natural outgrowth of the ground prepared by earlier investigators.

The fact that the development of every invention follows a definite law is also the explanation of the frequently observed fact that the same invention is made simultaneously by different inventors working independently. Working on the same basis of previously accumulated knowledge and placed under the same pressure of similar necessities they must necessarily reach the same results representing the last product of evolution. The accusation of plagiarism must therefore be made with great circumspection in matters relating to technical industries.

We can also understand from our present point of view that a man can become a genius of invention only by assiduous labor and study of all that is already known in the field in question. Every invention recapitulates in the head of its creator all the principal stages of its gradual evolution in the past history of the race. The layman as a rule merely rediscovers something which has long been surpassed in the art. For his invention represents the last step in order in the evolution of his knowledge which is not up to date.

To what extent the creative activity of the inventive mind depends on the stimulus of his environment is best recognized from two facts. The first of these is a well known observation familiar in the patent offices of all countries. Generally speaking in every domain of industry there is a steady production of inventors which remains approximately constant at all times. The moment however, that through any circumstances the attention and the thoughts of the world are directed to any particular problem and its solution the number of inventions relating to this particular field goes up by leaps and bounds.

The second fact which is to be mentioned as a sign of this stimulating influence of the environment is the observation that technical men who have proved themselves eminent inventors in their professional practice become almost entirely sterile as soon as they leave the battlefield.

If an invention represents only a small step forward as compared with the known art in a given field, the world is readily able to follow in thought this small step, and the value of the invention is understood without difficulty. If, on the other hand the invention represents a step in the evolution of the art, which is far removed from the last in the same series, then the world, and even the world of experts, often

* Translated for the SCIENTIFIC AMERICAN from *Technische Monatshefte.*

fails to follow the flight of the genius, and the inventor or scientific discoverer reaps, instead of fame, only ridicule and scorn. It is only in later days when a number of re-discoveries of smaller order have covered in a series of small steps the great advance which he had made in one that the world at large realizes the greatness of the genius who by this time is usually dead. In belated token of their appreciation the people then raise a monument to him who can no longer feel the pleasure of this poor compensation for the troubles and pains endured during his lifetime.

Mesothorium and Radiothorium

Substitutes for Radium

The development of radioactive investigations in recent years and especially the increasing employment of radium and its emanation in medicine have created a strong demand for radioactive substances which cannot be satisfied by radium itself. It is very difficult to produce radium in considerable quantities owing to the scarcity of raw material. As substitutes for radium the slowly disintegrating derivatives of thorium which are known as mesothorium and radiothorium naturally suggest themselves. In order to understand the possibility of such a substitution it is necessary to review briefly the chief properties of radioactive substances in general.

Radioactive substances are characterized by the property of emitting peculiar non-luminous rays which are recognized by three principal actions: the blackening of photographic plates, the production of fluorescence, and the discharge of electrified bodies. This discharge is produced by the power of the rays to divide the non-electrified molecules of air into positive and negative parts called ions which serve as conveyers of electricity. If an electrified body is placed in air ionized by the rays of radium the charge is quickly lost. The quantitative study of radioactive substances is based upon this property.

The rays are of three kinds which are called Alpha, Beta and Gamma rays. The Alpha rays are streams of material particles which are positively electrified and are projected with a velocity of about 10,000 miles per second. This great initial velocity, however, is so rapidly destroyed by the resistance of the air that the particles can penetrate only a few inches into the air. In this short journey they exert an astonishing ionizing effect. When the Alpha particles strike a screen coated with zinc sulphide they produce a scintillation due to fluorescence. The investigations of Ramsay, Rutherford and others have proved that the Alpha particles are positively electrified atoms of helium. Every substance which emits Alpha rays is therefore a continuous source of helium.

The Beta rays, like cathode rays, consist of negatively electrified particles, the mass of which is about 1/1800 that of the hydrogen atom. Their velocity is nearly equal to that of light. Owing to their great velocity and small mass the Beta rays are able to penetrate much deeper strata of air and thicker layers of solid substances than the Alpha rays, but for the same reasons they exert a much smaller ionizing effect in traversing an equal distance.

The Gamma rays are similar in nature to Roentgen rays. They easily traverse the human body and thick plates of metal, but their ionizing power is comparatively small.

The phenomena of radioactivity have found a satisfactory and fruitful explanation in the hypothesis of the disintegration of radioactive atoms which was advanced by Rutherford and Soddy. According to this hypothesis the atoms of radioactive substances are unstable and subject to continual decay. The Alpha and Beta rays are fragments of the disintegrated atoms. Radium, for example, emits Alpha rays, i. e., each atom of radium splits up into an Alpha particle or atom of helium and an atom of a new element which, owing to its gaseous nature, is called radium emanation. This emanation in turn spontaneously decomposes and produces a series of gradually disintegrating solid substances which are designated as active deposits. The last of these is the element polonium which was discovered by Madame Curie.

Radium itself is a disintegration product of uranium which gradually changes into radium, passing through the intermediate stages of uranium X and the recently discovered ionium.

The time in which a radioactive substance is half converted into the next member of the series is called the half period or disintegration period of the substance. The various products of disintegration are sharply distinguished by their half periods as well as by their radioactive and other properties. The longer the period is, the more stable is the substance and therefore the more useful for radioactive purposes.

The metal thorium is the first member of another radioactive series distinct from the uranium-radium series. Thorium and uranium are the two primary radioactive elements from which all other radioactive substances are derived. (The very weakly radioactive elements, potassium and rubidium, the position of which is not yet definitely established, are not here considered.)

The disintegration products of thorium, the nature of their radiation and their half periods are given in the following table:

Substance	Radiation	Half Period
Thorium	Alpha	About 3 x 10 years
Mesothorium 1		About 5.5 years
Mesothorium 2	Beta, Gamma	[illegible]
Radiothorium	Alpha	[illegible] years
Thorium X	Alpha, Beta	3.6 days
Thorium emanation	Alpha	54 seconds
Thorium A	Beta	10.6 hours
Thorium B	Alpha	55 minutes
Thorium C	Alpha	About 1 second
Thorium D	Beta, Gamma	3.05 minutes

Of these products mesothorium (or the mixture of mesothorium 1 and mesothorium 2) and radiothorium are comparatively long-lived, so that it is possible to produce them in large quantities in strongly active conditions.

Prof. Otto Hahn, whose article in *Die Umschau* is here condensed, states that he obtained radiothorium in 1905 in Ramsay's laboratory in London from the residues of thorianite and gave it the name of radiothorium because it exhibited all known radioactive properties of thorium to a greatly increased degree. Elster and Geitel and G. A. Blanc simultaneously and independently discovered radiothorium in the mud of radioactive springs. If radiothorium is actually the radioactive part of thorium, thorium and radiothorium should be contained in proportional quantities in the various thorium ores. This is approximately the case according to the experiments of Boltwood and McCoy. The investigation of thorium salts, however, led to the remarkable result that the activity of the salt is in general less than the quantity of thorium demands. Boltwood and Eve concluded from this fact that in the operations by which thorium or its salts are obtained from the ores the radiothorium is partly eliminated. This would be very remarkable in view of the fact that neither Boltwood and Eve nor Hahn was able to separate radiothorium from thorium by chemical methods. It was found also that the half period of radiothorium is about two years, so that a given quantity of radiothorium would be half destroyed in two years but would be reproduced to the same extent from thorium. The weakly radioactive thorium salts investigated by Boltwood, however, did not increase in strength to the extent required by the foregoing considerations. Hence Hahn suspected the existence of an intermediate product between thorium and radiothorium possessing a comparatively long period and chemical *properties different from those of thorium and radiothorium*.

Hahn then undertook a systematic study of various freshly prepared pure thorium salts and also of old thorium salts. He found that the radioactivity of the fresh salts was proportional to their percentage of thorium, but that the radioactivity gradually diminished. Preparations four years old were scarcely half as strong as fresh preparations. Still older preparations, on the contrary, showed increased activity. These phenomena can be explained by assuming that in the preparation of the thorium salts a hypothetical substance intermediate between thorium and radiothorium is eliminated, while the radiothorium already produced remains associated with thorium. In the absence of its hypothetical parent substance the radiothorium gradually diminishes and the activity of the preparation would fall to zero except for the fact that the intermediate product is gradually regenerated. After a time, therefore, the quantity of radiothorium increases and the radioactivity increases with it.

If this view is correct, the hypothetical intermediate product should be found in the residues left in the preparation of the thorium salts, and there it was found by Hahn, who named it mesothorium. The discovery was confirmed by Boltwood and McCoy. Both McCoy and Hahn computed the half period as about 5.5 years.

Preparations were then made to obtain mesothorium in quantity from residues left in the commercial preparation of thorium salts. In this process it was necessary to treat enormous quantities of material as appears from the following comparison. One milligram of radium bromide is about as active in penetrating rays as six kilograms of thorium oxide. The ordinary thorium ore monazite sand contains four or five per cent of thorium oxide, hence from 120 to 150 kilograms of monazite are required to produce a quantity of mesothorium equivalent to one milligram of radium bromide, even if no loss occurs.

The thorium residues are so abundant that strongly radioactive mesothorium preparations can be obtained by working up sufficiently large quantities. In this way about 2.0 milligrams of mesothorium equal in activity to pure radium bromide have already been produced, and a few milligrams of a substance *four times as strong as pure radium bromide* have been obtained. As radium bromide is about 6,000,000 times as active as thorium oxide, the mesothorium preparation just mentioned is about 24,000,000 times as active as thorium oxide, or 50,000,000 times as active as thorium nitrate, the ordinary commercial salt. The action of the strong mesothorium preparations is apparently identical with that of pure radium salts. This statement, of course, refers only to the more penetrating rays, as mesothorium does not emit Alpha rays. The Alpha rays of radium, however, are stopped by the ordinary glass container.

The production of mesothorium furnishes the possibility of obtaining radiothorium in very active form. *It is found impossible to separate radiothorium from thorium, but it can easily be separated from mesothorium as fast as it is formed.* If the radiothorium is not separated its action is added to that of the mesothorium. Radiothorium is similar in property to actinium which has been obtained only in very small quantities. Owing to the short life of thorium emanation *neither radiothorium nor mesothorium is available for certain purposes for which the comparatively long-lived radium emanation is employed*. It is possible, however, to separate from radiothorium the intermediate product thorium X, whose period is about equal to that of radium emanation and which is a continuous source of the short-lived thorium *emanation*.

As the period of mesothorium is 5.5 years and that of radiothorium is 2 years, freshly prepared mesothorium preparation increases in strength for about three years and by about 50 per cent, and then becomes weaker. The activity falls to its original value in about 10 years and to half that value in 20 years. *The fact that the activity diminishes so slowly and never reaches zero* is due to the presence of a small quantity of radium derived from the uranium contained in the monazite. As mesothorium, like radium, belongs to the group of the alkaline earths the two elements remain associated.

The production of mesothorium and radiothorium has the great disadvantage compared with that of radium that inordinately large quantities of material must be worked. One ton of uranium residues yields about one-third gramme of radium bromide, but one ton of thorium residues yields less than ten milligrams of a mesothorium preparation equal in strength to radium bromide. Nevertheless mesothorium can be prepared more cheaply than radium because uranium residues are valuable while thorium residues can be had in large quantities and have hitherto been a waste product.

Germany is the largest producer of thorium in the world and is able to furnish annually a quantity of mesothorium equivalent to more than *ten grammes of pure radium*.

Ancient Roman Mining

Interesting discoveries have been made in the San Domingo mines of Spain that show the methods followed by the ancient miners.

In some of these mines the Romans dug draining galleries nearly three miles in length, but in others the water was raised by wheels to carry it over the rocks that crossed the drift. Eight of these wheels have been brought to light by men working in these same old mines. The wheels are made of wood, the arms and felloes of pine and the axle and its support of oak, the fabric being remarkable for the lightness of its construction.

It is supposed that these wheels cannot be less than 1500 years old, and the wood is in a perfect state of preservation owing to its immersion in water charged with the salts of copper and iron.

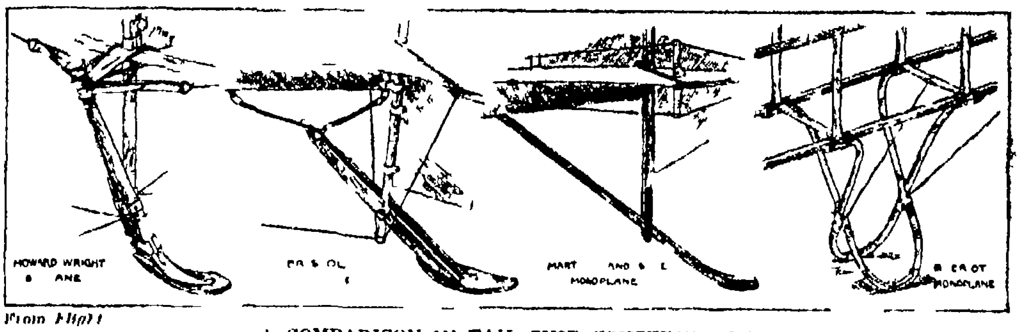
From their position and construction the wheels are supposed to have been worked as treadmills by men standing with naked feet on one side. The water was raised by one wheel into the basin from which it was raised to another stage by the second wheel, and so on for eight stages.

Aeroplane Under-carriages.*

Some Recent Designs

No better example of the manner in which practical considerations relating to matters of an entirely extraneous character often affect the direct solution of theoretical problems could easily be found than may be observed in the influence of the under-carriage on the evolution of the flying machine. It is true of course that aeroplanes must always alight on *terra firma* sooner or later, but the ability to do so gracefully and harmlessly might at first have been far more conveniently deferred to a later date had it been possible to do so. In those days when the ability of a machine to fly at all was the main question of importance. However, nowadays the marked success of passenger-carrying vehicles of the air and the rapidly increasing evidences of a more or less immediate definite utility in aerial navigation demand the fitting of perfected landing arrangements, and the time and care bestowed upon the design of the under-carriage no longer seems out of place. From the very beginning how very necessity forced this same purely mechanical problem on the attention of those who sought to fly. The inventor might have ideas galore, but before he could test the least of them it was always necessary to come down to earth in order to undertake the practical design of some suitable supporting member capable of preserving a machine during its all too protracted peregrinations on the ground. All kinds of different schemes have been tried at one time or another. Sir Hiram Maxim built a railway for his immense aeroplane of 1894. Langley built launching ways over the waters of the Potomac for his double tandem monoplane, which might well have been the first machine to fly in America. Lilienthal and the early pioneers of gliding carried their machines under their arms so that they might use their own legs for starting and alighting. The Wright brothers, who having adopted the prone position on their gliders used to have their machines carried by assistants for the purpose of launching, subsequently improvised a single starting rail when they developed their power-driven flyer. All special devices such as these served their purpose for the time being and to the extent that as they were used they were justified by the facility that they afforded the experimenters to get ahead on the real purpose of their undertaking, which was to learn something about the dynamic navigation of the air. It was always obvious that so soon as the practice of the art of flying should attain to any measure of popularity that the aeroplane of that day would have to be a self-contained machine capable of safely rising from and alighting on the ground by means of its own under-carriage.

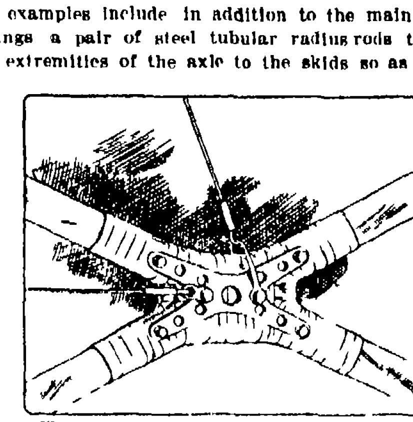
Considering the nature of early aerodromes and the conditions of the ground on which pilots must at all times be prepared to bring down their machines, it is really remarkable how satisfactory the simple and somewhat crude designs have proved to be. Nothing could well be less complicated than the conventional Farman type of wheel and skid combination that has been popular for over a twelvemonth. Examples of it may be seen on the Bristol biplane, Grahame-White biplane, Howard Wright biplane, Baby Wright wire-spoked pneumatic shod wheels. The axles are lashed at their centers to the skid by an elastic strap, which forms the sole flexible suspension in the system. If these elastic springs break the machine settles down on the skids proper, but so long as the elastic holds account of the use of stranded steel cables in place of rigid tubular steel radius-rods. On the Baby Wright biplane the elastic spring differs from the ordinary type, for here the axle carries a bracket fitted with parallel bolts, three on either side of the axle, and



From Flight

A COMPARISON IN TAIL SKID CONSTRUCTION

the weight is carried by the wheels. Under the tail plane is a small skid to protect the tail plane from coming in contact with the ground. It is a minor and comparatively insignificant structural feature, but a study of its details often reveals many points of interest. In respect to the mounting of the axles to the skids on the Farman type under-carriage the design generally only varies in minor details, for all the examples include in addition to the main elastic springs a pair of steel tubular radius-rods that tie the extremities of the axle to the skids so as to pre-



From Flight

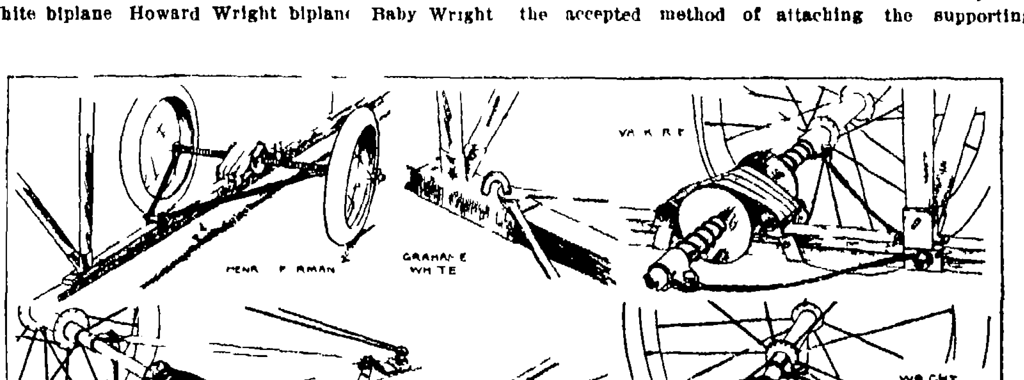
A CROSS JOINT ON THE MAURICE FARMAN OUTRIGGER

vent it from slewing, and some form of lateral spring to keep the skid more or less under the center of the axle. On the genuine Farman these springs are of the steel helical type and surround the axle. On the Bristol biplane elastic strips are used to tie the extremities of the axle to the skid instead.

A similar arrangement carried out in a particularly neat manner is employed on the Howard Wright biplane, where can be seen an excellent example of the accepted method of attaching the supporting each bolt carries a separate broad elastic band that is anchored to the corresponding member on the skid. The radius-rods on this very neatly constructed carriage too are brazed together so as to form a rigid A-shaped member, the apex of which is flexibly attached to the skid by an eye-bolt.

In all machines mentioned the skids themselves are fairly short, with more or less upturned extremities projecting a matter of perhaps 3 feet in front of the main planes. On the Maurice Farman aeroplane the under-carriage is distinguished from the Henry Farman by the continuation of the skid members as far as the elevator outrigger, on the lines originally introduced by Sommer. The Humber biplane is another example of this form of construction, but in this particular machine the skid extensions form separate pieces fastened in place by bolts to the skids proper, whereas on the Maurice Farman the skid is continuous. This Maurice Farman carriage is also particularly interesting on account of the joining in the outrigger framework of which the skid forms a part.

The other outstanding examples of this principle of carrying the skids right forward to the elevator are to be found in the Valkyrie and the Sanders aeroplanes, the former being an altogether distinctive type of under-carriage due to the peculiar nature of the machine itself. It is interesting however to compare the Valkyrie with the Sanders, in which the principal members of the under-carriage consist of two very strong girder type skids braced by wood struts and diagonal steel tape. In the Sanders biplane the under-carriage is distinctly a self-contained unit, whereas in the Valkyrie, where the same general principle is in use, the carriage seems to be so much more an incorporated part of the machine as a whole. It is not easy to suggest an alternative method by which the Valkyrie machine could be put together without a carriage of its present form, and this after all is some indication of a homogenous design.



From Flight

COMPARATIVE DETAILS IN THE CONSTRUCTION OF THE FARMAN TYPE WHEEL AND SKID COMBINATION

biplane and Dunne monoplane. Each of these machines has, except possibly for minor details, the conventional form of this type of under-carriage from the two strong ash skids placed well apart to give a wide base of support and trussed by vertical and oblique struts with wire bracing to the main spars of the lower plane. Each skid carries a short steel axle on the extremities of which are mounted two brackets for the main elastic springs. In most cases the tubular radius-rods are fastened to the skids by a bolt passing through the angle plate, but on the Grahame-White under-carriage this bolt is replaced by a U staple.

The Valkyrie monoplane, which has the Farman type wheels and axles on an under-carriage of entirely original design, illustrates an example of the steel helical lateral spring and is further interesting on

In all machines thus far compared the under-carriage has been characterized by the presence of two skids and four wheels, but among monoplanes it is uncommon to find more than a single axle in conjunction with a central skid. An excellent example of this form of construction may be observed in the Handley Page monoplane, which has a central skid of channel section timber and a very long axle also of timber, the flexibility of which constitutes the suspension. Above the axle rise two masts forming an A-type frame for the support of the fish-like body, and it may be observed that this frame is continued right through the body to form a mast for the bracing of the wings. In the Bristol monoplane, which is likewise characterized by a central skid and single axle, the body is supported by a pair of inverted A-type frames, the apices of which rest upon the skid. On this machine, however, the axle is not so long, and elastic suspension is employed as a means of attaching the axle to the skid. On the Handley Page monoplane these two members are rigidly connected. Another feature of the Bristol monoplane is the use of two long crutches to form struts between the extremities of the axle and the upper beams of the body, to which they are attached by elastic shoulder straps. Another interesting comparison with both the above-mentioned carriages is afforded by the Nieuport, which is similar in principle to the Bristol, in so far as the body is attached to the skid by two inverted A-type frames, but differs from both the Bristol and the Handley Page in having a tubular steel skid and an axle that is formed by a laminated steel spring. In the flexibility of this spring the axle is obviously similar in principle to that on the Handley Page.

*Reprinted from *Flight*.

Another variation in the central skid category is the class that is formed by machines like the Antoinette, in which the axle and skid are entirely independent structures, the skid taking the form of a projecting foot under the fore part of the machine only. An example of this system of construction more or less as introduced on the Antoinette is to be seen on the Martin Handasyde monoplane where however the suspension of the axle itself embodies many original details. In this machine the weight is carried on four elastic springs that are grouped round the central tubular steel column situated vertically beneath the body. On this column slides a cross head to which the springs and diagonal struts of the axle are anchored and a corresponding cross head at the base of the column forms the point of attachment of the inner ends of the divided axle itself. A modification of the original Antoinette combination is represented by the Kny aeroplane in which the foot like skid is hinged to the axle but this particular carriage is properly speaking in a category by itself because the axle is rigidly trussed to the body and the wheels are mounted, too on the axle by radius brackets fastened by coil springs. A massive wooden foot is attached to the body by a telescopic strut fitted with a helical spring buffer.

The Cody biplane also belongs to the central skid type of carriage. In this machine the axle is unusually short and guard wheels are fitted to the extremities of the lower main planes on that account. The suspension on this machine is effected by two very large and very long helical steel springs which extend from the axle to the main frame and when the machine is in flight the thrust of these springs is transferred from the axle extremities to the diagonal wires that brace the forward main spar in the lower plane.

The most elaborate looking carriage of all is that on the Bréguet biplane which really constitutes a three-wheeled under carriage on which the machine is entirely supported for there is no protective skid under the tail. Two of these wheels all of which are of very small diameter are mounted on the extremities of a rigid axle that is attached to the body by two telescopic struts fitted with helical spring buffers and oil dashpots. This axle also carries two short skids projecting forwards and the front ends of these which are normally quite clear of the ground are fastened to the same point of the body by rigid tubular steel struts. Between the base of these latter struts is another tubular steel axle forming part of a horizontal triangular frame at the forward apex of which is a wooden foot. The foot is hinged to the frame and a rearward extension thereof carries the third wheel of the set of three on which the machine is mounted. This wheel occupies a position in the center of the afore mentioned triangular frame work and being interconnected with the steering mechanism may be moved anywhere within the space thus defined. The forward apex of the frame is like the main axle attached to the body by a telescopic strut.

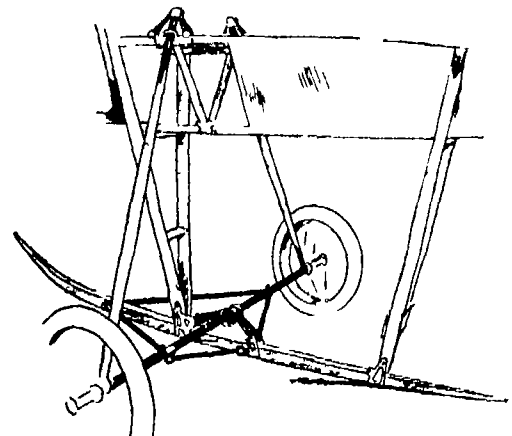
A machine that stands in a class apart so far as its carriage is concerned is the Blériot which has been little altered except in the matter of refinement since it was initially designed. In this machine the carriage is primarily a rectangular frame formed by top and bottom flat beams separated by two vertical struts and carrying between the extremities two vertical tubular steel columns. The body rests on the top beam while the lower beam forms the base of the structure and the point of attachment for the steel tapes that truss the wings. Attached to the steel columns are hinged triangular brackets that support the wheels the hubs of which are tied together by an ash strut and braced diagonally to the base of the carriage by wires anchored to rubber springs. This latter construction is for the purpose of keeping the wheels in line with the direction of motion. Additional struts rise from the base of the carriage to assist in the support of the engine frame which is situated in front of the body and also for the support of the body at a point farther to the rear but on this machine there is no skid of any description other than the simple little bamboo cross beneath the tail.

Our Iron Ore Reserves

A COMPREHENSIVE review of the situation with regard to the supply of iron ore in the future forms part of Prof. J. A. Kemp's paper Geology and Economics. The data are of such interest that a somewhat detailed quotation seems to be in place and is given below.

"In 1905 Prof. Törnebohm the eminent and greatly esteemed former director of the Geological Survey of Sweden, assigned to us a reserve of only one billion and sixty millions of tons. Obviously at an annual production of over fifty millions this reserve would only last twenty years. Much opposition arose at once however, to Prof. Törnebohm's data because from them had been omitted the red hematites of Alabama, which can be very accurately estimated, and which of themselves are thought by competent observers to have a half billion tons for the future. Additional modifications must also be introduced when we properly appreciate the downward tendency of workable percentages. The lower the percentage of iron which we require in the product of our mines the greater the amount of ore which at once becomes available. This is peculiarly true of iron because of its very wide general distribution.

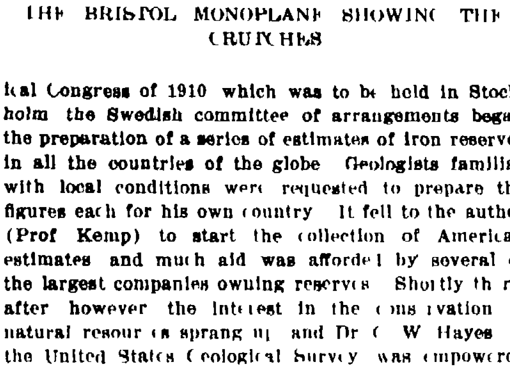
In 1907 in anticipation of the International Geolog-



From *Flight*

THE BRISTOL MONOPLANE SHOWING THE CRUTCHES

ical Congress of 1910 which was to be held in Stockholm the Swedish committee of arrangements began the preparation of a series of estimates of iron reserves in all the countries of the globe. Geologists familiar with local conditions were requested to prepare the figures each for his own country. It fell to the author (Prof. Kemp) to start the collection of American estimates and much aid was afforded by several of the largest companies owning reserves. Shortly thereafter however the interest in the conservation of natural resources sprang up and Dr. C. W. Hayes of the United States Geological Survey was empowered



From *Flight*

A COMPARISON OF SOME GIRDER SKIDS

to use all the resources of this great organization in assembling data on iron. In this way figures as reliable as can be expected are now available. We learn from them that we may consider three and one-half billions tons of 50 per cent ore as assured in the Lake Superior region. Of this great total three billions one hundred millions are in the Mesabi range of Minnesota. At thirty millions of tons per annum the present output of Minnesota we have a reserve for a century.

On the other hand if we drop to 40 per cent or slightly below still however remaining a few per cent above the Alabama grade the drill holes show above depths no greater than those already reached in some mines two or three hundred billions of tons of siliceous hematites giving amounts practically inexhaustible.

In the Alabama ore beds we feel assured of five to six hundred million tons of the grades now utilized and there may well be twice that number. The conservative estimate would afford enough to last at the present output of that State longer than a century. In addition there is much reason for thinking that there may be two or three times as much.

Speaking for the country as a whole we may say that there is an assured and demonstrated supply at present rate of output and at present percentage of yield for about a century. There is furthermore a less accurately measured but still very probable addition when we allow for lower grade but still practicable ores which will be sufficient to last at present rate of production for fifteen hundred years to come.

If however production increases as indeed it may with a rapidly growing population and if in this way heavier and heavier drafts are made upon even this great reserve where shall we look for more? There may be some new discoveries within the United States but at present it is impossible to speak definitely of them. We may ask if there are other supplies in neighboring lands. To this question we may answer yes. Along the north shore of Cuba toward its eastern end and near the sea three areas of what formerly appeared to be a barren ferruginous soil have been discovered and tested so that we now know that there are two to three billions of tons of a very pure iron ore which when deprived of the large percentage of water which it contains—a cheap and simple process—will yield from 40 to 45 per cent iron. This variety of ore already begins to enter our ports and the deposits will undoubtedly contribute in no unimportant way to the output of our furnaces.

The report of the International Geological Congress has shown further that in Newfoundland there are very probably more than three billions of tons of red hematite whose present yield averages 54 per cent. From Brazil moreover in the State of Minas Geraes but pretty well back from the coast and not yet opened up by rail as estimated by Dr. O. A. Derby there are from five to six billion tons of 50 to 70 per cent ore awaiting the drill and the steam shovel. Ore from Brazil faces a long sea voyage but the grade is rich and the iron masters of this and other countries are looking upon these deposits as well within the possibilities of the future. Ocean freights are kept at very reasonable rates in later days and on cargo on a steam ship even so low priced a commodity as iron ore if of good percentages and cheaply mined and taken relatively great distances. This is demonstrated by the shipment this year from the mines of Kiruna 11? miles within the Polar Circle in Lapland of 300 000 tons of ore 113 miles to the Norwegian coast by rail and over 4 000 miles to Philadelphia by sea with no great prospect of a return cargo. These shipments also demonstrate that we are not without the range to which European ores may be shipped when exceptionally rich. Some portion of the vast ore body of Kiruna with its demonstrated [illegible] millions of tons of 65 to 69 per cent ore will also reach American furnaces.

But even were our actual ores of present grade to become exhausted iron as a metal would not fail. The basic rocks with their low percentages still remain. The traprock of the Palisades contains 7 to 8 per cent of metallic iron a value that is far above the general yield of our copper ores in the red metal.

Iron therefore will never fail. It will probably not change in its general relations to modern conditions for a very long time to come so far as its ores are concerned. We may have greater anxiety about the supplies of coking coals than about the iron ores but there are always such possibilities of improvements or changes in processes that no one can justly give way to unqualified forebodings.

Mechanical Handling of Materials*

The Progress of Recent Years

By Richard Devens

WITHIN the last few years some of our railroad industrial and steamship companies have begun to realize the important part mechanical transference plays in the quick and economical handling of material The most efficient advances have been made in the handling of bulk material such as ore coal and grain while package freight comprising boxes barrels bags and other packages which make up the load of a freight car or the cargo of a steamship has just begun to receive serious consideration

EARLY ADVANCES IN IRON ORE HANDLING

It is no doubt a fact that the proficiency in handling bulk material was due to the difficulties to be overcome in the transportation and handling of iron ore to the center of the iron industry I have reference to the iron ore that was discovered in the Lake Superior country The first problem was the transportation and this was overcome in 1855 when the Federal Government completed its first system of locks at the falls of the St. Mary's River at Sault Sainte Marie Mich The second problem was the loading and unloading of the vessel The loading was readily accomplished by the building of a long line of pockets on a dock extending into the lake and the equipping of each pocket with chutes The pockets were of such height that the ore would flow from them over the chutes and into the vessel by gravity The railroad cars of the bottom dump type were brought over the top of the pockets and dumped into them

It is interesting to note that the method used in the first loading dock is the one on which all docks have been constructed since The unloading has been the most difficult to accomplish in a quick and economical manner The first vessels to carry iron ore were not constructed for the purpose and while they carried some ore in the hold most of it was carried on deck When it was carried in the hold it was hoisted to the deck by horse power dumped into barrows and then like the deck cargo wheeled ashore

The next step was the substitution of a small hoisting engine for the horse power This early method was in operation many years and it was not until the dock managers were forced into it by the great expense in carrying large storage on the dock that any mechanical devices were attempted

THE FIRST MACHINE FOR ORE LOADING

A cableway machine built and erected at Cleveland Ohio in 1880 under Alexander E. Brown's design and supervision was the first mechanical plant The next machines were of the bridge type The method of handling the iron ore over either the cableway or bridge was to fill iron buckets by hand in the hold of the vessel and then hoist them by the machine and dump them automatically into railroad cars or storage In the hold there were from 12 to 15 shovelers to each machine and there were two men on the machine one an operator and the other a fireman

Both of the above equipments were a great improvement over the early methods and handled the iron ore in a satisfactory manner yet they did not cut down the cost of the hand labor in filling the buckets in the hold This was a very large part of the cost of unloading An automatic filling bucket had been worked successfully for a number of years in coal and similar soft material but on account of the hard and lumpy nature of the early iron ores it could not be operated in them

THE GRAB BUCKET MACHINE GREATLY LOWERS COST

With the use of the soft Mesaba ores interest in the automatic filling or grab bucket was renewed and about ten years ago the first successful grab bucket machines were erected and operated at the Illinois Steel Company's plant at Chicago by Hoover & Mason This plant was designed to unload from the vessel direct into railroad cars The success of this plant was the beginning of the present methods of unloading iron ore There have developed two types of grab bucket machines—one with the grab bucket suspended from wire ropes and the other with the grab bucket carried on a rigid arm

The cost of filling the buckets by hand was about 13 to 15 cents per gross ton and the cost of hoisting and dumping into railroad cars or storage from 1½ to 2 cents per gross ton making the total cost of unloading from 14½ to 17 cents With the grab bucket machines this total cost has been reduced to from 1 to 2 cents per gross ton depending on the distance the ore is carried from the vessel

The hand filled buckets were of about one ton capacity as this size had been found to be the most practical for filling and handling in the hold With the grab bucket the size is only limited by the dimensions of the hatch and the shape of the vessel The first grab buckets for iron ore were of five tons capacity but since then machines have been built to handle seven and a half ten and fifteen tons

Besides reducing the cost of unloading the ability to handle in larger units has reduced the time Whereas with the hand filled buckets to unload a 6 000-ton vessel was a question of days it is now only a question of hours The steamer Morgan of the Pittsburg Steamship Company with a cargo of 11 319 tons of ore was recently unloaded at Fairport in five hours and fifty-eight minutes The work was done with six Brown electric unloaders

INCREASED NUMBER OF VESSEL TRIPS

These improvements have also increased the earning capacity of the vessel by making possible a greater number of trips during the season This is seen in the following comparative statement for the years 1906 and 1910 showing the average stay at upper and lower ports of the vessels of the Pittsburg Steamship Company

	Year 1906		Year 1910	
	Hr	Min	Hr	Min
Average stay in lower lake ports	36	15	22	22
Average stay in upper lake ports	22	25	12	22
Average time spent in port receiving and discharging cargoes	58	38	34	44
	Gross Tons		Gross Tons	
Average cargo carried	5 954		6 634	
Largest cargo carried	13 333		13 296	
	In 70 Min		In 45 Min	
Fastest loading record	9 277		9 788	
	Tons per Hr		Tons per Hr	
Rate of fastest loading record	7 288		13 051	

EUROPE AHEAD IN HANDLING PACKAGE FREIGHT

In the foregoing I have outlined the development of handling bulk material using iron ore as an example The handling of package freight has not been brought to the same degree of perfection In many manufacturing concerns mechanical devices have been installed to reduce the cost of handling and to hasten the transportation of their products but for quick and economical handling of freight at shipping docks and railroad terminals little has been done in this country In Europe greater advances have been made due largely to the encouragement given by the city or government which frequently itself equips the docks At Hamburg Antwerp Bremerhaven Glasgow London Manchester Havre and many other ports are found mechanical appliances each to meet the local requirements but all aiming to reduce the number and cost of handlings

In England at the freight stations and warehouses the practice is to instal jib cranes so arranged that they can serve all the floor space from car or wagon In this country many of the railroads have put in hand cranes of the pillar or bridge type for handling freight from cars to wagons or *vice versa* but they are mostly for heavy lifts and are slow in operation and cover only a limited area

Some of the railroads have put in electric cranes in their freight yards and water terminals for example the Pennsylvania Railroad Company on its Greenville docks the New York Central & Hudson River Railroad Company at Port Morris the Philadelphia & Reading Railroad Company at Port Richmond and the Central Railroad of New Jersey at Communipaw

PACKAGE FREIGHT AT TERMINALS

Many of the railroads are coaling their locomotives at greatly reduced cost and time by mechanical appliances but the question of handling their package freight at terminals is still open Most managers have known that there is a great loss of time in transferring freight at terminal and intermediate points but few seem to realize the high costs that this involves

Perhaps the most complex movements in the handling of package freight are at the large steamship piers due to the great carrying capacity of the large vessels, the many consignees each having his allotted space and the limited floor area that has to be cleared quickly to make room for the next vessel The larger railroad terminals also have their many consignees but the floor area is not so restricted

The placing of the packages in the proper space is done by the hand truck A sling load from the vessel or a railroad car may contain packages for several consignees The truck man cannot wait to sort as he receives them, so must load his truck with them as they come This means a long travel to get the packages to their allotted space In order to tier them several more handlings are necessary All this leads to congestion and increasing cost per ton This is further affected by the rise in the cost of labor materials rent and larger terminals Each terminal is a problem in itself as is each manufacturing establishment so that it is necessary to make a careful study of the conditions to be met before any mechanical method can be proposed

In the last thirty years there has been a steady increase in the capital invested in manufacture which means an increase of tonnage of all kinds of package freight carried by the steamship and railroad companies To meet this, the railroads have increased their rolling stock and either enlarged their terminals or built more In large cities this has been at great cost for land and buildings The method of handling the freight has remained the same.

At a terminal there are two kinds of freight—outbound and inbound The outbound is transferred from wagons into the outbound freight house and thence to the railroad cars or directly from the wagons to the cars The inbound is *vice versa*

All the above movements except between wagons and cars involve the sorting of packages and distributing each to its designated space It is also necessary to transfer cars from one freight house to the other as the use of the hand truck necessitates bringing the cars to the freight

REQUIREMENTS IN FREIGHT HANDLING

A mechanical equipment to be satisfactory must be able to distribute the outbound and inbound freight simultaneously there should be no rehandling and every square foot of floor space should be served with a single handling All motions of lifting and conveying should be done by power The machinery should be designed to give the greatest lift required and to transfer to any reasonable distance and then tier or lower into cars Continuous operation should be sought for to avoid delay

No part of the transference should be along the floor and the equipment should not take up any floor space that can be used for other purposes All movements of the mechanical equipment should allow of the assorting and distributing according to classification and allotted space readily and quickly There must be reserve capacity to prevent congestion in case of extra demands The justification for the investment of the mechanical installation lies in the reduction of cost and the saving of time in handling The expense should be in proportion to the size of the terminal

There are many companies in this country engaged in the manufacture of hoisting and conveying machinery While perhaps no one makes all the necessary appliances yet a combination of their product could be used to fill the special requirements of each terminal point

HOW TO MEET THE PROBLEM

Fully to cover the floor space and obtain all the different requirements for the satisfactory handling of the package freight three units or different types of conveying machinery are necessary These are the single rail electric trolley the bridge traveler and the cross traveler The electric trolley is the actual load carrying part of the equipment the single rail bridge traveler and cross traveler furnishing a combination of loop track system on which the trolley can reach any part of the area to be covered All movements should be so regulated that there will be no interference, and many trolleys can be in operation following one another Each trolley can draw a number of trailer trolleys, so that many packages can be hoisted and transported under the control of one man. This arrangement allows many loads to be transported in close sequence simultaneously, and with maximum hoisting and traversing speeds, gives the greatest range and capacity at a minimum of labor and maintenance At some freight terminals it may be necessary to have, in combination with the above

*Presented before the Congress of Technology Boston April 11th 1911 at the fiftieth anniversary of the charter of the Massachusetts Institute of Technology

mechanical conveyors motor trucks on the surface in others, belt conveyors. There is no doubt that some such scheme as outlined above when properly carried out to meet the special requirements at any terminal would materially reduce the time and cost involved in the present method. This has already been exemplified in the handling of bulk material.

Considering the special attention now being given this question by several engineers and the interest shown by many steamship and railroad managers it can be safely stated that within the next few years great changes and developments will be accomplished.

A New Gas Machine

Use of Gasoline for Production of Gas for Light, Power and Heat

THE consumption of gasoline and benzine has increased enormously during the last few years and this is in coincidence with the boom in the automobile industry. It was assumed erroneously that this extended use was merely due to this fact.

Especially during the last ten years petroleum and its by-products gasoline and benzine have been used extensively for lighting purposes either in a crude way by burning it in liquid form or by turning it into gas by applying heat to a specially constructed carburetor which usually is applied to each lamp.

Another manner of using benzine for producing gas was in the introduction of gas machines which made gas by compressing air the latter being forced over big areas of benzine or gasoline until it saturates with the vapor of the benzine and forms in this way a burnable gas.

Just as simple as the production of the gas appeared just as difficult was it to get this fluid of an always uniform quality. This condition arose from the peculiar qualities of the benzine which is not a homogeneous chemical body but only a mixture of different components of the hydro class which according to their origin or place of destination are more or less volatile; therefore it is only natural that the air passing over the benzine first takes up the more evaporable parts and leaving the heavier of which the air only can absorb a little and therefore the carburization becomes imperfect. The gas thus becomes steadily poorer in benzine vapor and in calorific value and as soon as fresh benzine is added the amount of hydro vapor is suddenly increased in the gas which causes the burners to emit a smoke or very big flame.

For the technologist the task was to produce an air gas which per cubic foot contains an exact determinable and constant amount of hydrocarbon vapor and this quantity must be of such a low percentage that the gas even in winter could be used in extended pipe conduits without danger of condensation.

Let the gas be compared with the dew in the atmospheric air. It is well known for instance that air at 50 deg. F. can intake and embody more water steam (H_2O) than air of 200 deg. F. and if saturated air of 50 deg. F. is conducted into a room of only 20 deg. F. condensation occurs. It is very much like this with the air or gasoline gas. The tension of a liquid at a certain temperature allows figuring out how much vapor of the liquid a cubic foot or cubic meter of air can take up.

The benzine which is usually used for gas production has a specific gravity of 0.640-0.670 and its main components have at 32 deg. F. a tension of about 71 millimeters at 10 deg. F. 90 millimeters and at 50 deg. F. 115 millimeters but we get the percentage of volume the air is able to take up by applying the following formula

$$V = \frac{P \times 100}{700}$$

wherein P means the tension of the liquid to be gasified at a certain or given temperature. Hence for instance at 32 deg. F. the air is able to take up 137 grains of benzine vapor per cubic foot; therefor the gas of such a composition could be used at a temperature down to 32 deg. F. but would condense below this point.

By embodying 107 grains of vapor in a cubic foot of air gas is produced which remains constant at a temperature of 20 deg. F. and this composition is usually satisfactory to suit the average atmospheric conditions for the simple reason that an extended pipe system (town piping for instance) always must be placed below the frost line and as a rule moving gas never will assimilate the temperature of its environments or will be much affected by the temperature.

It is understood that the amount of benzine to be mixed with the air could be reduced further but it is not advisable to do so, as with this decrease of benzine vapor, the calorific value of the gas would decrease. The gas of the above consistency contains about 7.7 pentane, 72.9 nitrogen 19.4 oxygen and develops about 340 B. T. U. per cubic foot to which 18 to 20 per cent in efficiency should be added for the reason that the small amount of H_2O the gas develops when burned, increases the intensity of the flame.

The specific gravity of the gas is 1.12 and the table below taken from the report of a highly recognized authority gives a comparison between different kinds of light showing the air required to get a perfect combustion and the products derived from it.

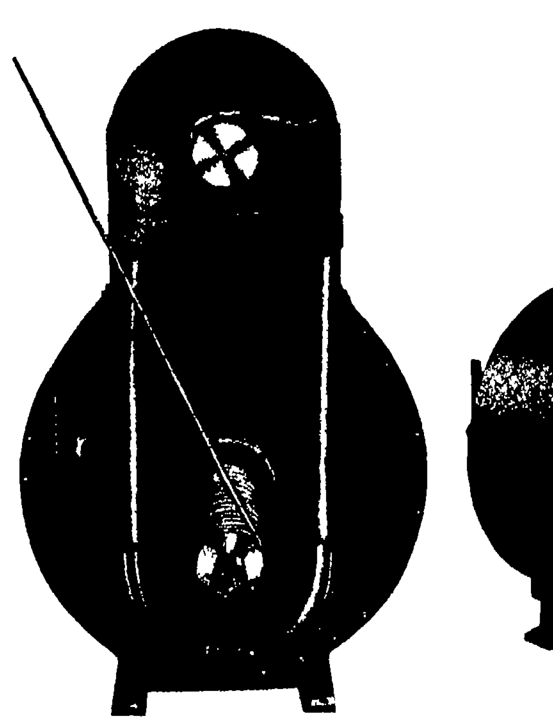
	Quantity liters	Candle power	Air required liters	Products of combustion CO_2	H_2O	N
Standard gas	100	58	211	38	46	246
Coal gas	100	40	625	50	1 0	500
Acetylene	30	40	3..	6.	30	300
Petroleum	1/5	50	2 125	272	337	1 700

Note.—28¾ liters are equal to 1 cubic foot.

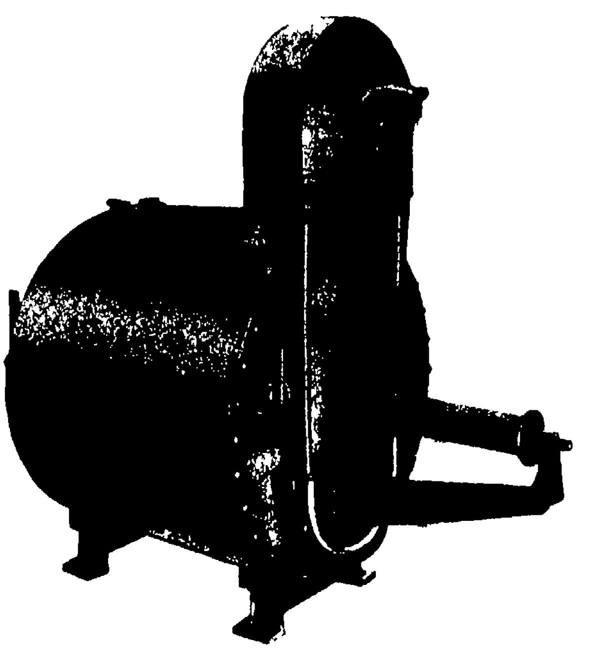
The principal idea of the gas machine shown in the accompanying illustrations and its process of making gas consists in: To drop exact measured quantities of gasoline or benzine into a rarefaction room (carburetor) where it evaporates and after this to mix the same with exact measured quantities of atmospheric air and to bring both together under a certain pressure which is necessary to conduct the gas to the burner, etc.

of the latter and the temperature conditions. The oil is fed into the carburetor in the following manner.

The turning of the sprocket wheel connected with the windlass operates the small upper sprocket wheel by means of the endless sprocket chain. As this latter sprocket wheel has but nine teeth it makes six revolutions while the windless makes one. To the axis of the sprocket wheel is fastened an eccentric which is grooved and into this groove an arm or pawl is adjustably fixed by a set screw. This pawl or arm reaches over and engages with its point a ratchet with about 1?0 teeth. This ratchet operates and controls the interior sprocket wheel which carries an endless chain of buckets. These buckets each contain an exact graduated quantity of oil and therefore bring a uniform quantity of fuel up from the bottom of the reservoir or return bent as the case may be. One complete turn of the ratchet wheel and consequently of the bucket sprocket wheel would empty a certain number of buckets. By sliding the pawl in one can regulate the number of teeth it will reach out and take. This is a valuable point to bear in



SIDE VIEW OF MACHINE FOR AUTOMATIC PRODUCTION OF A CONSTANTLY UNIFORM GAS



FRONT VIEW OF THE GAS MACHINE

This process is contrary to the previous methods of making gas which allow the air to take up as much vapor as the conditions of the liquid air and accompanying circumstances permit so that by a change of these conditions the quality of the gas is bound to change while the new vacuum process treated in this article takes care that the amount of the gasoline or benzine vapor never differs from the determined quantities.

This vacuum process further permits the use of the heavier and cheaper products of gasoline distillation—deodorized gasoline common motor gasoline etc. which cannot be used in any other gas machine.

In appearance the machine differs from those of other systems inasmuch that the carburization and the pressure process usually and for convenience take place at one time in the machine itself while in the other systems evaporization and pressure are two different operations.

It might be added however that the construction of the machine allows of transferring the twin operations to the outside of the building (outside carburetor) should conditions require it.

After the machine is wound up the sprocket wheel of 54 teeth attached to the outer circumference of the casing inclosing the planetary gears revolves with the inside drum. One revolution of the windlass unwinds about 10 inches of cable and causes one revolution of the inside drum making about 5 to 6 cubic feet of gas. To impregnate 1 cubic foot of air requires but a few grains of gasoline according to the quality

mind for if the gasoline is rich a smaller amount of gasoline must be fed and the pawl set accordingly to take less gasoline whereas if the deodorized gasoline is used as will ordinarily be the case the pawl must be set out further all of which can be best determined only after each machine has been installed and the quality of the gas has been determined.

In turning the smaller sprocket wheel the grooved eccentric turns and operates the pawl so that it reaches out and takes hold of as many teeth in the ratchet wheel as it may be set for. Therefore if the pawl is not engaged with the ratchet wheel it will not turn the same and will cause no feed of gasoline and consequently neither gas nor light is given out.

If we find by practical use of each installation that there is a sufficiently rich gas when the pawl reaches out and takes 14 teeth it will be seen that one revolution of the windless and consequently of the drum makes the sprocket wheel revolve 6 times and reach over therefore through the medium of the pawl and the take 6x14 teeth or 84 in all are engaged in one revolution of the drum which would figure down to 84/132 turn of the ratchet controlling buckets sprocket wheel or 14 buckets containing about 500 grains of gasoline for 5 cubic feet of gas. It will further be seen that from 1 to 22 teeth can be engaged by the pawl and here lies solely the regulation of gasoline feed. If your gas is too rich you can set for less teeth also if not rich enough for more but this regulation will be done but once and then the gas will be forever uniform provided always that the same quality of gasoline is used.

Moving Houses in Germany

An American Idea Transplanted

By A. F. Bock

THE moving of solid brick houses from one place to another is no longer an unshared privilege to America since recently this has been successfully effected in Germany at premises Nos 8 and 9 Seestrasse in South Berlin on each of which stood a two-storied solid brick house Not proving profitable the owner of the structure on the advice of Mr Richard Stephan a resident architect, decided to move one of the villas standing somewhat in the back ground to a place just behind the other When this was completed the ground at No 9 was free to be sold for building purposes

After the concession for this scheme had been granted by the authorities the work began First of all the walls of the house to be moved were wedged in slowly and by piecemeal immediately above the foundations and in the open spaces broad flanged Differdinger beams N P 24 were cautiously inserted For each wall two of these beams were used Then timber beams of 21x24 inch diameter the surface of which was mounted with 10 millimeter (0 394 inch) sheet iron two for each wall were placed horizontally on the foundations which before had been carefully leveled

Between timbers and beams a number of very strong

JACKS AND THRUST BLOCKS WITH WHICH THE HOUSE WAS MOVED

VIEW SHOWING THE FOUR TRACKS LAID ON CONCRETE FOUNDATIONS

MOVING HOUSES IN GERMANY

steel rollers were placed in spaces of 80 centimeters (31 5 inches) This work took a fortnight With the leveling of the foundations and when the masonry covering of the beams had well set the last remaining struts could be removed so that the house with all its weight of 400 000 kilogrammes (881 840 pounds) rested entirely on the steel rollers and could be easily pushed along

In the meantime for all the distance the house had to pass concrete foundations had been built which were rendered absolutely level and were covered with beams and iron plates in such a way that there were four tracks on which the house could be rolled along as represented in the illustration These preliminaries accomplished the proper work of moving the house could begin For this purpose a thrust block was fastened to the sliding beams (runners) and between these latter and the house three jacks were placed which had a pushing capacity of 15 000 kilogrammes (33 079 pounds) and a 40-centimeter (15 7 inch) stroke and were operated by three men at the same time This being effected the house could be moved as far as the stroke of the jacks permitted viz 40 centimeters (15 7 inches) After this the jacks were screwed back and between the thrust block and the former the operators inserted beams of the required length as shown in the illustration of the moving jacks and thrust blocks Now the moving could be repeated in the same manner as before always pushing 40 centimeters (15 7 inches) To secure the house against breakage while moving all windows were braced and strutted The inhabitants of the dwelling had all left, but a good deal of furniture still remained

The owner of the property intends to connect the two houses with a veranda after the moving has been completed and the villas stand one behind the other

The cost of moving repairs and reconstruction is considered to be nearly half as much as taking down and rebuilding the house

Tennessee's Resources Told in Pictures

IN this day and age when people write in shorthand they more and more want to read in pictures unless the matter is one in which they have already become interested Taking this view of the case the State Geological Survey has supplemented the bulletins it has been issuing which are intended primarily to give information when information is wanted or requested by a little bulletin describing very briefly the resources of the State but telling the story largely through photographs This is intended to interest the man who is now not interested but who may become interested and through that interest may ultimately move to Tennessee or invest in Tennessee Nor is this report intended alone for the people outside of the State Very few Tennesseeans realize the advantages the wealth the development or the future possibilities of their own State If they did there would be more boosting for Tennessee there would be less moving to Oklahoma there would be less need for the back home movement there would be fewer Tennessee capitalists looking to Texas or New York or other places for investment

The new bulletin is quite comprehensive in its scope describing not only the various mineral resources but also the soils the forests the topography climate transportation facilities etc even citing the State's wealth its debt tax rate etc It not only says that Tennessee is a pleasant place to live but it shows by selected pictures from the several sections of the State that it is It not only says the cities are progressive and busy but it shows by pictures buildings, homes parks, business sections wharves etc that the cities are busy up-to-date and attractive Attractive pictures of good roads and other country scenes show some of the phases of country life The forest resources are illustrated by cuts taken from the flank of the Great Smokies to the bottoms of the Mississippi Tennessee happens to have a number of industrial plants that are the largest of their kind south of the Ohio River Several of these are pictured in illustrating those industries. Pictures are also given of chert, limestone and marble quarries of coal iron and other mines, and iron foundries copper smelters, etc

On the whole, one can hardly look through the bulletin even though he does not have time to read it, without gaining the general idea that Tennessee is a pleasant land beautiful in its physiographic aspect, a good place to live, rich in many kinds of resources, and that those resources are being developed on a more or less large scale In addition to showing what already exists there, or is being done, the bulletin especially calls attention to opportunities for further expansion or for further development, either in agricultural development or in exploiting the State's wealth of minerals. It states that many of the mineral resources have hardly yet been scratched, and only awaiting capital to become the source of much profit. It calls attention to the fact that the opening of the Panama Canal is going to prove a gateway to the west coast of both North and South America, and to all of the Orient, and that in the new tide of commerce, which will take advantage of that gate, the South from its geographic position, has a great advantage over its more northern neighbors As Tennessee is probably the richest state of the South both in its mineral and non mineral resources, Tennessee ought to see a phenomenal growth during the next ten years But it is first going to be necessary that the people of Tennessee as well as those outside, realise the opportunities awaiting investment and labor and take advantage of those opportunities.

While the Geological Survey work will consist primarily in obtaining accurate information about the various resources of the State and then in supplying that information to those who may request it it believes that it is also part of its work to call attention to those resources in a way that would interest both people and capital, whether they are now interested or not

The bulletin has been attractively printed on calendered paper and reflects credit upon the printer, Brandon Printing Company of Nashville It can be obtained by applying to the State Geologist, Capitol Annex, Nashville or upon request accompanied by 2 cents in postage from those outside of Nashville.

New Standard Gage Electric Railroad

THE new standard gage railroad which will be opened in Sweden in 1914 presents a considerable interest. It belongs to the State railroad lines, and as we have elsewhere mentioned, runs from the mining district of Kiruna to the frontier Recently the contract was awarded for part of the electric locomotives to the German Siemens-Schuckert firm, and these are now building at the Berlin works. However, a Swedish company is constructing two high-speed passenger locomotives and two freight locomotives, while eleven freight locomotives will be built in Germany These last are of the double type and consist of two separate units coupled together Each unit or half-locomotive has three bar-coupled axles operated from a single electric motor Transformers on the locomotives are used for lowering the voltage. As each half of the locomotive is independent, this gives a good means of guarding against accidents. The motor is mounted inside the locomotive cabin and drives the wheels by crank drive, so that a large sized motor can be used and there is given better air cooling. The Porjus Falls will be called upon to furnish the current for the electric railroad, and at present the construction work upon the hydraulic plant is being carried out.

Giant Gas Engines and Blowing Tubs

TWELVE CAR TRAIN LOADED WITH A SINGLE BLOWING UNIT

THE beginning of the twentieth century has seen many advances in the methods and machinery employed in the manufacture of steel. One of the most notable changes has been the introduction of the large gas engine designed to operate on the waste gases from blast furnaces and used to drive the electrical generators which furnish power for driving the machinery about the plant. Another application to which the gas engine has been put is to drive the air compressors which furnish the blast to the furnaces. At the same time a new machine has been introduced to take the place of the older steam driven blowing engine. This is the Slick blowing tub. The first large installation of this type of blowing units was erected at the Homestead Works of the Carnegie Steel Company, where the makers, Allis-Chalmers Company, installed four 42-inch × 54-inch twin tandem gas engines driving 72-inch Slick tubs. When the big power house of the Indiana Steel Company at Gary was built, eight of these units were installed in that. Since then similar units have been installed in the South Chicago plant of the Illinois Steel Company, in the Algoma plant of the Lake Superior Iron and Steel Company, and others larger than any yet installed are now building for the central furnaces of the American Steel and Wire Company at Cleveland.

The design of the Slick tub makes possible the delivery of a much larger quantity of air from a smaller piece of apparatus than was possible with the older type of blowing engine. Two Slick tubs are all that are necessary for the largest furnace, while three or four of other types would be necessary.

The essential difference between the Slick blowing engine or tub, as it is commonly called, and other blowing engines lies in the method of admitting air to the compressing cylinder. In other types large valve area is required, which necessitates either large valves or numerous small valves. In the Slick design the entire cylinder of the compressor serves as the valve. The inlet ports in this design are located in the barrel of the tub and consist of a series of circular openings extending entirely around the circumference of the barrel at each end. The barrel is not attached to the heads but is supported and moves on independent slides at each side. Connection is made to the engine on each side and the barrel is given a reciprocating motion while the heads remain stationary. This construction gives great inlet area for a very small motion of the barrel and leaves the entire area of the heads free for the discharge valves.

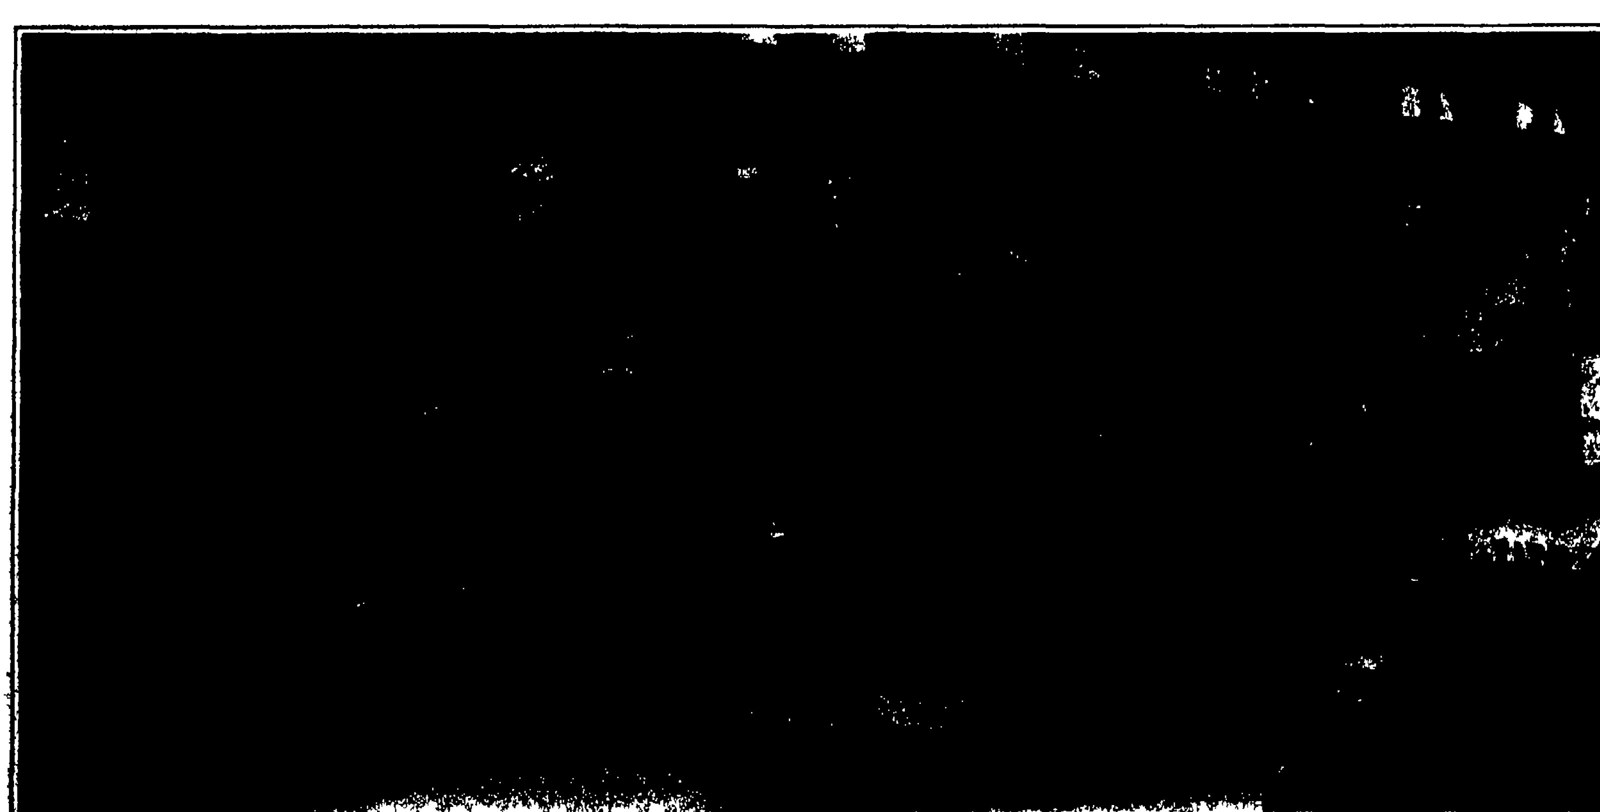
The advantage of this construction is that the air completely fills the tube with practically no drop below the atmospheric pressure at the beginning of the suction stroke. The large discharge valve area of the heads greatly reduces the clearance necessary in the cylinder and also prevents the air pressure in the cylinder rising much above the pressure in the receiver. The small movement of the valves and the large port openings permit of much higher piston speeds than can be used with other types of blowing engines and consequently the use of smaller machines for the same amount of air.

These Slick blowing tubs are used with both steam engines and gas engines, more frequently with the latter, however, as they were developed about the same time that the large gas engine came into use in the steel industry. The usual practice is to place the steam or gas cylinder at one end of the frame while the tub is fastened to the other. This gives a short and direct drive for the barrel from the engine shaft, while the air piston is connected to the cross head by means of distance rods and has the same travel as the gas piston. This gives a very rigid and compact machine.

The gas engine which Allis-Chalmers Company build to go with these blowing tubs embodies the most modern developments which experience has proved advisible, with the result that its design differs somewhat from European models in order to meet American conditions. Progress in the design of large gas engines has been much influenced by natural conditions existing in the steel industry, which presented an ideal field for their use in the utilization of waste gases. The conditions demanded an engine which would operate on a gas of low heat value and which was reliable for continuous and severe service.

The Allis-Chalmers gas engine is of the horizontal double acting four-stroke-cycle type, with the gas cylinders arranged in tandem. This arrangement applies power to the common piston rod at each forward and backward stroke and gives the same continuous application of power to the crank shaft that is obtained with the simple steam engine. When twin engines are used, as with the blowing tubs, four power strokes are obtained per revolution. These, with the use of a properly designed fly wheel, give a very even turning moment.

It is in the frame that the principal difference in design is apparent. Foreign practice favors the use of the center crank, which necessitates three bearings for a single engine and four bearings for a twin engine. The Allis-Chalmers engine requires but two bearings for either single or twin engine. Another essential feature of this engine is the use of an intermediate cross head between the two cylinders and a tail cross head behind the second cylinder. These support the pistons and piston rods so that they can travel without touching either the bore of the gas cylinders or stuffing boxes. This design also places the inlet valves at the top of the cylinders and the exhaust valves at the bottom, which is essential to the proper scavenging of the cylinder. Provision is also made for removing the cylinder heads without disconnecting the cylinders from the main frame or tie pieces. These gas engines give the impression of solidity and simplicity and show great strength. Their quiet running and freedom from vibration are



THE ALLIS-CHALMERS TWIN TANDEM FOUR-CYCLE GAS ENGINE

GIANT GAS ENGINES AND BLOWING TUBS

particularly apparent This is true with overloads as well as underloads and there is in fact no noticeable change in the operation under wide variation in loads

As the point of greatest stress in a gas engine is in the frame the weight of the frame of this engine is made about one fourth the total weight The jaw in which the main bearing shells are held and which is subject to the greatest stresses is made particularly heavy and rigid It is further strengthened by two steel tie bolts extending across the jaw above the shaft which eliminate all bending stresses in the frame at this point but do not interfere with the removal of the main bearing cap

The cylinders are cast in one piece and a tough fibrous iron is used which is well adapted to meet the strains encountered The outer cylinder walls with the tie pl e form a continuous frame work and provide a very rigid construction The inner wall of the cylinder is subjected to the explosive pressure only Gas and air inlet passages and a distribution chamber are cast integral with the cylinder

To provide a wearing surface the cylinder is fitted with a liner of a special grade of very hard fine grained iron which has particularly good wearing qualities and which readily takes a high polish and thereby reduces friction A special patented construction of a tongue and groove fit at the middle of its length together with a shrink fit over its entire length holds the liner firmly in place while permitting free expansion with the cylinder walls

The valve gear is of the stratification type which permits control of the engine by varying the relative proportion of air and gas The valve is double seated with the air admission between the two seats and the gas admission above the upper The relative amounts of air and gas are controlled by an auxiliary lay shaft actuated by the governor The two inlet valves for each cylinder are located at the top and the two exhaust valves at the bottom so that all impurities leave the cylinder in the most natural way The exhaust valves and all the parts of the engine coming in contact with the hot gases of explosion are water cooled

These engines are started by means of compressed air and an auxiliary starting gear which is automatically cut out when the engine is ready to operate on gas The method of starting is very simple and the time occupied is inappreciable In one of the large power houses where these engines are used to drive alternators it is usually less than one minute from the time an order is given to start the engine to the time it is put in service and delivering load The record time is 37 seconds

One of the accompanying photographs shows a train loaded with a single Allis-Chalmers gas engine blowing unit The apparatus loaded on the train contains the parts of a twin tandem gas engine and the Slick blowing tubs for the unit The first two cars are loaded with the main engine frames weighing approximately 180 000 pounds each the third car supports the main shaft and cranks the next four cars each carry a gas engine cylinder the next two each hold a tie piece and tail piece for one gas engine while each of the last two cars is loaded with a Slick cylinder and some of the accessory apparatus Many of the detail parts are not shown in this photo

During the past few months the Allis Chalmers Company has shipped four gas engine generating sets and two gas engine blowing units to the Lake Superior Iron and Steel Corporation at Sault Ste Marie, Canada, and has two more of the blowing units nearing completion Each one of these units requires twelve cars for its transportation and its weight is approximated 1,000,000 pounds.

These gas engine units are being installed in a large extension of the Lake Superior Iron and Steel Corporations plant at Sault Ste Marie Ontario Canada The original rail mill will have a largely increased capacity and new plate and merchant mills will be built as well as coke ovens Operations will be started at the plant in the near future For furnishing power for the mills and blowing the furnaces the company purchased the above units from Allis Chalmers Company They will be supplied with gas from the blast furnaces.

The gas engines are all alike being of the twin tandem four-cycle type with cyclinder 34 × 48 inches. They conform to the company's standard in all respects Four of these engines are direct connected to 1 765 K V A 25 cycle 3 phase 2,300-volt alternators running at 107 R P M These sets will supply power for driving the motors about the mill

The other four units are to be connected to the new Slick blowing tubs manufactured by Allis-Chalmers Company These tubs are 64 × 48 inches and are arranged to operate duplex on the opposite side of the main shaft from the engine Each blowing unit has a capacity of 25 000 cubic feet per minute when running at 72 R P M but can be speeded up to 85 R P M if necessary

When the new works are completed this will be the largest steel producing plant in Canada and naturally the most modern Mr Alfred Ernst has been consulting engineer on the work and much of its success will be due to his efforts

Heating and Ventilating the Yarrow Home

A Series of Interesting Experiments

The question of providing the best system of ventilation and heating for public buildings and especially for Hospitals and Convalescent Homes is of so much importance that the following experiments cannot fail to be of interest

On the occasion of the annual gathering at the Yarrow Home on July 17th 1909 certain changes which had recently been made in the heating and ventilation of the Institution were described by Mr Yarrow

The system of heating and ventilation was carried out in a very complete manner when the Home was constructed and was based upon the best knowledge available at the time but experience has indicated that in many essential particulars the system adopted was far from satisfactory and it became evident that changes must be made

The heating was secured by means of numerous radiators in the usual manner fresh air from outside being admitted through openings at the back of the radiators thus coming in direct contact with the hot surfaces and getting warmed on its passage into the building This at first sight appears correct but a little consideration shows it is open to objections What really happens is that the radiators very soon get covered with dust brought by the incoming air and this dust as is well known brings with it numerous microbes Often these radiators are fixed in such a position that it is impossible to clean them efficiently Sometimes they are in recesses to be out of the way at other times the design of the radiators is such that it is impossible to get brushes between the heating tubes On some systems the heating is done by means of hot pipes under the floor with gratings above them and on others the radiators are enclosed in ornamental cases for the sake of appearance In most cases it is found that the radiators are of such a design or so placed that it is impossible to secure the cleanliness and freedom from deposit of dust so essential to good sanitary conditions

Mr Yarrow pointed out that the conviction was forced upon everyone who had studied the subject that the only form of really good radiator is one of such design and so placed that it can be cleaned and dusted daily with facility Probably to carry this out in the best manner the radiators should consist of polished tubes because being bright any deposit of dust is made visible and in addition servants naturally if they take a pride in their work see that any polished surface is kept in a creditable condition

Having these considerations in view the inlets which previously conducted the fresh air into direct contact with the radiators were permanently closed so that now the air has not the opportunity of depositing its dust upon the heated surface of the radiators or of carrying into the rooms the already accumulated microbes

Mr Yarrow then described the system of ventilation originally adopted which consisted of horizontal air ducts along the ceilings of the rooms These air ducts terminated at each end of the building in tall ventilating shafts The tendency for the hot air to pass out in this way is due to the difference in weight of the hot air inside the shaft and the cold air outside the building just in the same way that a chimney over a fire allows the hot products of combustion to pass upwards In such ventilating systems however the difference of temperature and consequent weight of the air is so very small that the draught is necessarily sluggish consequently to reverse the direction of the current of air requires very little counteracting influence

Mr John Sampson a member of the Committee of Management of the Home drew attention to the effect which wind had on ventilation and demonstrated in the clearest possible way that wind striking the building on one side had a tendency to increase the pressure of air in the rooms on that side and at the same time to diminish the air pressure in the rooms on the opposite side Now in those rooms where the pressure was diminished the reduced pressure had clearly a tendency to upset the system of ventilation causing the passages which were intended as upcasts to be downcasts

Numerous experiments were tried in all the rooms not only when there was no wind but when the wind blew on the building from different quarters It was found that when there was no wind the ventilation acted perfectly and as was intended but the moment a slight wind arose which at Broadstairs is of general occurrence it was found that in many of the rooms the air instead of passing away through the ventilating passages and up the shafts was actually drawn down owing to the suction due to the reduced air pressure in those rooms on the sides of the building opposite to those upon which the wind blew Now it is self evident that if the air enters the building after having passed through passages which from their nature can never be cleaned and which are charged largely with dust full of objectionable organisms and which were never intended for admitting air but for letting it out the result must be most unsatisfactory and there appeared to be a reasonable probability that many sore throats had been due to this cause

The committee being firmly convinced from the above considerations that the system of ventilation had been founded on wrong principles ordered all the openings in the ceilings of the rooms leading to the ventilating passages to be closed They had the beds removed from the sides of the dormitories and placed in the center and gave instructions for the windows to be always slightly open so that the ventilation of each dormitory should depend entirely upon the passage of air across the rooms entering the side where the wind blew and finding exit on the opposite side As there scarcely ever exists a time when there is not more or less breeze, it would appear that this was both a simple and efficient means of continually changing the air

As the result of this investigation it would appear that one of the secrets of ventilation is to prevent air passing through any passages where dust and dirt can accumulate In fact the air prior to entering the rooms should pass over the minimum surface

A doll's house was used in order to illustrate by actual experiment what occurred when a current of air blew on one side of the home A fire was lighted in a room in the doll's house and the smoke ascended and was seen issuing from the chimney A rotary fan actuated by an electric motor produced a current of air corresponding to a moderate wind—that is to say from 12 to 15 miles and hour—which was allowed to impinge on one side of the doll's house and it was at once seen when the window was open in the doll's house on the side opposite to that on which the air impinged that smoke was immediately drawn down the chimney instead of passing upwards owing to the reduction of pressure on the side opposite to that on which the current of air was blown

The following description was given by Dr Dawson

The bacteriological examination of the air not only confirmed the opinion that under certain conditions what are intended for ventilating outlets became inlets but also showed the vitiation of the air in Ward No 1 which resulted

Two prepared plates were exposed beneath the air shaft in the ceiling of the ward These plates were so to speak back to back that is the medium on the one looked upward toward the opening in the ceiling and the medium on the other looked downward toward the floor Plates were exposed actually within the air shafts Others were also placed on the beds in the ward and finally a plate was placed midway between the floor and ceiling underneath the air shaft All these plates were exposed for a period of five minutes The results were as follows

The plates within the air shaft, and the plate immediately beneath it showed a rich growth of microorganisms whereas the plate under the air shaft whose medium looked downward was comparatively free The plates also placed upon the beds in the ward contained only a few colonies.

Further than this among the rich crops of microorganisms found on the plates near the air shaft were many pathogenic varieties, and especially noticeable among these were the *Micrococcus Catarrhalis* and *Staphylococci* which are so often associated with sore throats whereas in the plates remote from the air shaft the pathogenic organisms were *exceedingly* few The fact that the plate near the air shaft which looked upward was richly covered with organisms—whereas the plate immediately beneath it which looked downward showed very few—shows that the air was traveling *into* the room and not *out* of the room through the so-called outlet This conclusion was further confirmed by the plates inside the shaft con

...the same varieties of organisms as the plate immediately beneath the grating

In Ward No 2 very similar in size and shape a control experiment was conducted the air shaft in the ceiling being blocked up, and plates being exposed in the same position as in Ward No 1 The plates in every instance showed but a feeble growth of micro-organisms, one of the plates showing only 17 colonies as against 89 colonies found on the similar plate correspondingly situated in Ward No 1 It is clear, therefore that the air was a great deal purer when the ventilating outlet in the ceiling was blocked up

Now the Yarrow Home has been troubled for some time past with small epidemics of sore throats and it has been in some instances established that the sore throats do not spread from person to person but would break out in different wards where the inmates have not been in contact

These troubles entirely ceased when the ventilating shafts in the ceilings were closed The fact is that the ventilating shafts which lead from the ceilings of the wards to the outer air are in close juxtaposition. As long as there is no wind it is probable that these shafts would operate as outlets as they were originally intended to do but directly there is a wind these outlets become inlets and impure air enters the wards and the air of one ward can communicate with the other

This investigation also shows once more that all air shafts are dangerous unless they are so big and so situated that they can be easily and regularly flushed with water Unless this is the case the air shafts collect more and more dust and the air which passes along them becomes increasingly dust laden and therefore microbe laden The wards have been far more healthy at the Yarrow Home since these air shafts were blocked up and the windows and chimneys have been relied upon for ventilation

The examination of the air was made at the suggestion and under the supervision of Dr Dawson assisted by Dr Moon The bacteriological experiments were carried out by Dr Adler

On November 1st six months after the above changes in the heating and ventilation had been made Miss Chambers the lady superintendent of the home reported as follows

We have found a very appreciable reduction in the *number of sore throats during the past six months* and of the few cases we have had all have been children with adenoids and enlarged tonsils or who suffer from repeated sore throat affections at home We have had a case of measles and two of chicken pox during the last six months but no spread of infection from either as formerly experienced

The Bee as an Engineer

The Structure of a Piece of Honeycomb

By A H Godard

Honey bees have always been a subject of great interest for the naturalist and one of the most interesting features of their work is the home and store house which they build for themselves (Fig 1)

Nearly everybody has seen a piece of honey comb but probably few realize how perfect a piece of architecture it is for the purpose intended It is perfect because it combines these three qualities *it has no waste room it has the greatest possible strength and it is constructed out of the least possible material*

If we look at the face of a piece of comb we observe that the cells are six sided Did you ever stop to think why? The answer is because that is the only shape that will fulfill the above conditions Let us see In the first place there are only three forms of cells that can be placed side by side without leaving waste spaces between (see Figs 1 2 3 4 5) There are the triangle the square and the hexagon Secondly the more nearly round a hollow object is the more pressure will be required to crush it a fact well known to every one and thirdly the more round it is the less material will it take to complete its peripheral wall One might almost imagine that these last two facts are recognized by the bees themselves for in the case of a special cell that they construct for their queen where there is only a single cell built up on the edge this cell is always round and not hexagonal But to prove the third proposition the economy of material let us look at Fig 6 which represents four different forms with an area of uniformly 144 square inches The triangle will be about 18¼ inches on a side and 54¾ around The square will be 12 inches and 48 inches around The hexagon will be about 7½ inches on a side and 45 around while the circle which we have said we can not use would be only 42½ inches around So again we find the hexagon requiring less material than the other forms and thus fulfilling all three of the conditions named

So much for the sides Now let us look at the bottom of the cell Usually a piece of comb is about an inch in thickness but you will notice the cells only run half way through that there is a partition in the center which forms a bottom for the cells on both sides of the comb (see *A* Fig 7) Now these cells from opposite sides do not meet haphazard but if you will look into an empty cell (see dotted line cell Fig 8) you will notice that what is the center of the cell on one side coincides with the point where three cells come together on the opposite side Again the bottom of the cells are not flat like the bottom of a tumbler as represented by Fig 7 for in that case there would be the square corner and the same waste of material as in the square cell but each cell is carried out to a point past the center of the comb (Fig 9)

The question then arises how can this be done so as to have opposite cells match? This can best be understood by a simple illustration Cut off from a common six-sided lead pencil four pieces an inch or more long sharpen them exactly alike bluntly cutting only from the flat sides then tie three of them together to represent one side of the comb and try to fit the fourth piece and you will find that they will not match So we must try again Now sharpen your pencils once more, this time by cutting the corners instead of the flat side and be sure you cut only every other corner This will give you three surfaces instead of six Now tie together again and you will find a perfect fit (see Fig 10)

Now if you should look into a cell you would see three flat surfaces running to a point, as represented by the dotted line cell (Fig. 8)

But this is not all If this point were made too long or too short then again there would be waste of material as well as strength There must be a certain specific correct length Let us look once more

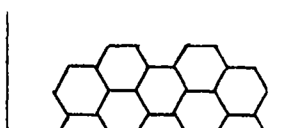


Fig 1

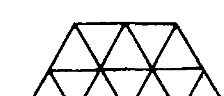

Fig 2

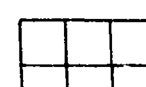

Fig 3

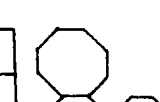

Fig 4

Fig 5

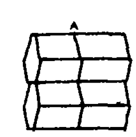

Fig 7

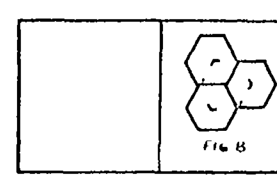

Fig 8

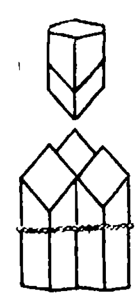

Fig 10

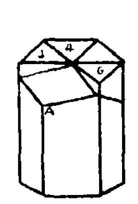

Fig 11

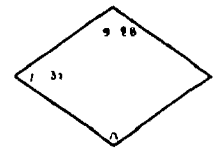

Fig 12

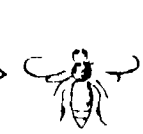

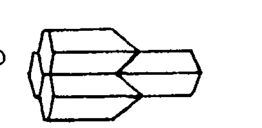

Fig 9

into the cell and we find the three end surfaces are *rhomb shaped like Fig 12 with two obtuse and two* acute angles (see obtuse angle at *A* Fig 11) and it is evident that as the point of the cell is moved in or out this and the other angles will change the farther the point the more nearly square the rhomb will become and of course the less the obtuse angle will be Many years ago a naturalist requested a celebrated mathematician to solve this problem What should be the angles of the facets of a three sided pyramid terminating a six sided prism so as to combine the greatest strength with the least material You will notice that this is the problem before us His answer was 109 degrees 26 minutes for the obtuse and 70 degrees 34 minutes for the acute—values falling within one-thirtieth of a degree of what the comb actually measures the exact measurement being 109 degrees 28 minutes and 70 degrees 32 minutes Notice how this piece of bridge work in the center of the comb stiffens and braces the structure

So far the material for the comb is supplied by the bees from their own bodies issuing from the over lapping joints or rings seen on any working bee But there is still one place of the comb that is a little weak namely *the mouth of the cell* This weakness is remedied by the use of a substance which the bees gather from the barks of trees and which has been called "propolis" a Greek word meaning "before the city" This material is of a much harder and firmer nature than the comb itself If you take a piece of white comb and tip it so that you can just glance across the surface you will discover the presence of the propolis by its brown color

The writer has seen strips of comb a foot wide and four feet long sustaining a weight of thirty or forty pounds of honey while the comb itself would probably not weight more than five or six ounces We need not hesitate to say that such a structure compares favorably with some of the best achievements of the modern engineering skill of man

A New Variety of Selenium

L C Brown has discovered a new variety of selenium in which the electric resistance is increased instead of being diminished by exposure to light Its specific conductivity is one million times greater than that of ordinary selenium Thirty experiments were required to produce five specimens of the new form of selenium which is very unstable during the process of formation In every case the selenium was crystallized in molds of enameled porcelain Two German silver wires about ⅛ inch apart served as electrodes The resistances of the five specimens each measured in the dark two hours after its removal from the crystallization oven heated to 28 deg F differed very greatly the values expressed in ohms being 13 12 117 161 and 187 The surface of the selenium was smooth and reddish gray at first but the tint afterwards became redder and darker The resistance of one specimen rose from 117 to 118 ohms in 10 seconds exposure to the light of a 16 candlepower carbon filament electric lamp at a distance of four inches The return to the initial resistance appears to take place as rapidly and completely as it does in ordinary selenium cells Several years ago Brown advanced the theory that ordinary selenium is a mixture of two or more allotropic forms He regards the new variety of selenium as a mixture of the same ingredients in different proportions

Diesel Marine Engines—II*

A Resume of Recent Performances

By Herr Th Saeuberlich of Osterholz-Scharmbach

Continued from Supplement No. 1846, page 318

The reversing gear of this engine differs from other known designs The principle employed is to move the valve shaft on which two separate sets of cams are fashioned endwise the valve levers being raised by cams just before this movement takes place and lowered again when it is complete These movements are effected in the following very simple way and by the use of a single hand wheel

The shaft *a* -Fig 8—passes over all the cylinder covers being carried by the columns *b* of which there are two in each cover To this shaft are keyed the fingers *c* one over each exhaust and suction valve and the lever *d* which is linked by *e* to the

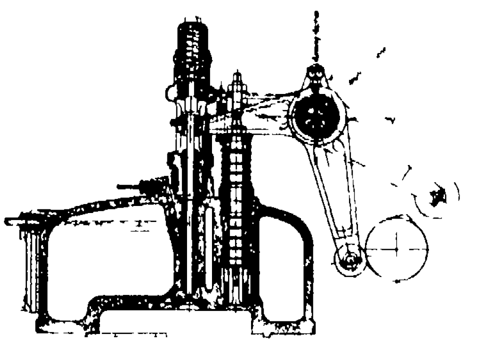

Fig 7 AIR AND OIL VALVES AND GEAR

curved lever *f f* in turn being coupled to the reversing cylinder which has pipe connection *g* and *h* coupled to the valve box beneath the hand wheel Here either valve can be released by movement of the ⊥ lever *l* which is effected by one end or other of the notched quadrant *n* coming into contact with it this quadrant being keyed to the hand wheel shaft The valve being opened further movement of the plate releases the lever and the valve again closes Owing to the form of the quadrant *n* and the notches in the quadrant *p* this movement can only be effected in the central position II In Fig 10 is seen a sector T which is provided with a cam face which moves the lever *B* and thus moves the reversing cam shaft V endways The sector is coupled by the link shown to the shaft *u* The action of the reversing gear will now be easily understood The hand wheel is moved to the middle position and is then revolved till the stop *r* on the notched quadrant comes against the quadrant *p* and stops further movement During this action the valve *i* would be opened for a short time allowing compressed air to get under the piston *k* forcing it up This causes movement of the linkage and presses the valves down into the cylinder When they have reached their lowest position the action of the cam *T* moves the cam shaft endways By that time the piston *k* has returned to its starting position lowering the valve rockers on to the second set of cams The glycerine dashpot acts as a brake to prevent reversal taking place too violently It must be added that during this process the rollers of the starting and fuel valves are lifted off their cams and do not interfere with the motion This is effected as seen in Fig 7 by mounting the respective rockers on eccentrics keyed to the shaft *w* By turning the sleeve the fuel valve lever moves away from its cam while the starting valve lever approaches its own cam In this position both levers are free and the shaft can be moved endways By further movement to the starting position the fuel valve lever leaves its cam contact with its own Rotation is given to the eccentric sleeve in the manner shown in Fig 9, from which it will be seen that it is coupled by the rod *L* to the shaft *M*, to which is also keyed the hand wheel bracket *H* This bracket with the hand wheel can be moved to three principal positions on the notched quadrant the first for running the second neutral, and the third or lowest for starting Further notches for high and slow speed are also provided This control is effected by the link *d* which acts upon the fuel pump regulator rod As the centrifugal governor shown also acts upon this rod an elastic coupling in the form of a flat spring *F* is provided The governor was originally provided for the test stand but in view of the fact that the engine might run light has been retained

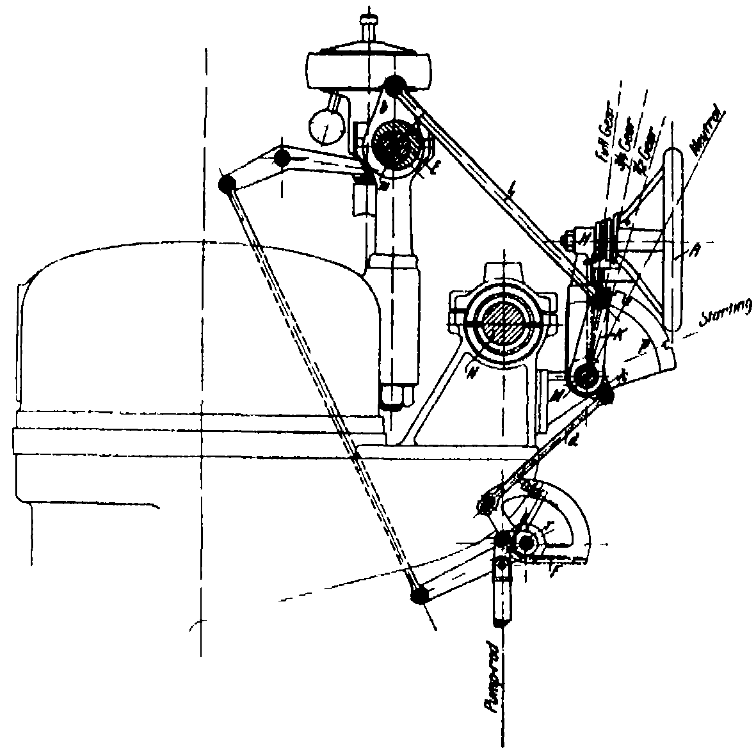

Fig 9—CAM LIFTING AND GOVERNING GEAR

It has already been pointed out that in a four-cycle engine all four cylinders might be in such a position as to render starting by compressed air in the cylinders impossible and that therefore arrangements had been made to use the air compressor for starting under such conditions This air pump is shown in section by Fig 11 It is a two-stage compressor with the low pressure stage double acting and without suction valves, air being admitted by the piston overrunning a central port On this low pressure cylinder are placed the starting valves *A* and *B* operated by the cams and links shown The compressor being double acting it is easy to arrange that it shall start in any position which it is not possible for the power cylinders to start from Diagrams from the compressor are given in Figs. 12 and 13, and enlarged views of the valves in Fig 18 The fuel pump is illustrated by Fig 17 There is one plunger to each main cylinder, but the plungers are coupled in pairs so that only two eccentrics are required. The governor already described acts, as shown in Fig. 17, upon the suction valves. The pump body is a single piece of wrought iron.

method of constructing the valve cams is shown ig. 15 The exhaust and suction cams are of cast , and the starting cam of cast iron By this od a small diameter of cam results and quietness unning is secured.

e lubrication of the gudgeon pin which is always oublesome matter is effected in this engine by the ce shown in Fig 14 Here the tube *A* on the pis at each outward stroke is driven into oil contained in the cup shown some oil enters the tube and being retained by the little ball valve is driven up by the next descent of the tube

The method of driving the cam shaft is illustrated by Fig 16 It will be seen that the arrangement permits endways movement of the shaft, while the long bush acts also as a thrust block

It is not generally possible to obtain such good diagrams from high speed as from slow speed engines owing to the very short space of time in which explosion has to take place but almost ideal cards as shown in Fig 19 are obtained from this engine The average pressure shown by this diagram is about eight atmospheres The fuel consumption measured on the test bench amounted to between 215 and 220 grammes per effective horse power per hour

Practical Results The service boat in which the engine just described is fitted has been for a long

Thirty maneuvers can be carried out per hour with out alteration of the air pressure in the starting tanks while with the quantity of air stored in the starting tanks 60 consecutive maneuvers can be carried out The starting tank holds 250 liters and when quite exhausted it can be repumped to full pressure in 15 minutes

(To be concluded)

Radioactivity as a Kinetic Theory of a Fourth State of Matter*

THERE are many points of resemblance between the movements of the molecules of a gas and the move ments of those corpuscular radiations with which we have become acquainted in following up the discovery of radioactivity In both cases we find that things of extremely minute dimensions are darting to and fro with great velocity and in both cases the path of any one individual is made up of straight portions of various lengths along which it is moving uniformly and free from external influence and of encounters of short duration with other individuals when energy is exchanged and directions of motion are altered There is even a resemblance in the universality of each movement The motion of molecules is a fundamental fact throughout the whole of our atmosphere and in deed in all material bodies the motion of the radiant particles emitted by radioactive substances is also widely distributed and of great importance Taking Eve s estimate of the usual ionization of the air we can calculate that in this room in every second some thousands of α and β particles enter into existence complete their paths through all the atoms they meet and sink into obscurity some of them viz the α particles as atoms of helium These last move through definite and well known distances in the air For ex ample a third of those which are due to radium products move through a range of just above 4 centi meters an equal number have a range of just below 5 centimeters and again an equal number move through 7 centimeters and the speed is so great that the life of each α particle as such is completed in about a thousand millionth of a second They leave their mark behind them in the ionization of the air through which they have passed and in the heat into which their energy has been commuted The former effect is easily detected by the sensitive measuring in struments which we now possess the latter is too small to measure and must be greatly increased by the aid of radium itself before it can be investigated But on a large scale which takes into account the distribution of radioactive material through the earth the sea and the air the effects are of first rate im portance to the physical conditions of our earth

If we compare the movements a little more closely we find differences as interesting as the resemblances The motions which the kinetic theory of gases con siders are those of the molecules of which gases con sist In the case of radioactivity the things which move are quite different They are sometimes elec trons, which have come to be called β rays when their speed is great and kathode rays when it is somewhat less or they are γ or X rays which are new things to us or if as α particles they are helium atoms such as we have known before they move with ex cessive speeds which give them quite new properties In general the radiant particles move hundreds of thousands of times as fast as the gas molecules do and it is no doubt on account of this fact as well as through their usually extreme minuteness that their power of penetrating matter is so great. When two molecules of a gas collide they approach within a fairly definite distance which we call the sum of the radii of the molecules and the approach is followed by a recession and new conditions of motion Each molecule has as it were a domain into which no other molecule can penetrate But the defences which guard the domain are of no account to the vigorous movements which we are considering now The radi ant particles pass freely through the atoms and their encounters are rather with one or other of a number of circumscribed and powerful centers of force which exist within the atomic domain and act with great power when and only when approached within dis tances which are small in comparison with the atomic radius It is on this account that the new theory opens out to us such possibilities of discovering the arrangement of the interior of the atom Never be fore have we been able to pass anything *through* an atom our spies have always been turned back from the frontier Now we can at pleasure cause to pass through any atom an α particle which is an atom of helium or a β particle which is an electron or a γ or X ray and see what has happened to the particle when it emerges again and from the treatment which it seems to have received we must try to find out what it met with inside

The newer movement exists superimposed upon the other Its velocities are so great that the gas (or liquid or solid) molecules are in comparison per fectly still There is as it were a kinetic theory within a kinetic theory there is a grosser movement of gas molecules which has long been studied and in the same place and at the same time there is a far subtler and far more lively movement which is prac tically independent of the other Your vice president Sir William Crookes was the first to find any trace of it The behavior of the kathode rays in the vacuum tubes which he had made showed him that he was dealing with things in no ordinary condition Whatever was in motion was neither gas nor solid nor liquid as ordinarily known and he supposed it must be possible for matter to exist in a fourth state We have gone far since Sir William s first experi ments The X ray tube and radium have widely in creased our knowledge of phenomena parallel to those of the Crookes tube But I think we may still be glad to use Sir William s definition

There is another very striking characteristic of the newer kinetic theory which differentiates it sharply from the older The experiences of any one of the radiant particles in an atom which it crosses are quite unaffected by any chemical combination of that atom with others that is to say by any mole cular associations it may have Naturally this sim plifies investigation We may no doubt ascribe this state of things to the fact that a radiant particle is concerned rather with the interior of the atom than with the exterior and that it is the latter which is of importance in chemical action

Let us take notice of one more important differ ence The molecules of a gas move with velocities which vary at every collision yet vary about a cer tain mean But the peculiar motion of the radiant particle is only temporary For only a very short time can any ray be described as matter in a fourth state at the end of it the extraordinary condition has terminated the particle has lost its tremendous speed or suffered some other change and the ray ceases to exist Speaking technically we are dealing with in itial not permanent, conditions

Let us now come back to resemblances between the two kinds of motion for there is one point of sim ilarity which is not quite so obvious as others I have mentioned and is I think of the greatest importance, in fact it is largely on account of this similarity that I have ventured to put the two theories together for comparison

When the first experimenters in radioactivity al lowed their streams of rays to fall upon materials of various kinds they found that the irradiated sur faces were the sources of fresh streams of radia tion The secondary rays were sometimes of the same nature and quality as the primary sometimes not. Further they found that the secondaries on striking material substances could produce tertiaries, and so on The examination of all the variations of this problem—the investigation of the consequences of changing the primary of changing the substance, and last, but not least, of changing the form of the experi mental arrangements—has been the cause of an enormous amount of work. There is a large litera ture dealing with secondary radiations of all kinds which I imagine but few have read with any com pleteness and the subject has become, on the surface at least, complicated and difficult. Now I believe that it is possible to clear away the greater portion of this complexity at a stroke by the adoption of a hypothesis which makes it possible to describe and discuss the whole of these phenomena in a very simple way When an encounter takes place between two gas mole cules we suppose that the sum of the energies of the two is the same after the collision as before, and further that there are just two things to consider— two molecules—after as well as before I think that we may carry this idea over almost bodily to the newer theory A radiant particle encounters an atom The particle is a definite thing it contains a definite amount of energy and whether it is an α or β, or γ or X ray its energy is to be found almost entirely in side a very minute volume The encounter takes place When it is over there are still two things an atom and a radiant particle going away from it. The sum of the energies of the two is still the same, which means that we deny a possibility much considered at one time viz that in the encounter the atom could be made radioactive and could unlock a store of en ergy usually unavailable We suppose that there is no energy to be considered except the original energy of the radiant particle, and we suppose that there are not now two or more radiant particles in place of the original one which also is a limitation on previous ideas It is a theory which ascribes a compuscular form to all the radiations Each particle α β γ or X is to be followed from its origin to its disappear ance and we have nothing to think of but the one particle threading its way through the atoms It loses energy as it goes though little at any one col lision and it passes out of our reckoning when it has lost it all There are no secondary radiations other than radiant particles moving in directions which are different from those in which they moved at first. Even when a kathode ray excites an X ray in the or dinary Rontgen tube or the X ray excites a kathode ray in a manner almost as well known it is hardly an exception to this rule The kathode ray has an en counter with an atom and disappears simultaneously the X ray comes out of the atom a circumscribed corpuscle carrying on the energy of the kathode ray There is a change but it extends only to the external characteristics of the carrier of energy The X ray passes through the glass wall of the X ray bulb or at least it does so sometimes it may pass through other matter as well but sooner or later it has a fatal en counter with an atom and the reverse change takes place In all cases in that of the undeviating α ray or the β ray which suffers so many deflections or the γ or X rays it is a matter of tracing the movements of individual minute quantities of energy until they finally melt away

Let us consider one or two simple experimental re sults from this point of view in order that we may il lustrate this corpuscular theory and at the same time may learn something of the properties of the cor puscles and of the arrangements of the atoms through which they pass

We take first one of the simpler cases the move ment of an α particle through a gas The relatively large mass of the particle gives it an effectiveness which the other radiations do not possess. It moves straight through every atom it meets and ionizes most of them Very rarely does it suffer any deflec tion from its course until its velocity is nearly run down Then indeed it does appear to depart con siderably from the straight path and it may be that it is much knocked about by collisions before it finally comes to comparative rest. In this way we may ex plain the distribution of the ionization along its path which increases slowly at first and rapidly after wards until the α particle has nearly finished its journey it then falls off rapidly Considering that the ionization increases as the particle slows down and spends more time in each atom and considering the more broken nature of the path near its end, the reason of these peculiarities is clear enough Apart from its comparative simplicity there are some other very interesting features of the particle s motion It is found for example, that the loss of energy which the particle incurs in crossing an atom is proportional to the square root of the atomic weight very nearly, and there is no certain explanation as yet of this curi ous law And again Geiger has examined the small scattering that does occur, and found that α particles when moving quickly may be swung round completely even by the thinnest films of gold leaf, though the number is so small that the effect would have remained undetected had it not been for the scintillation method which he and Rutherford have perfected He has found that about one particle in 8,000 is returned in this way from a gold plate, which need consist only

* Discourse delivered at the Royal Institution by Prof William H Bragg, F R S

few thicknesses of gold leaf in order to give the maximum effect.

Now let us taken an example from the behavior of β rays. The β particle is so light that it is easily deflected even though it moves several times as fast as the heavier α particle Because it therefore possesses little energy its effects are much smaller and no one has yet succeeded in handling a single β particle in the same way as Rutherford and Gieger have handled the other We are obliged to content ourselves with observations of the effects of a crowd of β particles since the combined action of many is necessary to give us an observable result and at the same time that the β particle gives much less effect than the α it has a much more irregular course so that the problem is doubly difficult We are in fact only just beginning to understand it There is a compensation in the fact that its very liability to deflection makes it all the more interesting an object as is possible—and this is the particular β ray problem I wish to consider now—to examine the deflection of a single β particle by a single atom the parallel result in the kinetic theory of gases has never of course been achieved

Suppose that we project a stream of β rays against a thin plate and measure the relative number sent back which we do by measuring the ionizations caused by the incident and returned rays respectively We do this for varying thicknesses of the plate and plot the results as for example Madsen has done His plate was made of gold leaves which could be had of extreme fineness From the relation thus obtained it is possible to obtain with confidence the amount of β radiation that would be returned by the thinnest plate that could be imagined only one molecule thick In such case the particles turned back could have had but one collision and we have achieved our purpose Madsen's figures show that a plate weighing four milligrams to the square centimeter turned back a tenth of the β particles that fell upon it and so far as can be judged the ratio of the proportion turned back to the weight of the plate would be almost doubled for very thin plates We could go more into detail and find the distribution of those that are returned we should then have data from which we might determine in some measure the distribution of the centers of force inside the atom We cannot follow this up now but I would like to direct your attention to a curious indication which we obtain when we compare the results for gold with those which Madsen found for aluminium They show that the lighter metal turns back fewer β particles and that its power of absorbing a stream of rays is rather an absolute abstraction of energy There is clearly an actual absorption effect which is to be distinguished from the scattering effect Indeed the two effects are obviously of different importance in the two cases When a β ray strikes a gold atom it must be much more liable to deflection than when it strikes the lighter atom of aluminium On the other hand I think it can be shown clearly that in plowing through aluminum atoms there is a relatively quicker absorption of energy We may illustrate this by a rough model Let us stand an electro-magnet upright on the table and let us suspend another magnet so that it can swing over the fixed one and just clear it If we draw back the swinging magnet and let it go toward the fixed one the currents running so that the two repel then as the moving magnet tries to go by there will be a deflection depending on the relative speed the closeness of approach and the strength of the poles This may represent the turning aside of an electron by a center of force inside an atom Now let the magnet at the table be supported by a spiral spring so as to be still upright but have some freedom of motion then when the experiment is repeated the swinging magnet pushes the other more or less to one side It is less deflected but it has to give up some of its energy This is exactly what happens in the case of the β particle The center of force in the gold atom behaves like the stiffer electro magnet on the table It deflects the electron more but robs it of less energy in doing so It will not do to suppose the gold atom to differ from the aluminium atom simply in the number of centers of force such as electrons which it contains if it is supposed that they all act independently There is some other fundamental difference equivalent to a difference in the stiffness with which the electrons are set in their places There are two things to be expressed in the behavior of the atom toward the β particle as has been pointed out several times H W Schmidt has actually calculated them from experiments which gave them indirectly and somewhat approximately The method I have just outlined gives one of them directly viz., that which is called the scattering coefficient, and I think the other can also be found directly by a method which will serve as an illustration of the behavior of γ rays.

We must first, however, consider the part which γ and X-ray play generally in this theory Workers are by no means agreed as to the proper way in which to regard them but there is no need to enter at once on a discussion as to their nature It is well known that they have the most extraordinary powers of penetration and are unaffected by electric or magnetic fields They have one property which alone as I think brings them within our experience that is to say the power of exciting β rays from the atoms over which they pass Were it not for this they would still be unknown When we examine this production of β rays we find that in the first place their speed depends on the quality of the γ rays which cause them and not on the nature of the atoms in which they arise In the second that the β rays to a large degree continue the line of motion of the γ rays as if the latter pushed them out of the atoms and lastly that the number of the β rays depends on the intensity of the γ rays It is these facts which suggest the simple theory I have already described The γ ray is some minute thing which moves along in a straight line without change of form or nature which penetrates atoms with far greater ease than the α or β particle which is not electrified and which sooner or later disappears inside an atom handing on a large share of its energy to a β particle which takes its place The absorption of γ rays is simply the measure of their disappearance in giving rise to β rays one γ ray producing one β ray and no more

We find the same sort of scattering in the case of γ rays as in that of β rays Of a stream of rays directed against a plate which it can penetrate easily we find that a few are turned completely back a very much larger number are only slightly turned out of their path and the rest go on The scattered rays are very similar to the original rays there is no need to suppose that the original ray disappears to be replaced by a secondary any more than there is to suppose that α and β rays disappear and are replaced by others in similar cases When therefore a γ ray enters an atom three possibilities await it The first is a negative one it may go through the atom untouched and this must happen in the majority of cases the second chance is that of deflection and the third that of conversion into a β ray using the word conversion in a general sense without going into details as to the nature of the process

Now we may consider our γ ray problem Suppose a stream of these rays passing over a block of any substance such as aluminium or zinc or lead When they are really penetrating rays they are equally absorbed by equal weights of these materials which means that in equal weights equal numbers of β rays spring into existence If these β rays were able to move through equal weights of the metals we should find in each metal the same density of β rays and the important point is that this is independent of whether the rays are straight or crooked in their paths If ten lines of given length were begun in every square centimeter of a sheet of paper the ink used in drawing them would be independent of the straightness of the lines but proportional to their length Now if we make a cavity in each metal the β rays will cross it in their movements to and fro and if a little air is introduced into the cavity the ionization produced in it will be a measure of the density of the β rays and therefore the average distance each moves in the metal Experiment shows that we get twice as much ionization in a cavity in the lead as in a similar cavity in the aluminium and we conclude that the β particle really has a longer track in the heavier metal This experiment gives us the second constant of β ray absorption that is to say the rate at which its energy is taken away from it the other experiment gave the chance of deflection only We see that the path of a β ray in aluminium is more direct but of less length than in lead in the latter metal it has really a longer path but it does not get so far away from its starting point because it suffers so many more deflections

Finally let us take a problem from the X rays Let us see how we may test the idea that X and γ rays do not ionize themselves but leave all the work to be done by the β rays which they produce Suppose a pencil of X ray to pass across a vessel and to produce ionization therein It is convenient to use not the original X rays which are heterogeneous but the rays which are scattered by a plate of tin on which the primary rays fall Such tin rays as we often call them briefly are fairly homogeneous and give kathode rays of convenient penetration In some experiments of mine the rays crossed a layer of oxygen 3 45 centimeters wide having a density 0 00137 and the ionization produced was 227 on an arbitrary scale The result may be put in the following way Suppose provisionally that all this ionization is done indirectly the oxygen has concerted so much X ray energy into kathode-ray energy and these kathode rays penetrating their one or two millimeters of oxygen, which is all they can do have ionized the gas Then we may say that, in crossing a layer of oxygen weighing $3\ 45 \times 0\ 00137$, or $0\ 00473$ grain per square centimeter enough kathode rays have been produced to cause an ionization of 227 units and therefore that a layer weighing one milligram per square centimeter would produce 48 units in the same way We now proceed to compare this production in oxygen with the similar effect in a metal such as silver Stretching a silver foil across the chamber in the path of the rays we find that under the same intensity of rays the ionization is largely increased and the change is due to kathode rays which the X rays have generated in the silver Not all these rays get out of the silver but we can overcome this difficulty by taking silver foils of different thickness drawing a curve connecting the effect of the foils with their thickness taking the curve back to the origin and so finding what would be the effect of a foil so thin that all the kathode rays did get out In my case I found that a milligram of silver produced enough kathode rays to give an ionization 1 80 This is thirty three times as much as the oxygen could do Now according to our theory this should be because silver absorbs tin rays thirty three times more than oxygen does and experiment showed this to be very nearly the case In finding the absorbing power of oxygen I measured first those of carbon and oxalic acid and then proceeded by calculation for the absorption in a gas is difficult to determine

Two interesting points appeared in this experiment In the first place the ratio between the two quantities of kathode rays which appear on the two sides of a silver leaf through which the tin rays pass is nearly constant for different thicknesses of leaf With the thinnest leaf obtainable each quantity was about half its full value It would have been desirable to have had still thinner leaves but it is fairly clear that the ratio would be nearly the same for extreme thinness The kathode radiation which appears on the side of the leaf whence the X rays emerge is 1 20 times that which appears on the other and we may take it that this would be the case even if the leaf were but one atom thick Thus when an X ray plunges into an atom in which its energy is converted into that of a kathode ray the kathode ray may emerge at any point but there is a 20 per cent greater chance that it will more or less continue the line of motion of the X ray than that it will not In previous work on the conversion of γ ray into β ray energy I have found that the β ray may practically be supposed to continue the line of motion of the γ ray so that there is a great difference in behavior of the two classes of ray in this respect It is remarkable that the scattering of the γ rays shows also a much greater dissymmetry than is found in the case of X rays It looks as if the β rays that appear when γ or X rays impinge on atoms are related rather to the scattered than to the unscattered primary rays Putting it somewhat crudely no doubt it might be said that when a γ or X ray is deflected in passing through an atom it runs a risk of being converted into a β ray in the process so that β rays are found disturbed about the atom in rough proportions to the secondary γ or X rays In the case of γ rays this practically amounts to their all going straight on at first in the case of X rays the distribution is more uniform

Another interesting point arises in this way When the X rays from tin are allowed to pass into the ionization chamber through increasing thicknesses of silver foil the kathode rays grow at a rate which is not represented by the exponential curve usually assumed The amount is for some time more nearly proportional to the thickness of the foil A second foil adds its own effect without destroying much of the one on which it is laid This may easily be ascribed to the relation of the ionization due to the β particle to the energy it has to spend The ionization is nearly all at the end of the path and the second layer does not absorb the rays made in the first because they are still at the beginning of their career

These few experiments which I have described may serve to illustrate both the justice and the convenience of placing all these rays α β γ and X in one class We are tempted to consider them all as corpuscular radiations of some sort and we then look upon our researches into their behavior as attempts to understand the collisions of the various new corpuscles with the constituent centers of force in the atoms But if we ascribe corpuscular properties to the γ and X rays we are led far away from the original speculations as to their nature Stokes supposed them to be spreading æther pulses but in his theory the energy of the pulse spreads on ever widening surfaces as the time passes and is utterly insufficient to provide the energy of the β rays which the γ or X rays excite Some sort of mechanism has to be devised by which the energy of the γ ray moves on without spreading so that at the fateful moment it may be all handed over to the β ray which carries it on I had the hardihood myself to propose a theory of this kind My idea was that the γ or X ray might be considered as an electron which had assumed a cloak of

darkness in the form of sufficient positive electricity to neutralize its charge Nor do I see any reason for abandoning this idea, for it is at least a good work ing hypothesis It means of course that not only does the energy of the β ray come *from* the γ ray but the β ray itself

Many insist that my neutral corpuscle is too ma terial and that something more ethereal is wanted for it appears that ultra violet light possesses many of the properties of X and γ rays It can excite elec trons to motion and sometimes the speed of the elec tron depends on the quality of the light, and not on the nature of the material from which it springs They propose therefore a quasi-corpuscular theory of light γ and X rays being included The immedi ate objection to this proposal is that it seems to throw away at once all the marvelous explanation of interference and diffraction which Young and Fres nel founded on a theory of spreading waves, and I do not think anyone has yet made good this defect. The light corpuscle which is proposed is a perfectly new postulate It is to move with the velocity of light keeping a circumscribed and invariable form to have energy and momentum and to be capable of replacing and being replaced by an electron which possesses the same energy but moves at a slower rate and of course it has to do all that the old light waves did The whole situation is most remarkable and puzzling We are working and waiting for some solution which perhaps will come in a moment unexpectedly Mean while we must just try to verify and extend our facts and be content to piece together parts of the puzzle since we cannot as yet manage the whole My object has been to show you how we may conve niently bind together a large number of the phe nomena of radioactivity into an easily grasped bundle using a kinetic theory which has many points of re semblance to the older kinetic theory of gases

Surface Tension and Lead Poisoning

The surface of the mercury in a barometer is con vex but when a glass tube is partly filled with water the surface of the liquid assumes a concave form A glass tube or rod which has been immersed in water remains wet after it is withdrawn because a film of water adheres to the glass but mercury does not adhere to glass or wet it Every liquid assumes a concave surface when in contact with a solid which it wets and a convex surface in contact with a solid which it does not wet Water does not wet grease and therefore it assumes a convex surface in a greased glass tube and the form of convex drops when sprinkled on a greased glass plate The leaves of plants are covered with a film of wax and for this reason are not easily wetted Dew stands in drops on leaves without wetting the surface and the funnel shaped leaves of some plants collect rain in the form of a large flattened drop which does not wet the leaf. In the absence of wax or grease water readily wets vegetable tissue for which it possesses a strong affin ity When leaves are exposed to long-continued rain their thin coating of wax is gradually washed away and they then become soaked with water

The feathers of ducks and other aquatic birds shed water and do not become wet because they are satu rated with oil This oil is not washed away as the wax is washed from leaves by long-continued rain because the feathers possess a stronger affinity for oil than for water

What has all this to do with poisoning? Prof O N Witt gives the answer in a long and very entertaining article in *Prometheus* from which only the essential facts are here cited

White lead like the feathers of birds is more easily wetted by oil than by water and when once saturated with oil is permanently protected from the action of water and aqueous solvents Hence though white lead is very poisonous it can be safely used as an oil paint even in kitchens House painters and artists have long since ceased to use dry ground white lead which is both troublesome and dangerous to work with and buy white lead ground in oil In this way the danger of lead poisoning is removed from the painter s shop but not from the white lead factory where the white lead is first dried in heated rooms then finely ground and finally ground again with oil Although every precaution is taken in these operations it is impossible to prevent some of the poisonous white lead being scattered as fine dust in the air which the workmen breathe

One day a genius whose name is lost to fame reflected that as white lead is produced in the wet way as a chemical precipitate it is already as finely divided as possible and that there would be no neces sity for grinding it if it were not agglomerated by drying But is it necessary to dry a substance which possesses so much greater affinity for oil than for water? Experiment proves that when the wet precipitate of white lead is ground with linseed oil, the water is expelled and rises to the top of the mass as a clear liquid which can be poured off The few drops of water which adhere to the pigment are care fully wiped off. This new process almost entirely eliminates the danger of lead poisoning by white lead dust scattered in the air of the factory

Magnalium Equalizers

An apparatus whose function is to acquire the poten tial prevalent at the point at which it is placed, thus rendering it accessible to measurement, is termed an equaliser To illustrate its use by an example, we may suppose that the upper of two metal plates *A* and *B* shown in Fig 1 to be charged from a storage bat tery so that an electrostatic field is established whose direction is indicated by the three arrows, represent ing lines of force between the two plates. An equal izer *P* connected to an electrometer then indicates the potential at the point occupied by the equaliser

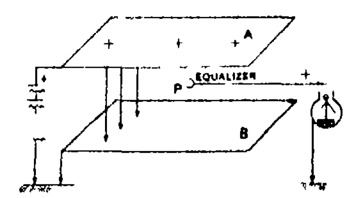

Fig 1

Different types of equalisers have been employed Among these may be mentioned the familiar points or combs diagrammatically represented at *a* in Fig 2 The form shown in Fig 2 *b* depends for its action upon the discharging properties of a stream of water droplets while *c* indicates a similar use of a flame and *d* is intended to denote diagrammatically the use of radioactive substances connected to the electro meter to effect equalization

The mode of action of this last type of device may be briefly outlined as follows The radioactive preparation consisting as a rule of a sheet of platinum coated with polonium strongly ionizes the air in its immediate proximity thereby rendering the same con ducting So long as there exists any difference in potential between the equalizer and its surroundings the ions bearing the corresponding charge fly to meet the plate and charge it up to the proper potential.

All these forms of equalizers possess certain disad vantages which render them ill adapted for the investi gation of the electrical conditions of the atmosphere In the case of balloon ascents the flame type of equal izer is out of the question The water drop equalizer requires frequent attention and polonium is a costly material It is therefore gratifying to hear that another type of instrument has recently been intro duced which depends on a certain action of light, and which is in many respects superior to the older forms. It has been known for some time that plates of zinc or aluminium with a freshly exposed bright surface exert an equalizing influence under the action of light This effect however dies down very quickly Recently however it has been shown by Dember that the alloy of magnesium and aluminium known as magnalium is peculiarly well adapted for use as an equalizer Freshly scraped magnalium retains its equalizing prop erty for several hours and when it has lost its activity it can very quickly be restored by simply polishing its surface

It seems then that we have now a thoroughly satis

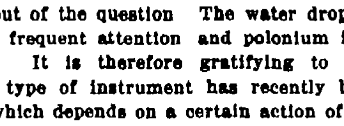

Fig 2

factory agent at our disposal and one which is not dependent upon narrowly prescribed laboratory condi tions but which will readily adapt itself to the exigen cies of circumstances —Excerpt from *Prometheus*

The Great Red Spot of Jupiter

Jupiter, the giant of our family of planets is now in a very favorable position for observation It was in opposition to the sun on May 1st, will be visible all night during the entire month of May and will be evening star until September

This great planet, which possesses 1 300 times the bulk and 310 times the mass of the earth accom plishes its rotation on its axis in 9 hours and 50 min utes As the equatorial circumference is 275 000 miles, the linear rotational velocity of a point on the equator is nearly 8 miles per second In consequence of this enormous velocity or rotation the planet is greatly flattened at the poles.

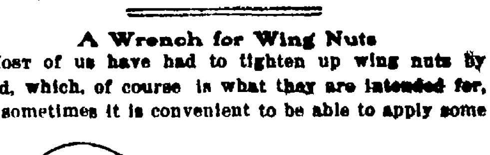
The telescope shows a series of bands or belts crossing the planet's disk parallel to the equator and continually changing in width, form, [illegible] general appearance. They are sometimes called [illegible] clouds, but they more probably represent currents [illegible] the mass of the planet, somewhat analogous [illegible] terrestrial Gulf Stream. The whole globe of Jupiter is composed of parallel circular currents, moving with different velocities, the equatorial current being the swiftest. A similar phenomenon is observed in the sun, which does not rotate as a rigid mass, but moves most rapidly at the equator The velocity is not even constant for the same current. Spots near the equator of Jupiter, which accomplished a complete rotation in 9 hours 50 minutes and 6 seconds in 1[illegible], occupied 9 hours, 50 minutes and 24 seconds in performing the rotation in 1895. In short, Jupiter is a planet which is not yet solidified

A very remarkable detail of the surface of Jupiter, which is sometimes very conspicuous and at other times is barely perceptible (probably owing to clouds in the planet s atmosphere) is a large oval spot of ruddy hue situated in the southern equatorial belt, between 25 and 30 degrees of south latitude. This spot is 26 000 miles long and 9,300 miles wide, and it covers as large a proportion of the planet's surface as Australia covers of the surface of the earth The red spot moves a little less swiftly than the equatorial current and with a slightly varying velocity accomplishing its revolution about the planet in 9 hours, 55 minutes and 35 seconds in 18[illegible], and in 9 hours, 55 minutes and 42 seconds in 1900.

In a contribution to the April number of *L'Astronomie* quoted in *Cosmos* Antoniadi expresses the opinion that this great red spot is the first continent in process of formation on the liquid surface of Jupiter This floating continent or island is still only a thin crust for although the materials of the current in which it floats are observed to be deflected by it and to skirt its shore the Spanish astronomer Sola has also seen these materials vanish at the eastern shore and reappear at the west, as if they passed be neath the continent The terrestrial granitic conti nents in their initial stage of formation were likewise thin crusts floating on the surface of the hot and liquid globe

A Wrench for Wing Nuts

Most of us have had to tighten up wing nuts by hand, which, of course is what they are intended for, but sometimes it is convenient to be able to apply some



A WRENCH FOR WING NUTS

tool for the tightening up of these nuts For such a purpose the simple little tool illustrated in the accom panying line engraving taken from the *Horseless Age* will be found convenient. The wrench is made of flat stock about 3/16 inch thick. The handle *A* is made in various sizes according to the size of the wing nut five times the distance across the wings of the nut being the usual practice Two slots *B* are cut at right angles to each other in the circular part of the wrench as shown. At their intersection the central opening is enlarged so as to permit the screw on which the wing nut turns to enter —*Machinery*

Black English Stone Pulp.—Heat pumice stone to redness quench it with water crush it to a fine powder and sift through a hair sieve. Put the pow der into a suitable vessel and add enough varnish to make a thick paste Add lamp black, then more var nish and rub it down until the fluid is uniform With this mass well beaten cardboard or double paper is coated dried coated a second time, then dried and pressed

The Heilmann Suspension for Automobiles

By Jacques Boyer.

In automobiles of the usual construction the center of gravity is higher than the axles The result is extensive vibration of the vehicle and torsion of the springs. Moreover the shocks caused by inequalities of the road are transmitted directly from the wheels to the axles. The springs attached by their middle posts to the axles follow the oscillations thus produced, but the chassis and the body of the car, which are suspended from the ends of the springs are prevented by their inertia from following these rapid vibrations Hence the springs and their connections are strained and are soon worn out. In light cars these defects are party obviated by pneumatic or solid rubber tires but the vibrations of heavy vehicles cannot be overcome by these very costly additions.

An elegant solution of the difficulty has been proposed by J J Heilmann, the inventor of the first electric locomotive In the Heilmann compound suspension for automobiles all oblique bearings and torsional stresses are eliminated, and the center of gravity is brought as near the ground as possible while the weight of the car acts along the vertical lines which pass through the centers of the wheels and the points of contact with the ground but is borne entirely by the hubs and not by the axles

The details of construction are shown in Figs. 1 and 2, which represent vertical sections of the vehicle in the planes of the rear and front axles respectively The weight of the chassis and body is carried by the rear and front supporters *a* attached to the longitudinal bars *b* of the chassis These supporters pass over and outside the wheels and rest on the hubs *c* Each wheel is absolutely independent The axles *d* carry no weight except their own and serve merely to connect the wheels together They are connected to the front hubs by Cardon joints *e* and to the rear hubs by balls *f* Each wheel is consequently free to rise independently of the others in surmounting obstacles The axles move freely in guides *g* attached to the chassis.

The weight is transmitted to the hubs by the following mechanism Each hub turns in all bearings *i* in a saddle *h*, which has four lugs of which two are above and two below the hubs These lugs are attached by short suspending links to the ends of two carriage springs of the ordinary type *l* with their concave sides below The two sheaves *m* which are bolted to the middle parts of the springs are connected with each other by an ovoid frame *n* which surrounds the saddle without touching it at any point

Fig 5—WHEEL OF CAR WITH HEILMANN SUSPENSION

The outer portion *o* of the supporter *a* rests on the spiral spring *p* which rests on the upper spring sheaf *m*. Vertical rods *r* attached to the top and bottom of the saddle *h* pass through tubes rigidly connected with the upper and lower spring sheaves *m* and guide the wheel in rising over obstacles The Cardan joints allow the front wheels to be turned around a vertical axis in steering The tires are composed of chrome leather very strongly compressed which nearly eliminates the noise produced by the rolling of the wheels

The diameter of the wheels is 4 feet and 5 inches, but as the weight is borne by the supporters described above and not by the axles the center of gravity can be brought lower than in a car of the usual type with much smaller wheels The large wheels possess the advantages of better adhesion to the ground diminished coefficient of traction and smaller velocity of rotation for a given speed of travel—not to speak of their esthetic superiority The weight of all the springs of a car designed to carry a load of 4½ tons in addition to its own weight does not exceed 135 pounds

Another distinctive feature of the new Heilmann car is a system of steering which is entirely independent of the various connections and mutual reactions between the front wheels and the chassis which are described above so that the wheels can be turned without regard to their momentary positions relative to the chassis The mechanism by which this result is produced is shown in Figs 3 and 4 which represent respectively side and front elevations of the steering gear The rotation of the steering wheel 1 transmitted to the endless screw 2 moves the nut 3 which by means of the fork 4 causes the bent lever 5 to turn on its point 6 which is attached to the chassis 7 The lever 5 is connected by the link 8 and the joints 9 and 10 with the support 11 which slides along the guiding rod 12 attached to the chassis by the bars 13 The support 11 has a vertical slot containing the sliding piece 14 which is jointed at 15 to the plunger 16 This plunger penetrates more or less deeply into a cylinder 17 which is attached to the wheel by means of the piece 18

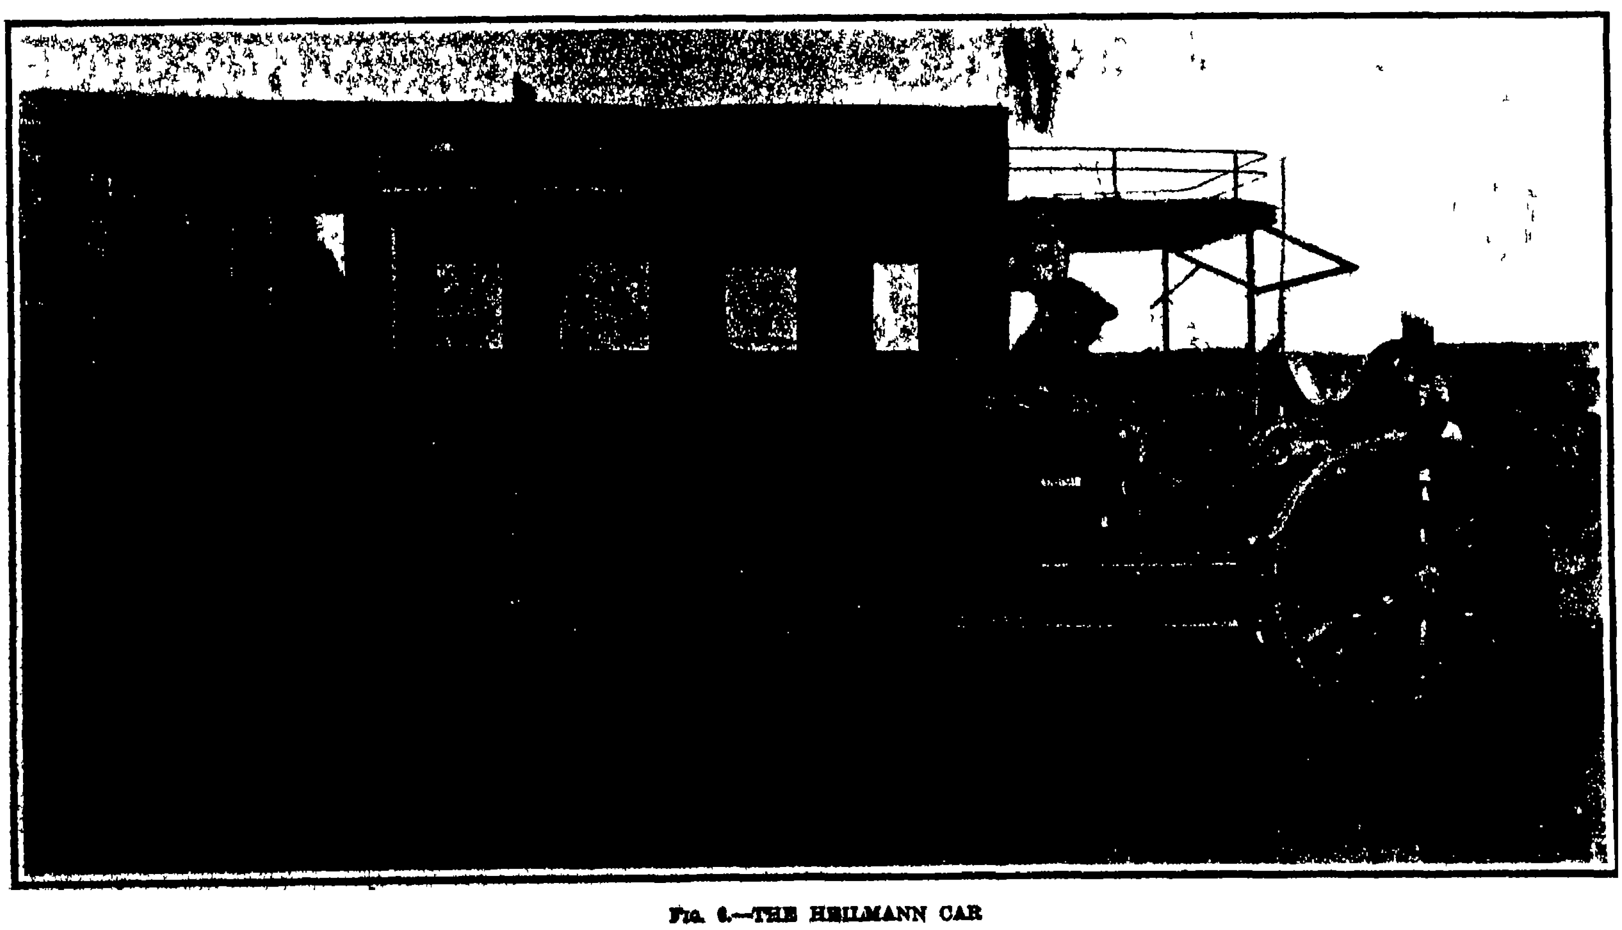

Fig. 6.—THE HEILMANN CAR

Hence when the support 11 is moved forward or backward by turning the steering wheel 1 as has been explained the motion is transmitted by the sliding piece 14 to the extensible steering lever which is composed of the plunger 16 the cylinder 17 and the piece 18 and the wheel to which this piece is attached is turned to the right or left through an angle which corresponds with the position to which the support 11 is moved along the guiding rod 12 and also with the depth to which the plunger 16 penetrates in the cylinder 17 The freedom of movement of the sliding piece 14 in the slot of the support 11 allows the entire steering lever composed of 16 17 and 18 to rise and sink with the wheel as the latter passes over obstacles without interfering with the operation of steering

The Heilmann car no doubt needs some improvement in details and a more pleasing appearance may be given to the rather heavy vehicle by skillful constructors In any case the Heilmann suspension which aims at no less than the greatly desired elimination of rubber tires both solid and hollow constitutes an important advance in automobile construction

Light-Weight Alloys for Aerial Engines and Aeroplanes*

It is generally recognized that future improvements in aerial navigation will be greatly facilitated by a decrease in the weight of the machinery With this end in view metals or alloys of low specific gravity are being eagerly sought to supplant the heavy metals generally in use The field of investigation however is so far very narrow it being at present limited to the two metals aluminium and magnesium The alloys so far developed consist of various proportions of these two elements modified by small additions of heavier metals

A number of alloys of this type have been experimented with and several have been patented The best known are duralum and magnalium One of the latest discoveries in this line is called duralumin which is of German origin as in fact are most of the light alloys Extraordinary claims are made for this alloy It is stated that it has practically all the properties of steel that it can be drawn rolled stamped or forged either hot or cold that its tensile strength ranges from 30 000 to 88 000 pounds per square inch according to its degree of hardness and that these qualities are found in an alloy containing from 90 to 95 per cent of aluminium so that the specific gravity is very nearly that of aluminium

Duralum contains copper and phosphorus in addition to magnesium The composition is given as 79 per cent of aluminium 11 per cent of magnesium and 10 per cent of phosphor-copper The percentage of phosphor in the copper is very low—only 0 5 per cent It is likely that the composition of this alloy however is slightly modified in practice because 10 per cent of copper is exceedingly high even in the absence of magnesium and when the hardening effect of 11 per cent of this latter metal is taken into consideration it would seem that an alloy of the composition as given would be too brittle to be of any practical value

Magnalium is composed of aluminium and small percentages of magnesium an analysis showing from 1 58 to 1 60 per cent of this latter element It also contains small percentages of copper nickel tin and lead the last mentioned metal probably being an impurity The specific gravity of this alloy varies from 2 5 to 2 57 According to Prof J W Richards the tensile strength of magnalium sand castings containing 2 per cent of magnesium is 17 900 pounds per square inch with an elongation of 3 per cent while with 10 per cent magnesium the tensile strength is increased to 21 400 pounds per square inch with a 2 4 per cent elongation It will be seen that the addition of magnesium hardens the metal Chilled castings of magnalium with 2 per cent magnesium have been found to possess a tensile strength of 28 600 pounds per square inch with an elongation of 2 per cent, and 10 per cent magnesium alloy chilled castings have a tensile strength of 33 600 pounds per square inch and an elongation of 3 40 per cent This is a peculiar condition as compared with that of sand castings The same peculiarity is found in water-chilled castings, where the 2 per cent alloy has a tensile strength of 40 000 pounds per square inch and a ductility of 1 per cent while the 10 per cent alloy has a tensile strength of 61 100 pounds per square inch with an elongation of 4 70 per cent.

In another series of light-weight alloys aluminium is replaced by magnesium for the basic metal. This produces a lighter alloy, as the elements of high specific gravity with which the magnesium is alloyed exist only in small proportions Alloys of this kind contain from 80 to 95 5 per cent of magnesium the remainder being made up of other metals, principally aluminium These alloys it is claimed can be readily machined, soldered welded forged and cast. An alloy of 92 per cent magnesium and 8 per cent aluminium has a specific gravity of 1.75 and is claimed to be equal in strength to the best gun metal, although the metallurgist may doubt this broad statement. The difference in general between gun metal or bronze and the light-weight alloys is that gun metal may combine high tensile strength with great ductility while the alloys of low specific gravity are more of the nature of cast iron and high tensile strength is obtained only at the expense of ductility Various useful magnesium alloys have however been produced such as electron and ruebel bronze These will no doubt be found of great value in the construction of aerial machines but there is a danger of their being discredited by extraordinary claims by the makers which will cause them to be used for purposes for which they are not suited

There are a number of light weight metals besides aluminium and magnesium but there is no likelihood of their being used for practical purposes on account of their scarcity Among these metals are lithium rubidium and beryllium Lithium is the lightest of all metals known its specific gravity being only 0 57 It possesses however but few of the qualities usually associated with metals It is very soft, and melts at a low temperature and it is hardly likely that it can be used in sufficient quantity with other metals to appreciably lower their specific gravity in order to produce a light weight alloy Rubidium and beryllium both having specific gravities of from 1 5 to 1 7 are too expensive to be of any commercial value at the present time The last mentioned metal has many qualities which would make it a desirable one for aerial work but the ores of this metal do not occur in sufficient quantities to justify the prophecy that it will ever be used as extensively as aluminium, although this latter metal only a comparatively few years ago also was very expensive. It is therefore, likely that nearly all investigations relating to light weight alloys will continue to be based on combinations of magnesium and aluminium with small percentages of heavier common metals

Greek Marble

WITH reference to the architectural glories of classic antiquity, it may be said that two special advantages came to the aid of the artist's genius and the skill of the constructor These were superior climate and super-excellent material. It has been pointed out that, were it not for the perfection of their marbles, it is questionable whether even the fine climate of the Mediterranean would have stimulated the architects of Greece and of Rome to create almost imperishable constructions to be objects of admiration and attempted imitation in our own day, and it remains a curious fact that we moderns still have to turn to the quarries of classic times for statuary marble while it has been contended only Greece can yet supply the finest marbles for constructive purposes

During the fifteen hundred years that followed the destruction of Greek independence art culture practically disappeared from the land While the Moors of Spain were patrons alike of art and learning, and saved much of the science and many of the literary masterpieces of classic times from destruction the Turk seems to have been too busy with the scimitar to have encouraged any arts but those pertaining to the comfort of the governing classes

The famous marble quarries of the Pentelikon near Athens remained therefore undisturbed and silent until the last century when after the coronation of the first King of Greece the erection of a royal palace again called attention to the national wealth in the finest of stone The road to the foot of the Penteli hills was reopened the bridges repaired and a large quantity of the famous old marble employed in the construction of a new Athens.

It was wisely decided that the old Greek quarries should remain untouched so that we have clear evidence of the mode of working these in other times Although the layers are not horizontal but are dipping inward the blocks have all been cut and removed by wedges horizontally to the vertical smoothly chiseled walls The quarries form therefore a series of gallery like right angle stone chambers from which perfectly regular parallelopipedic stone blocks of every size even to the largest, were taken as the thickness of the layers had not to be considered in this manner of extraction

As the modern system is, however to prevent diagonal stratification and also to avoid the more readily weathered seams of mica shale, the marble is preferably quarried from its natural layer This Pentelikon marble forms a great part of the ranges and, fortunately the upper portion The lower part up to five hundred and fifty feet is limestone in transition but thence up to eleven hundred feet it is pure marble

The Pentelikon marble is harder has a finer grain and is said to be in every respect superior to the much vaunted Carrara marble of Italy

Greece not only supplies the Pentelikon pure white marble accepted as the best of building stones but furnishes also fine black and yellow marbles Then too there is the beautiful *Rosso-Antico* presenting streaks of blood and fire in a broad belt, as well as the *Verdi Antico* from one of the islands with its beautiful mottled varieties

Model of a Detached Escapement for Pendulum Clocks

MR A MALLOCK exhibited, at the recent soirée of the Royal Society a model of a detached escapement for pendulum clocks, which also illustrates a simple method of keeping the density of the air surrounding a pendulum constant. The pendulum is "free" in the sense that during the swing it makes no intermittent contacts with any solid Near the end of each swing an electric contact is made by a fine wire dipping in a mercury cup The current then established passes through the coils of an electromagnet which, by means of a 'remontoir working a reciprocating lever causes a very weak spring, to act so as to maintain the oscillation. Constant density in the air surrounding the pendulum is approximately secured by the covering bell glass, whose edge dips in a deep but narrow annular canal, partly filled with mercury An alteration of one inch in the height of the barometer alters the density of the inclosed air by about one part in a thousand.

Electric Lamps and Wireless Telegraphy

THERE is reported in Germany a curious instance of the capture of a wireless telegraph message by an electric lamp An inhabitant of Brunswick, who had such a lamp in his laboratory, was surprised to observe that its brilliancy varied with the unmistakable rhythm of Morse signals. Not only did the light vary, but the sounds always given forth by the arc of the lamp varied in consonance. With a little attention he was able to decipher a message which was being sent out from a radio-telegraphic station three kilometers—nearly two miles—away.

The Electrolytic System of Amalgamating Gold Ores

The Electro-chemist in the Mine

By Elmer Ellsworth Carey

The increasing demand for gold has turned the at tention of miners and metallurgists to new fields and new methods, and every year brings down the cost of mining and milling new extraction methods are being tried, and every effort is being made to save values in low grade and refractory ores The tailing piles of yesterday are now being reworked and to-morrow the tailings piles of to-day will yield further values as the march of progress discloses new methods sys tems and appliances

The favorite ore of the miner is the so-called free milling' In such ore the gold particles are com paratively large and are generally imbedded in quartz free from sulphur arsenic etc Values in such siliclous ores may be recovered by the standard sys tem of amalgamation Then there are other ores where crystals of iron pyrites (sulphides) are found in the quartz and within the pyritic crystals may be found gold particles in a finely divided state The values in such crystals cannot be re overed on the usual mill plate as the particles of gold are coated with various substances preventing amalgamation The present practice is to separate the pyritic crystals from the crushed ore by various types of concentrat ing tables This so-called concentrate is then sent to a smelter or it is ground in tube mills (100-200) mesh and delivered to the cyanide tank where the extrac tion ranges from 85 to 96 per cent.

Concentrates can only be sent to a smelter where the values are high enough to pay transportation and reduction charges the cyanide process is expensive and unsatisfactory unless we admit Mr Clancy s claim that he has solved the cyanide problems by his system of electrochemical cyanidation.

Another method calls for fine grinding (100 mesh) and electro-amalgamation An ideal plant for this process consists of some type of rotary crusher with outside screening possibly a secondary crushing de vice to finish the work of the first crusher and from *the crusher the pulp ground sufficiently fine to re* lease all economic values is passed over electrolytic amalgamating devices The released values are re covered in the form of amalgam Concentration cyanidation and smelting are unnecessary and the metallurgy of gold is reduced to its lowest terms

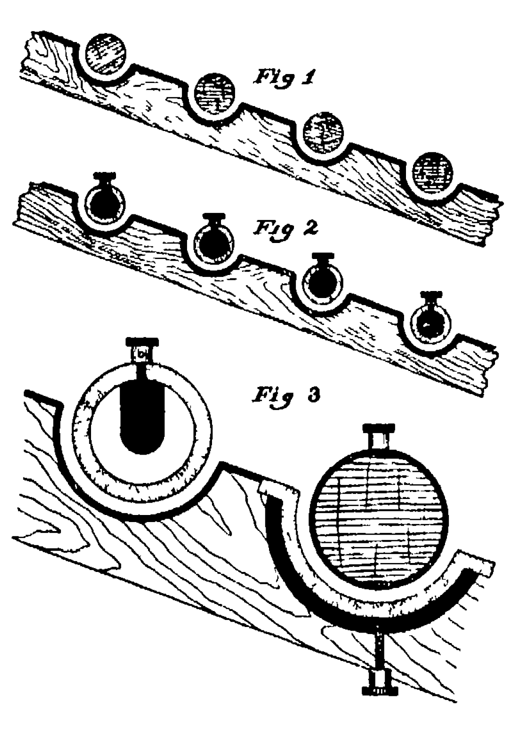
The theory of electrochemical amalgamation has been before the mining world for half a century one of the earliest authoritative papers on the subject may be found on p 205 of Vol I of the Proceedings of the (London) Institution of Mining and Metallurgy Early investigators found as many difficulties as the pioneers in the art of aviation With no informa tion no reserve of text-book knowledge no authorities to consult no works on electrochemistry it is not strange that the electrolytic method of gold recovery made slow progress All the problems of current density anode troubles forms of construction etc had to be laboriously and expensively worked out To obtain working data regarding the system will cost an independent observer several thousand dollars and a year or two of time beside he will draw heavily on his stock of good nature patience and perseverance

In electrolytic amalgamation the sole function of the electric current is to deposit hydrogen sodium potassium or ammonia in the mercury The sole func tion of sodium or potassium is to de-oxidize water and the final work in the chain of reactions is the liberation of nascent hydrogen at the surface of the mercury As the particles of gold sweep over the electrolytically excited mercurial surface all sub stances usually preventing amalgamation are auto matically and almost instantly destroyed or rendered inert. Grease is saponified by the caustic soda oxide coating on gold particles is reduced by hydrogen in a word, gold particles are cleaned and amalgamation quickly follows.

It has been known for some decades that in some way amalgamation was intensified in the presence of the electric current, the problem was to devise a ma chine to utilize the electrical action to the best ad vantage Many complicated devices for this purpose have been patented, but as is usually the case the suc cessful apparatus is simple—almost childishly simple So simple is the device that extracts all released values, and so broad are the claims made for it that the builders of our metallurgical temple have persist ently rejected this stone. I will follow the scriptural allusion no farther, but I earnestly suggest that in dealing with any difficult extraction problem the claims of electro-amalgamation be considered.

* [illegible] mercury wells are described in Vol. II [illegible] American Electrochemical Society, of Prof R H Richards work on ore dressing by making the baffle in such wells an anode using suit able material and employing an 8 to 12 volt current of high amperage we have an electrolytic amalgamating device The objections to the use of such mercury wells disappear when they are electrified and their ex traction efficiency is greatly increased The interior of such wells must be lined with some very refractory substances The ideal amalgamator provides a method by which the gangue is brought closely and intimately into contact with a mercurial surface which acts as a cathode provide these conditions and arrange for suitable capacity and durability etc and the low grade and refractory ores of the West soon yield their gold

To day the mining industry is at a standstill be cause new conditions call for new methods The old style mining engineer must give way to the metal lurgical and chemical engineer There are no prob lems in metallurgy that cannot be solved by the appli cation of the proper electrochemical principles Elec trochemistry has devised profitable methods of ex tracting the useful metals from other ores and electro chemistry will also find methods for releasing the



noble metals from Nature s refractory grasp There is more gold in the West than has been mined lying in plain view in tailing piles low grade veins desert sands beach and river deposits of the West there is sufficient gold awaiting the electrochemical engineer to pay the combined national debts of the world There will be no great advance in the mining industry until the technical schools have furnished a supply of electrochemical metallurgists for the problems of the mining industry to-day can only be finally solved by the electrometallurgist

Mr Clancy has spoken rather disparagingly of the electrolytic system of gold recovery He says One of the most severe criticisms on electrolytic processes is where the direct precipitation of the values from the ore pulp is concerned the objections probably be ing due to the scouring of the plates by the circulating ore and the consequent loss of finely divided gold amalgam in the ore pulp

With the use of the electrolytic sodium mercury cells, as above mentioned there is no scouring of the plates and no loss of finely divided gold amalgam on the contrary mill pulp after passing the electro lytic sluices, contains only encased values The aqua regia test shows no free values It is true that the electrolytic plate amalgamation to be successful re quires considerable experience in the art, but it is possible to arrange electrolytically excited amalgam plates so that the dire results mentioned by Mr Clancy do not occur Electrolytic amalgamation will give extraction results equal to electrolytic cyanidation, and when cost of installation operation and mainte nance is considered, all comparison ceases. Scores of investigators in the last twenty-five years have given testimony as to the efficiency of electrochemical cyan idation the method of regenerating the cyanide solu tion and the recovery of values not amenable to straight cyanidation have frequently been referred to in the technical and mining journals Mr Clancy de serves credit for calling attention anew to the utility of electrolytic lixiviation and his standing is such that many engineers will doubtless turn their atten tion to electrolytic process However I regret that Mr Clancy should have found it necessary to disparage electro amalgamation which is now slowly being rec ognized by progressive mining engineers as an im portant factor in milling But let no one imagine that he can run a few wires from a power line into a solu tion tank and have a successful electrolytic cyanide plant and let no one imagine that he can connect his battery plates with a low voltage generator and thereby greatly increase the extraction This would be on a par with the village mechanic who purchased working drawings of an aeroplane and set out to build a flying machine

A simple but very interesting experiment which may throw some light on the wonderful activity of hydrogen sodium amalgam and the value of electro lytic amalgamation is made by placing a piece of plastic sodium amalgam the size of a pea in a test tube and adding an ounce of water heavily saturated with ammonium chloride Test the amalgamating powers of the very curious resultant amalgam by copper and iron wire

Those who wish to investigate the records of the Patent Office for progress in electrolytic amalgama tion will find the various types of electric amalga mators described in the following United States patents

626 099	579 211	592 793	418 134	370 366
402 711	669 058	548 265	307 081	285 523
641 360	690 524	328 [illegible]	757 557	497 958

DESCRIPTION OF APPARATUS

An electrolytic amalgamating apparatus should be *so constructed that there is a constant and regular* electro-deposition of sodium (or some similar ele ment) in the mercury and provision must be made for passing auriferous pulp or sand over the mercurial surface so that every particle of gold is forced into intimate contact with the mercury With the auto matic deposition of sodium and suitable mercurial contact no free values can possibly escape and the ideal milling plant of the future will consist of some type of rotary crusher producing a 100 mesh product followed by a series of electrolytic amalgamators Such an arrangement will extract all values shown by any free gold test

The ideal electrolytic amalgamator consists of a series of electrolytic sodium mercury cells followed by another electrolytic amalgamating device in which the values are recovered on silver plated copper plates of suitable construction With the mercury wells high amperage may be employed liberating large vol umes of hydrogen which removes all coatings (oxides sulphides grease talc silicious coatings etc) from the microscopic gold particles In the secondary amal gamator the plates offer a large cathode area so that all portions of the pulp are forced into contact with a highly active mercury surface The supplementary amalgamating device above mentioned consists of a silvered copper plate of suitable width this plate con tains parallel transverse semi cylindrical depressions (grooves pockets or riffles) the full width of the plate into these grooves project cylindrical terra cotta cylinders having a quarter inch clearance from three to four inches in diameter these cylinders contain a graphite core one inch in diameter connected as an anode

The pulp passes under the cylinders and sweeps gently over the curved (cathode) amalgam plate while gravity the force of the water and centrifugal force tend to drag each gold particle into contact with the highly excited mercury surface With such a series of amalgamating riffles supplied with a low voltage current of proper density we have an amal gamating device of wonderful activity It is not too much to say that this simple device will extract 99 per cent of the values which may be saved by any sys tem of lixiviation the cost of extraction being insig nificant.

Fig 1 shows a section of a new type of mill plate which I have devised The sides are not represented The silver plated copper plate (being of the usual length of amalgamating plates) contains transverse parallel semi-cylindrical grooves into which fit solid cylindrical wooden baffles, these baffles may also be made of standard piping or casing, from three to four

inches in diameter with the ends closed The clearance between the plates and the baffles is from three sixteenth to one-quarter inch One piece of copper plate may be used with the proper depressions pressed therein or preferably a number of overlapping plates may be used each plate containing one or two semi cylindrical depressions The plates are held in position by their own weight fitting closely to the sides and can be quickly removed from the device for cleaning up The device may be given any desired grade and the plates are dressed and operated as the usual mill plate A mill plate arranged as described will make a better extraction on the average ore than the usual type of amalgam plate there being no loss of amalgam

In Fig 2 is illustrated an electrolytic mill plate constructed similarly to the one shown in Fig 2 which will not only recover all values saved by the standard types but in addition all free values in siliceous pulp and slimes all values in placer material beach sand and all black sand values are also recovered The cylindrical baffles are made of terra cotta and each contains a graphite core connected to the positive lead of a low voltage generator the amalgam plates are connected to the negative lead of the generator

In the first groove or riffle shown in Fig 3 the water and pulp passes over the amalgam plate as in Fig 2 in the second riffle of Fig 3 the amalgam plate connected to the negative lead forms a casing for the baffle and the pulp stream passes *under* the mercurial surface thus bringing the surface of the water into intimate contact with the electrically excited mercurial surface or a copper cylinder, silver plated may be used as a baffle and at the same time act as an amalgamating surface. A gold saving device may consist of a series of such riffles as shown in Fig 3 arranged alternately such an arrangement is particularly useful in treating pulp containing gold in a finely divided form or for recovering values in slimes or in solutions By screening placer material to 10 or 12 mesh and passing the under-size over an electrolytic amalgamating sluiceway of suitable length all fine rusty float coated and greasy gold is recovered

With the standard system of mill plate amalgamation many difficulties are encountered with the device just outlined all the usual amalgamation troubles disappear The plates may be dressed by hand in the usual manner once a day by adding a mercuric solution to the water the proper amount of mercury will be deposited electrolytically to keep the plates in excellent condition Electrolytic sodium amalgam containing gold is soft, yet tenacious, it is plastic and arrests every particle of passing gold, yet such amalgam never crumbles Such an apparatus will extract [illegible] gold from material having any kind of gangue, clayey, sulphurous, arsenious, etc, and there is no fouling [illegible] formation of sulphide coatings, no discoloration by tellurides arsenides, etc.

In certain classes of base ores it may be necessary as a preliminary measure to treat the pulp for 30 minutes by electrolytic pan amalgamation before passing the pulp over the electric sluice, and for ores containing gold in chemical combinations (sulpho-tellurides etc) a preliminary roasting may be required.

In the near future we may look for a greatly increased production of gold due to the application of electrochemical methods in mining and milling operations were electro-amalgamation and electro-cyanidation to-day in general use in other mills now in operation the gross output of gold would be increased [illegible] per cent The great increase in the future supply of gold however will come from vast low grade deposits and ledges which cannot now be economically mined A new field containing fabulous treasures awaits the command of the modern Aladdin—the electrochemical engineer

Proposed Applications of Electric Ship Propulsion

The Explanation of New Designs

By W L R Emmet

The writer has published a previous paper on the subject of electric ship propulsion and has in that and elsewhere given out a good deal of information concerning designs which have been prepared The purpose of this paper is to describe some of the newest designs of this kind which have been made and to explain some of their features more fully so that their merits may be intelligently considered by engineers who may be interested

The use of electric motors to propel ships may at first seem inappropriate since with such a method the power of steam must first be converted into mechanical work then into electricity and then again back into mechanical work All of these processes involve appreciable percentages of loss which seem to discourage the undertaking and it is only by the most careful scrutiny of all features that the relative desirability of such an undertaking can be ascertained Some of the important reasons for the adoption of electricity may however be suggested by the following comparative figures

	Revolutions per Minute	Weight Lbs per Horse-power	Rankine Efficiency
12 000 kw high speed turbine without generator	1800	8 5	1%
Group of Parsons marine turbines designed to give 28 000 horse power to four propeller shafts	320	12 0	
North Dakota turbines two each 12,000 horse power	300		50%

The large differences shown by these figures are incident to speed the ship turbine being very large extent of its application is still entirely problematical. In the case of electric propulsion no such uncertainty exists We have proved by application to other arts that certain results can be accomplished in a thoroughly reliable manner and the designs here discussed simply deal with cases comparable with the simplest and most direct uses of electric power on shore

The comparison of weights and efficiencies of turbines shown by the figures given above apply only to certain conditions and in other cases the comparison might be very different so that in such a problem every case must be considered on its merits and its merits cannot be judged until all features of design and operation are worked out in detail An idea of the requirements of ship propulsion may be given by the following rough statement of conditions

The power required varies approximately in proportion to the cube of the ship's speed The speed of revolution of shafts must be suited to the power delivered and the speed of the vessel if good efficiency is to be obtained There is much difference of opinion concerning the possible relations of propeller speed and efficiency The following figures gives an estimate of propulsive coefficients of a large battleship These figures are ascertained by comparison of several sources of information and should be considered only as a rough approximation.

In all vessels quick stopping and reversal is of great practical value and this quality is particularly valuable in warships The effectiveness of reversal is dependent both upon the area of propeller blades and upon the torque available for reversal of propellers so that the requirements of reversal afford an operate marine turbines at speeds below their best point of performance and consequently their efficiency falls off very rapidly with further diminutions of speed In an electrically propelled ship an excess speed condition can be adopted for the maximum revolutions so that the loss of efficiency with diminishing speeds is relatively less

Propulsive Coefficients

Revolutions per Minute	Two Propellers
100	0 56
150	0 539
200	0 507
250	0 485
300	0 470

One of the important advantages of electric propulsion as compared with other possible methods of speed reduction lies in the fact that arrangements can be made by which the ratio of the reduction is changeable so that the turbine may be run at its most effective speed under more than one condition of the vessel's operation The possibility of such a change in speed ratio is particularly valuable in connection with warships since such vessels need very high speed for emergency conditions and also need to operate economically at low speed so that their radius of action may be made as wide as possible with a minimum dependence upon coaling stations. It will be seen that these qualities cannot well be combined in a ship whose propellers are driven directly by turbines even if she is equipped with special turbines for cruising conditions The importance of high

SECTION AT FRAME 89 LOOKING AFT

Turbine electric propelling apparatus installed in engine-room of battleship with all auxiliaries specified for direct turbine installation

complicated and expensive and relatively inefficient, while the high speed machine is very simple in construction small and highly efficient. It is therefore primarily for the sake of speed reduction that we turn to electricity as a propelling force.

It has also been proposed to use mechanical gearing for the same purpose, and something has already been accomplished in that direction The use of gearing for such a purpose is, however still practically undeveloped and the requirements are such that the additional reason for desiring low propeller speed the area of low speed propellers being larger the tendency to slip is diminished In some turbine ships, a good deal has been sacrificed for the sake of quickness of reversal and the qualities of different ships in this respect are very different. It may be said that with fairly large and low speed propellers, a reversing torque equal to 60 per cent of full load running torque will bring a ship up to the best standards of quickness in reversing

Since practical propeller speeds are always much slower than desirable for turbines, the tendency is to speed being much greater in turbines of small capacity than in large, the cruising turbines which require only a small capacity cannot be made efficient.

In this paper some specific information is given concerning two cases of electric propulsion designs One of these relates to the apparatus covered by a proposition recently made to the government for propelling machinery for Battleship No. 35 The other applies to the machinery covered by propositions recently submitted to shipbuilders for propelling machinery to be used in one of the government colliers recently authorized by Congress. The first [illegible]

* Presented at the Pittsfield-Schenectady mid-year convention of the American Institute of the Electrical Engineers, Feb. 1911. Copyright 1911, by A. I. E. E.

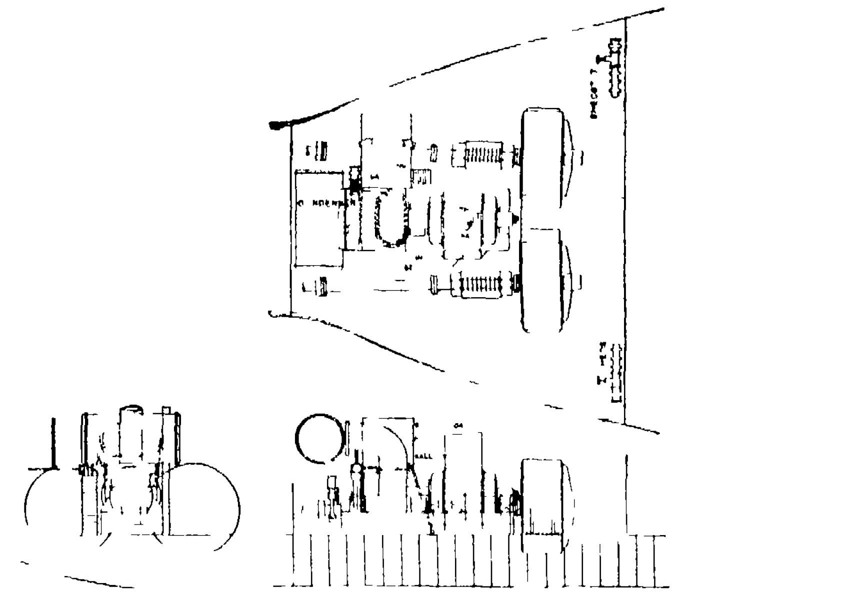
that of a high speed warship the arrangement has been made such that two ratios of speed reduction can be used, the change from one to the other being accomplished by changes of connection which accomplish a change in the number of poles of the propelling motor. In the second case no such pole changing is used, the ratio between turbine and propeller being fixed at all speeds.

In the battleship, two generating units and four motors are used so that an additional gain in economy can be effected at all speed by operating with one half of the apparatus in use. In the case of the collier there is only one generating unit and two motors so that all the apparatus is used at all speeds. In the case of the collier however the speed conditions are very favorable to the turbine and the speed efficiency curve is extremely flat as compared with that of turbines generally used for direct propulsion of ships.

DESIGN MADE FOR UNITED STATES BATTLESHIP NO. 35

The installation proposed for Battleship No. 35 is shown by the accompanying drawing which shows not only the electric generating and transmission apparatus but all the auxiliaries which are installed in the engine room in the government designs for direct turbine drive. The position of shafts and arrangement of engine room in this case is identically the same as that proposed by the government for direct drive by Curtis turbines. The apparatus is installed in two engine rooms separated by a water tight bulkhead. In each engine room would be installed one 12,000 kilowatt generating unit and two motors each having a capacity of about 7,000 horse-power. These two motors are coupled together into a single unit and connected to the propeller shaft. One of these motors is of the K type with squirrel-cage armature, the stator windings being so arranged that they can be connected either for 30 or for 50 poles, a suitable group of heavy toggle switches which effects this pole changing being carried by the frame of the motor itself. The other motor is of the M type with a definitely wound rotor connected to slip rings through which an external resistance can be inserted in series. These slip rings are short circuited by a very simple and effective sliding spring arrangement. When this short circuit is accomplished the external resistance is entirely cut out. This M motor is wound for 30 poles, and with its resistance cut out has exactly the same characteristics as the K motor when the latter is worked with its 30-pole connection.

The resistance used with the type M motor is for the purpose of affording the desired torque in reversing and these resistances constitute a very important feature of the proposed designs since under conditions of reversal they must absorb nearly the total electrical energy of the system. These resistances have been developed by careful experimenting and are capable of accomplishing the desired result in a very compact space and with very large factors of safety. They are made of non-corrosive material and the heat from the electrical energy dissipated is delivered to the sea water which freely circulates through the resistance compartments by convection. They are easily disconnected and taken apart, or if desirable renewed and will afford an entirely satisfactory solution of a problem which has sometimes been very embarrassing in large induction motor installations. The accompanying drawing shows the arrangement of these resistances in sufficient detail to be intelligible.



TURBINE ELECTRIC PROPELLING APPARATUS

Installed in engine room of Collier with [illegible] the steam auxiliaries shown

The switching apparatus is so arranged that all switches can be worked from either engine room, the shafts being carried through bushings in the water tight bulkhead. When the ship is operated at high speed with both generating units the engine rooms will be operated separately but when the ship is operated from one generating unit it will be more convenient to control everything from one engine room and the switches are so arranged that this can be done, the position of every connection being visible and controllable from either side of the bulkhead. The accompanying tabulation and curve sheet shows the propeller speed, horse-power and water rate of turbines for every different speed of the ship and shows the apparatus which would normally be in use under each condition of speed.

The conditions for different speeds are those which will give the best economy and which would ordinarily be used for continuous operation at such speeds but it is possible to vary the speed of the ship up and down with any arrangement of motors by simply changing the steam admission to the turbines, the only limit being the safe speed and safe carrying capacity of the apparatus. Normally the ship would be operated at higher speeds with two generators and four motors all of the motors having the 30-pole connection. The turbine speed is then reduced in the ratio of 7.5 to 1, the generators having four poles. When the speed becomes sufficiently reduced improvement of economy can be effected by disconnecting one

of the generators and two of the motors as shown by the curve and when the speed had fallen sufficiently low a still further gain can be accomplished by connecting the remaining motors for 50 poles instead of 30 poles When this change is made the ratio of reduction is increased from 7 to 1 to 12 5 to 1 and a new cycle of favorable speed operation in the turbine is begun The economy in speeds between 12 and 14 knots is of vital importance in war ships and the very fine economy under these conditions afforded by this design will immensely increase the military value of a vessel so equipped

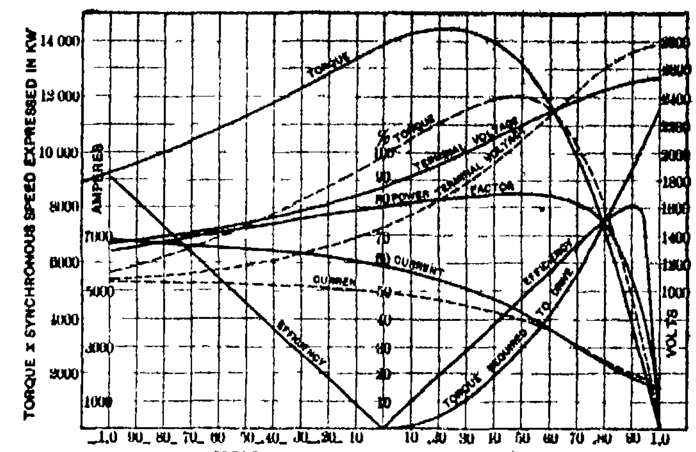
Lbs Steam per shaft h p per hour	13 2	13 4	11 8	11 3	11 25	1[illegible] 3

Since the power required to propel a ship falls rapidly with diminished speed and since it is not necessary to maintain any fixed frequency voltage or degree of excitation the magnetic densities of the apparatus can be varied as the speed reduces so as to give the best efficiency consistent with the torque required With such an equipment the excitation could be derived either from an outside source or partly from an outside source and partly from a direct-coupled exciter In this case it is proposed to excite from an outside source the ship's regular circuit but this excitation can be varied by a rheostat so that the best possible electric efficiency is maintained

In the installation here described it is proposed to ventilate the apparatus by air from the upper deck One duct will convey air to each piece of apparatus and another will discharge it outside the engine room the apparatus being so designed as to impel the proper amount of air through these ducts In this and other cases of electric ship propulsion it might be desirable to ventilate the apparatus by drawing air through it by blowers and delivering the air so heated to the furnaces Such a process would effect appreciable economy and would probably be desirable It has not been considered in this case because there was not time to study the practicability of arrangements

In this battleship installation it is not proposed to make any changes of connection of circuits resistances or poles while the current is flowing Preliminary to all such operations the field switch will be opened The switches proposed are of the toggle type not designed to open under load and are arranged with electric locks so that they cannot be moved when the system is alive The turbines are arranged with speed governors of the ordinary type which are capable of closing any valves which may be open if the speed rises The number of valves which can be opened at any time is however governed by hand control and the speed governor is in capable of adding to the number so opened When the field circuit is interrupted the generating unit rises to its maximum speed and runs idle until the circuit is re-established In the meantime the desired connections are made and the field re-established whereupon the generator and motors resume the proper speed relation and proceed to accomplish the desired result

When these electrical conditions are considered it would simply be necessary to open the field circuit and change to the proper connection and the currents resulting from such wrong connections would not be harmful since the mistake would be apparent and soon corrected The case is therefore very different



BATTLESHIP NO 35

Conditions of combined operation of motors and generators and reversing resistance in circuit and generators at full speed Dotted lines show torque voltage and current when only one generator is used The power factors and electrical efficiencies are about the same with either one or two generators External resistance 0 207 ohm per phase rotor resistance 0 0069 ohm per phase

from that of an ordinary electric circuit where all sorts of needs must be provided for from a source of fixed potential and where the generating plant constitutes a battery capable of delivering power in indefinite quantities either for use or for destruction in the case of short circuits or wrong connections

The following is a list of the weights of the different parts of the installation proposed The aggregate weight of these parts is probably not much less than that of the turbines alone which would be used for direct propulsion The generating units in this case however include heavy cast iron bases and there would be a considerable saving on account of the supporting structures which would be used with turbines for direct propulsion The absence of any system of forced ventilation also increases the weights In other cases of battleship propulsion which have been studied considerable savings of weight have been effected and it is believed that with the best arrangements similar economies could be accomplished in this case

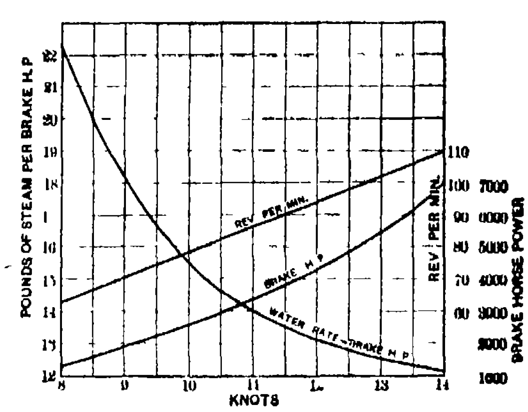
	Pounds
Two generating units	674 000
Accessories	2 600
Four motors	408 000
Switchboard and switches	5 000
Field rheostats	1 600
Water-cooled rheostats	6 000
Cables	17 800
Total weight	1 115 000

EQUIPMENT FOR NAVAL COLLIER

The installation proposed for a naval collier is similar in general principle but much simpler than that proposed for the battleship The requirements of this ship being to operate continuously for long periods at a speed near the maximum there is no particular need for high economy at lower speed and it therefore becomes desirable to simplify the apparatus as much as possible in the interest of lightness cheapness and good economy at the normal operating speed of the vessel which would be about 13 or 14 knots. In this case only one generating unit and two motors are used

Another difference between this case and that of the battleship is that it is proposed to use oil switches so that changes of connection can be made without the trouble of interrupting the field circuit. When the resistances are in circuit in the motors, [illegible] propeller could be reversed independently by [illegible] throwing the lever of an oil switch. This qualit[illegible] instantaneous reversal would be valuable in a shi[illegible] this kind since such large freighters steer very b[illegible] at low speeds so that it is very desirable to steer by the propellers in anchoring or docking

For this collier installation the method of ventilation proposed is somewhat different from that in the case of the battleship The generator would be ventilated in the same way by a duct from the deck above and another duct to take away the heated air In the case of the motors it is proposed to take the ventilating air from the engine room and deliver it to the suction of a blower which puts air into the Howden draft system of the after fire room This



PERFORMANCE CURVE ELECTRIC DRIVE UNITED STATES COLLIER

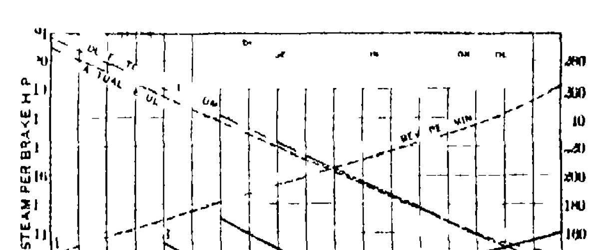
100 lb gage 0 deg fahr superheat 28½ in vacuum—displacement about 20 000 tons

would afford effective ventilation for the motors and about the right amount of ventilation in the engine room without the use of any other blowing apparatus

The accompanying curve sheet shows the steam consumption per shaft horse-power which would be required with this apparatus at different speeds of the vessel These results are susceptible of exact calculation since generating units and motors almost exactly similar to those proposed have been repeatedly tested It is very difficult to get at any accurate estimate of the steam consumption of such a ship when operated by reciprocating engines, but all comparisons which have been made indicate that the turbine electric apparatus would effect some economy in steam consumption although it is probable that the saving as compared with the best engine equipment would not be very large. The demand for electric propulsion on one of these colliers has come from the Navy Department through a desire to demonstrate the practicability of this method of propulsion The case is not particularly favorable to electric propulsion and should not be taken as a basis of comparison of the system with other methods Electric propulsion will make its best showing in vessels requiring a very large amount of power or vessels which require a good economy at low speeds as well as at high High-speed warships or very large moderate-speed liners afford the best fields for its application.

ELECTRIC CHARACTERISTICS

The accompanying curve sheets show the characteristics of the combined action of motors and generators proposed for these two installations. Two of these sheets show conditions of operation [illegible] with resistances in circuit and the other [illegible]

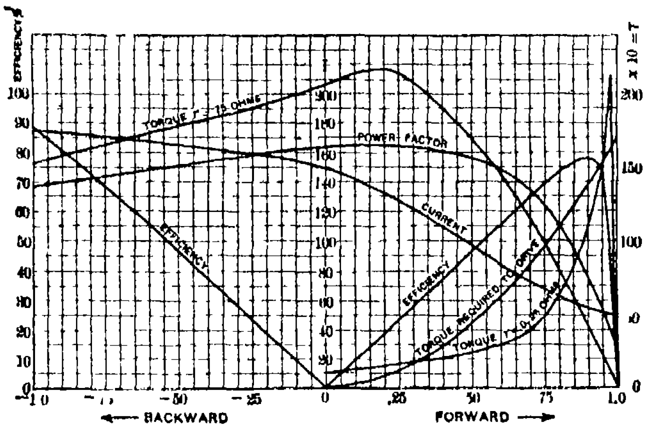


PERFORMANCE CURVE UNITED STATES BATTLESHIP NO 35

Pressure 20? lb gage [illegible]0 deg fahr superheat 28 in vacuum

will be seen that an immense advantage results from the fact that they are not bound to any fixed frequency or voltage The generator is designed simply to do the work required of it and it is incapable of delivering a current in excess of the safe carrying capacity of any conductor in the system No kind of wrong connections can result in any burn-out If a wrong connection should be made

conditions in the collier installation without resistance in the motor circuits and with the generator operated at various speeds. From these curves the torque available under any condition of operation and also the current, voltage and necessary excitation can be seen or readily estimated No curves are given to show the conditions of operation without resistance in the battleship installation because the character istics under such conditions are virtually the same as those in the collier and are sufficiently illustrated by the curves given in the case of the collier These curves shows the effect of different degrees of excita



UNITED STATES COLLIER

tion upon power factor and efficiency As a vessel so propelled is slowed down the excitation could be reduced in proportion to the propeller speed and the maximum degree of reduction in excitation will give the best electrical efficiency From the curves here given however the decline of excitation is less rapid than that of the speed this degree of diminution be ing chosen so as to give an ample margin of torque under all possible conditions of operation In prac tice whenever the ship is operated under any fixed condition of speed the excitation should be reduced to the lowest possible point necessary to maintain the required torque on the propeller Since the margin of torque assumed in the curves given is very ample the electric efficiencies would be even better than those indicated by the curves

In connection with this paper which gives specific information concerning two sets of designs the author has thought it desirable to give also some fig ures concerning other cases which have been studied with greater or less degrees of thoroughness in order that an idea may be formed regarding the relative desirability of such methods in connection with ships of different kinds The accompanying tabulation gives some such figures

Some of these designs for apparatus to propel ships have been criticised on the ground that the weights of electric apparatus shown were small in comparison with weights of similar kinds of apparatus used on shore This is to some extent true first because the structural part of these devices has been designed with a view to economy of weight although the designers have not gone nearly as far in this direc tion as it would be possible to do, and secondly be cause this ship apparatus is rated on a maximum output basis, whereas apparatus for other purposes provides for overload There have been some further weight economies possible on account of the special conditions relating to the operation of such ap paratus A careful comparison with a number of cases where large apparatus of similar character has been installed on shore shows that on a basis of very reasonable temperature rise, the magnetic weights in all cases agree closely and that these electrical de signs are in every respect normal and conservative

A Few Odd Things

It is said that in a room in Pompeii which was buried by Vesuvius' ashes eighteen hundred years ago, the excavators broke into a room full of glass of many kinds window glass ground glass cut glass and many varieties of colored glass and the Romans claim that they got malleable glass from the Arabians

Pliny tells of Nero having a ring with a gem in it through which he looked at the gladiators to see them more clearly Evidently old Nero had a monocular opera glass Ruskin in one of his lectures to his students said Gentlemen we are the best chemists in the world No Englishman ever could doubt that but we cannot make such a scarlet as that and even if we could it would not last for twenty years yet this is five hundred years old Such a dye could cer tainly be warranted against fading

Copper Production and Copper Reserves

In his economic studies of the world's supplies of the principal metals Prof J A Kemp devotes a sp cial section to copper Speaking of this in *Science* he says

Greatly stimulated by the development of elec tricity in later years the production of copper has advanced by leaps and bounds At present the United States are the heaviest producers with Spain follow ing next but only yielding one-eighth as much The United States furnish over half the total In 1850 th United States yielded 728 tons in 1900 over 303 000 and in 1908 471 000 Meantime in 1850 the price of copper was about 30 cents per pound Its lowest point in recent years was nine cents in 1894 Its highest 25 cents was attained in 1907 We may each of us imagine the variation in the profits of a mining enterprise as between 11 cents a pound and 15 cents let alone 20 or 25 cents Mining costs smelting and freight charges show no such variation so that with rising prices profits greatly increase Indeed few of the metals have such ups and downs as does copper

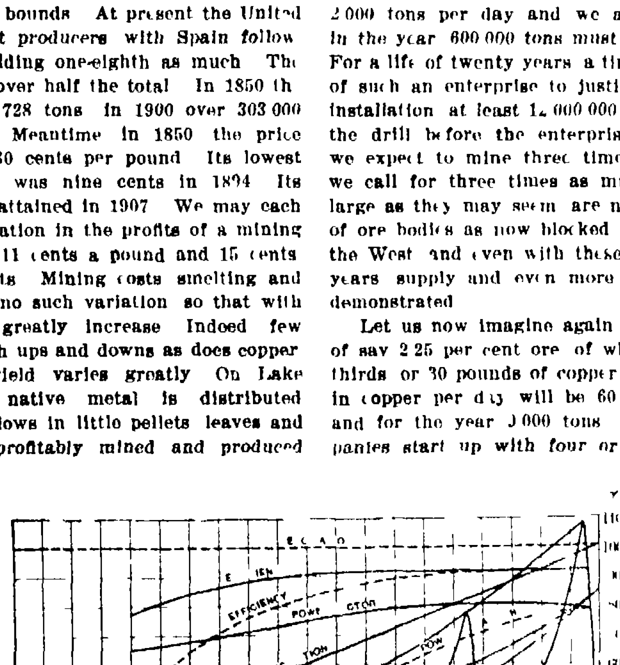
In its ores the yield varies greatly On Lake Superior where the native metal is distributed through ancient lava flows in little pellets leaves and sheets it has been profitably mined and produced through periods of years when it constituted but three-quarters of 1 per cent of the ore The general run is, however 1 per cent and above If we recall that in a ton of 2,000 pounds 1 per cent is 20 pounds and three-quarters of 1 per cent 15 pounds and if copper is selling at say 13 cents the mining manager must break down hoist concentrate with attendant losses, and smelt an ore worth less than $2 for all the metallic contents which it contains We can thus gain an idea of the close and economical work re quired and the ability demanded of a manager As the price rises the profits greatly increase, and tem porarily idle mines are brought within the widening remunerative zone and are quickened into life As the price falls the mines dangerously near the line close down and production ceases The lowest cost of production claimed is from the low grade and very large ore bodies of the West and is placed at or about 8 to 9 cents per pound laid down in New York

In copper ores outside of the Lake Superior region we usually find the metal in combination with sulphur The ores as they come from the mine may be rich enough to go directly to the smelter or they may require concentration before the grade is sufficiently high The ores which are directly smelted reach the minimum of copper in the boundary district of Brit ish Columbia but associated gold and silver raise the value per ton above $4 Copper ores yielding copper alone were smelted at Ducktown Tenn dur ing long campaigns at a little less than 2 5 per cent In earlier years and in many mining districts ores as high as 20 per cent were found rarely even higher but they in time were exhausted and 5 per cent would be quite rich for day in and day out averages

We can not predict copper with the certainty of iron It seldom appears in bedded deposits which can be measured In the deep mines we can not always see ahead for more than a year or two In some mines we know from exceptionally complete development of twenty years supply But the great advance in copper mining has been the entrance of relatively low grade ores into the productive field The wall rocks of ten years ago have become the ores of to-day Where we find in porphyries or schists copper sulphide disseminated in fine particles or as coatings along crevices and in sufficient richness to yield 2 to 2½ per cent throughout very large bodies it can be mined very cheaply and concentrated in enormous quantities so as to return a safe margin if the ore lies near the surface steam shovels make excavation extremely low in cost The huge pits and open cuts of this type of mine in the West are now among the great sights for the traveler Mills whose insatiable crushers take as much as eight or ten thousand tons per day are no longer unknown The drill blocks out the ore before mining begins and reserves can be estimated more closely than in the vein mines

If a mine is called upon to furnish a mill with 2 000 tons per day and we allow 300 working days in the year 600 000 tons must be supplied per annum For a life of twenty years a time practically demanded of such an enterprise to justify the great expense of installation at least 12 000 000 tons must be shown by the drill before the enterprise can safely begin If we expect to mine three times this amount per day we call for three times as much ore These figures large as they may seem are not beyond the estimates of ore bodies as now blocked out in several places in the West and even with these great demands twenty years supply and even more in instances have been demonstrated

Let us now imagine again a 2 000-ton daily output of say 2 25 per cent ore of which the mill saves two-thirds or 30 pounds of copper in the ton The output in copper per day will be 60 000 pounds or 30 tons and for the year 9 000 tons Should three new com panies start up with four or five times this output



UNITED STATES COLLIER

Showing condition of combination of generator and motors with varying speed of generating unit and with no external resistance in rotor circuit Dotted lines refer to constant full load excitation Full lines refer to variable excitation Torque curves for motor are given separately for different fixed generator speeds All other curves apply to normal condition where speeds of motors and generators vary together

16 000 to 4 000 tons will be added to a yearly supply which in 1909 was 5 2 168 tons We see great need of a growing demand in order that these vast con tributions may be absorbed

How long will our copper hold out? For the im mediate future there will certainly be no scarcity Copper does not oxidise as readily as iron and is not lost The world's stock steadily accumulates But twenty years is not a long look ahead Are there new countries which will be producers? Some old mines in Europe are no longer sources of the metal

"We do know of possibilities in Alaska that will

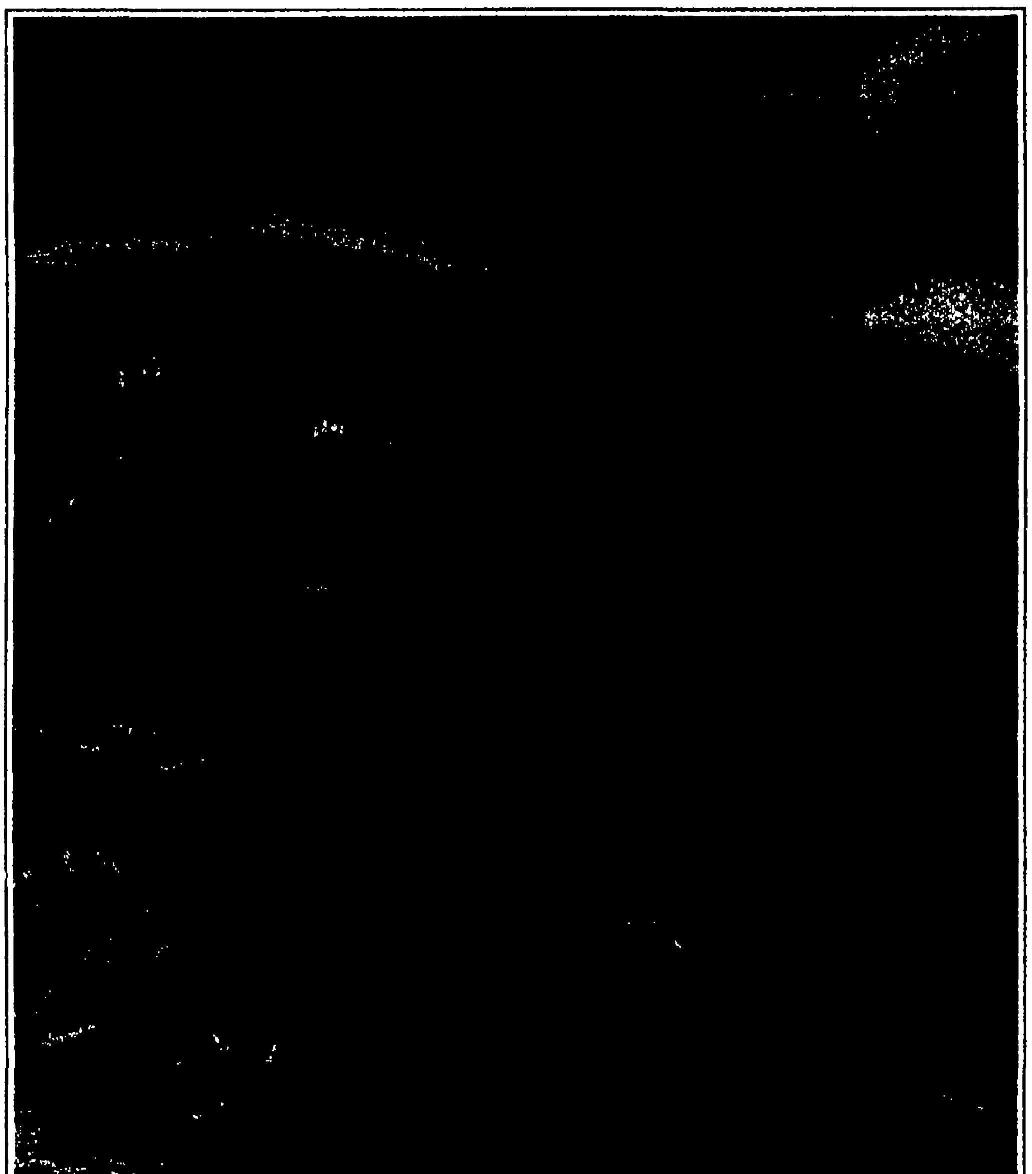
add some contributions We know of new or recently opened ore bodies in Peru Bolivia and Chile that promise well We hear of very large deposits in the southeastern corner of the Congo State once worked by the ancients now revived by the moderns, and possessing large reserves of 15 per cent copper ore The Cape to Cairo Railway will give them great impetus For the immediate future there is no lack, but if we look fifty years or a century ahead we can speak with less confidence. In a general way we may say that probably new discoveries will, for a time at least, more than keep pace with demands. But when we look fifty years into the future we are not so certain It behooves the producers to use no treatment of an ore except a careful and economical one. If tailings and waste from our mills now contain one-third the copper in the original ore, they should be impounded and kept from being washed away by floods, against the possible call of the future. We dare not say that they will never be within the range of profitable treatment, even though their low percentage places the copper beyond reach to-day The copper situation is not one to excite anxiety, yet it is also one not to encourage extravagance."

The New Rigid Dirigible of the English Navy "N I"

A Giant Airship of Novel Construction

By Carl Dienstbach

THE Zeppelin Airship Construction Company has always firmly refused to build any airships for foreign countries on the ground that its plant is virtually a gift and a trust of the German nation that contributed nearly $2 000 000 to Count Zeppelin's enterprise and that therefore none of the experiences and facilities of the Zeppelin dockyard should inure to the benefit of foreign governments



By Courtesy of the Illustrated London News.

THE BRITISH NAVAL AIRSHIP N I THE FIRST DIRIGIBLE BUILT FOR THE ENGLISH NAVY

In England the authorities have been so severely criticised for trifling with the serious question of an aerial navy and merely building a series of pygmy military dirigibles for experimenting and training purposes that the English people bought by subscription the two latest and best French airships the big Clement Bayard II and the new gigantic Lebaudy, and presented them to the government Patriotic and welcome though this action was it may be said to have been inspired by a popular misunderstanding of the government's policy For England the first necessity is a naval dirigible An airship that must be capable of hovering over the channel fleet's field of action and follow the home fleet far out into the North Sea had not yet been developed abroad nor could it be created over night Endurance staunchness, economy of fuel at high speed insensibility to weather and sun were the qualities most desired. The authorities were soon aware that the type perfected by Count Zeppelin and his engineers and pilots came nearest to meeting these requirements, but all endeavors to profit directly from the priceless experience and skill acquired by the Count and his staff during nearly a decade of painstaking labor met with a flat refusal Nothing remained but to make the experiment unaided and it must be conceded that the English have approached this task with a deliberateness and thoroughness worthy of its importance What it really meant may be gathered from the failure of the Schütte-Lanz giant rigid dirigible whose wooden frame cost hundreds of thousands and finally became far too heavy In England a colossal revolving arm or whirling table was erected at great expense for the sole purpose of testing the naval airship's propellers under the conditions that prevail in actual flight, and for developing the most economical type

The English N I as the new aerial dreadnought is called has just been completed after remaining on the stocks for nearly three years From the "Zeppelins so far built it differs in the displacement, which exceeds even the big Deutschland's by fully 1 000 cubic meters, being 20 000 instead of 19 000 The length is 510 feet instead of the "Deutschland's" 485½ and the beam 46 feet. Instead of aluminium the new lighter and stronger alloy, duralumin, has been used in the hull

A noteworthy innovation is found in the engine room. Reliability of the propelling machinery of airships was for a time sought in multiplying the motor units "Deutschland and Z VI had three motors, the new Krell I has four motors Most recently this tendency has undergone a temporary change. It is now the fashion to install more powerful units, engines that are to all intents and purposes identical with those of the 'big gasoliners of the ocean and like them are not much given to breaking down Thus the new German military airship M IV is driven by only two engines but each of 200 horse-power and the English N I built more for endurance than extreme speed over water has also two 200 horse-power motors for its greater displacement In the M IV" these motors have each six cylinders and are very heavy the engines of "N I have eight cylinders each and are built by the firm of Wolseley of heavy gasoline traction frame As Count Zeppelin's Deutschland developed a speed of nearly 38 miles an hour with three motors of 115 horse-power each the N I that has finer lines at the stern is expected to make 43 miles an hour with 55 horse-power more and only 1 000 cubic meters more displacement—which results solely from increase in length not of beam

In still larger airships there will be again multiplication of motor units—to distribute the load—but each motor being of 200 horse power sufficient reliability will also be guaranteed in the single unit The N I is equipped with powerful apparatus for wireless telegraphy

Copying Process for Printed Matter and Manuscripts

A NEW method for photographic printing was presented to the Académie des Sciences by M De Fontenay and it is likely to be of great service in some kinds of work It is used in reproducing any sort of printed matter or manuscript such as pages of books or engravings letters etc and these may be even printed or written on both sides He uses an ordinary printing frame and places in it first a sensitive photographic plate with the glass side outwards and then the printed page in contact with the emulsion This is exposed to light in order to make the print The black parts of the page absorb nearly all of the light and on the contrary the white portions diffuse the light and reflect it upon the corresponding parts of the sensitive layer After developing the plate we have a negative somewhat similar to that which would be given by making a print by transparence in the usual way The new method exposes the whole of the photographic plate and the printed page lies back of it so that the process would seem paradoxical at first, and it would appear that the plate should be fogged This is not so as is proved by its development Any ordinary developer will answer It is found that the exposure should be made by red light and green or yellow light also gives good results but blue and violet do not succeed Slow plates appear to be the best and even photographic paper could be used, were it not for the fact that the grain of the paper is apt to spoil the effect. The new method is likely to prove of value It will render great service where a copy is to be made strictly like the original with opaque sheets or those having printing on both sides, including book text, engravings, figures bound in a book, parts of maps, and the like. Such are generally copied by the camera, but this is often cumbersome and cannot be used in all libraries. It is also difficult to make a copy in full size, not considering the distortions given by the lens. At present we are able to make copies in any library where darkness can be obtained for a short time so as to allow of putting in the plate, and such copies are very exact. A printing frame is not indispensable, and the sheet can even be applied by the hand. All the outfit that is needed is a few plates and a box of matches, or better, a pocket electric lamp. The archaeologist or other worker when traveling and not having a camera at hand can thus very easily secure copies of valuable documents.

Demolishing a Reinforced Concrete Building

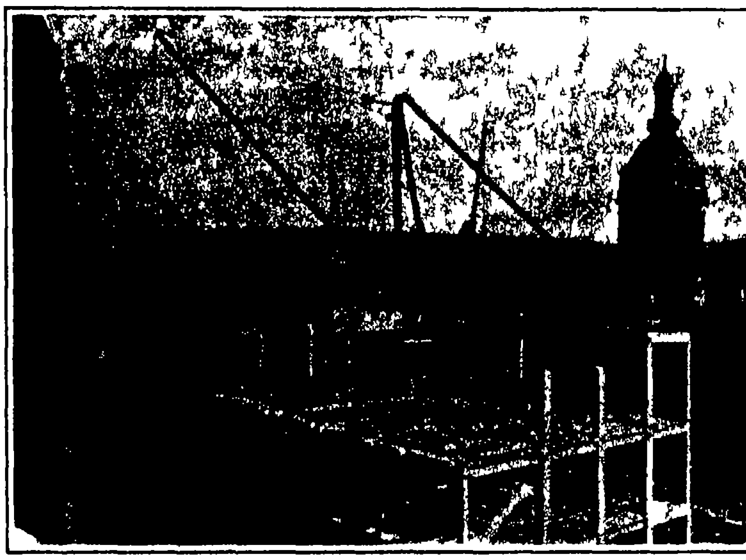
Steel Rods in Reinforced Concrete do Not Rust

The illustrations show a number of views of the operations in progress in the demolition of a seven story reinforced concrete building at Baltimore. This structure was erected shortly after the great fire of 1904 and is consequently comparatively new, and built on the modern lines of this type of construction. The massiveness of the building which was regarded as fireproof, is shown by the fact that some of the larger pillars and girders in the framework weigh no less than one ton to each linear foot. These are 3 feet in thickness and 5 feet in width and one of the main girders supporting the upper framework is no less than 49 feet long. It is reinforced with 42 steel rods extending entirely through the concrete. Twenty-six of these rods are 2 inches in diameter and sixteen 2½ in diameter. In some parts the thickness of the reinforcement is as much as 3 inches. The total weight of the concrete in the building is estimated at nearly 8000 tons not counting brick used in partitions and elsewhere. The floors are of a layer of concrete 2 inches thick set into a mesh of ¼ inch steel wire while the stairways are molded of concrete blocks.

This seven story building which has been utilized for newspaper publication is to be replaced by a sixteen story office building and every part even to the foundation must be removed. A contract has been concluded to demolish the building in 90 days. Work was commenced in March and is progressing so rapidly in spite of the great weight that must be removed and the difficulty of severing the heavy framework into sections for removal that during April fully 75 per cent of the building had been torn out and turned into concrete ballast for railways and into scrap steel.

The system employed is notable for its time and labor saving features. Beginning at the top the roof members had to be cut and burned into sections that could be readily lifted by a boom derrick and lowered by block and tackle to wagons in the street to be hauled away. As much of the concrete work averages 7 tons in weight for a length of 6 feet, the majority of the posts, girders and other material have been separated into this size. The first process is to cut through the concrete. This is done by compressed air hand drills operating at a pressure of 125 pounds to the square inch. The steel point bores into the material making an opening varying from 6 inches to a foot in width, so that very little debris results. The tool is guided between the steel rods removing all the concrete until they are completely exposed in the concrete fissure.

The steel is not cut by saw or chisel, but severed by corroding heat. A Linde compressed air coal gas burner is used. Portable reservoirs are filled with gas at a pressure of 1,[illegible] pounds. The burner is connected with tubes for conveying the gas, also oxygen. The flame composed of these elements develops a heat of fully 2 000 degrees. The burner is pressed against the rod until the latter becomes red hot. Then the oxygen is applied to the metal and corrodes it, so that it becomes honeycombed. As the flame is small in dimensions less than a half inch of the metal is removed in severing the rod. How rapidly the work is done appears from tests made on the Baltimore building which show that one man can with the burner do as much as eleven men with saw or chisel in the same time.



THE BOOM DERRICK USED FOR LOWERING THE MATERIALS TO THE WAGONS

In removing the concrete sections two boom derricks are used. The boom of one is 60 feet long and from it extends a block and tackle of a capacity to handle any weight which is to be conveyed. When a piece of girder or pillar is ready to be taken out the end of the boom is swung over it in the usual manner, and the load clamped by chains, when it swings out and down into the wagon. The pieces are taken to a dump yard near a railroad track where a skull cracker having a drop of 60 feet and a weight of 2 000 pounds crushes the concrete into fragments. It is then loaded on cars for ballasting and the steel is sent to the mill for rerolling.

Considering the operations performed in the work of demolishing the power plant is comparatively small. The compressed air is supplied by two compressors of 30 horse power each. The air is forced through iron piping laid in the building and tapped at several different points with wire-wound flexible hose. Thus the drills are operated for cutting the concrete. An equipment of 40 drills is installed but 25 have been found sufficient to do the work, the others being held in reserve in case of a tool breaking or becoming dull. The burners are connected with metal tanks which one man can carry from place to place, but the tubes connecting the tank with the burner are long enough to allow the operator to separate the metal of a half-dozen sections or more before moving the reservoirs. After the concrete has been cut out there is no time lost. As the air tool finishes its work the burner takes its place and such is the rapidity of the action that the largest concrete form may be severed in two places, lifted out by the derrick and lowered into the wagon in less than a half hour. The wrecking of the News Building means a loss of nearly $300 000, its cost for construction. The only salvage is the value of the concrete ballast and what the mill pays for the steel which is classified as scrap. The work is an illustration of how modern enterprise does not hesitate to sacrifice property where its increase in business requires greater facilities for operation.

The South Sea Swells

Every reader of books of travel will remember with what frequency in the old narratives of experiences in the South Seas reference is made to the heavy swells of the ocean which impressed the navigators with the idea of their remoteness from land.

The great size of the sea waves in high southern latitudes has been explained by the fact that south of the Cape of Good Hope and Cape Horn there is neither windward nor leeward shore and the prevailing wind in all longitudes is westerly. Thus when a west wind springs up it finds a long westerly swell the effect of a previous wind still running. The new born wind increases the steepness of this swell and so forms majestic storm waves which sometimes attain a length of twelve hundred feet from crest to crest. The average height attained by sea waves in feet is about half the velocity of the wind in miles per hour.

Research as a Financial Asset*

The Money Value of Pure Science

By Willis R Whitney

Director Research Laboratory General Electric Company Schenectady, N Y

It is only in our century that there could be much significance to such a title as Research as a Financial Asset This is an industrial century and whether we are proud of it or not we are an industrial people For some reasons it may be thought unfortunate that so large a proportion of man's energies should be devoted solely to the industries In some eras we find that there was a predominance of art over industry in others literature was predominant in still others war and conquest Once territorial discovery and acquisition predominated and now in our own times the principles of community interest have so greatly developed that we are accustomed to seeing many people who instead of directly producing their own necessities of life are more generally repeatedly producing some one little article which contributes in the lives of others This we recognize as a natural tendency to higher efficiency Our intricate and delicately balanced system of work is becoming continually more complex but is certainly still covered by the elemental laws of demand and of survival New discoveries in our day are largely mental instead of geographical and the old battles of conquest have become wars with ignorance They are struggles to overcome inefficiencies attempts to broaden the common mental horizon as our ancestors broadened their physical horizon Very few people realize the rapidity with which technical advances are being made Few realize how the way of this advance has itself advanced I might make this more clear by an illustration

Consider for a moment the increasing uses of chemical elements and compounds New combinations in alloys medicines dyes foods etc and new uses and new materials are being produced daily For a more simple comparison consider only the advances in technical uses of the metallic elements

Copper iron and five other metals were known and used at the time of Christ In the first 1800 or 1900 years of our era there were added to the list of metals in technical use (pure or alloyed) about eight more or a rate below three a century There has been so much industrial advance made within the past twenty or thirty years that fourteen new metals have been brought into commercial use within this period This is almost as many in our quarter century as in the total preceding age of the world Of course this rate as applied to metals apparently cannot continue but there is no reason to question the possibility of the general advance it indicates For centuries a single metal was made to serve for all uses which that metal could fill Then two metals divided the field each being used where it was preferred for any reason Alloys began to displace metals to a limited extent While the engineer still uses iron for his railroad iron for his buildings and iron for his tools these irons are different and have been specially developed for those uses The electrical engineer prefers copper for his conductor certain irons for the frames of apparatus other special irons and steels for the shafts the magnetic fields etc and the specialization to best meet specific wants is still under way I suppose that this kind of complex development is largely responsible for research laboratories

A research laboratory is a place where men are especially occupied with new problems presumably not too far in advance of technical application By this group devoting its entire attention to the difficulties of realizing already well defined necessities or of newly defining and realizing together the efficiency of these processes is increased Men specially trained for this very purpose are employed and they are usually just as unfitted for successfully manufacturing as those who efficiently reproduce are of discovering or inventing It is merely an extension of the principle of the maximum efficiency A man with his entire attention devoted for months or years at a time to the difficulties of a single problem should be better able to reach a solution than the man who can devote only irregular intervals to it He should then also be the better prepared for a second problem

A research laboratory is also a place equipped with apparatus especially designed for experimental work In a busy manufacturing plant if a foreman has an idea pointing toward an improvement of his product he frequently has great difficulty in finding the time the necessary idle apparatus the raw materials and the incentive to try it In the laboratory all of these are combined and there is added a system of co-operation of permanently recording results and an atmosphere of research

The mathematics of co-operation of men and tools is interesting in this connection Separated men trying their individual experiments contribute in proportion to their numbers and their work may be called mathematically additive The effect of a single piece of apparatus given to one man is also additive only but when a group of men are co-operating as distinct from merely operating their work rises with some higher power of the number than the first power It approaches the square for two men and the cube for three Two men co-operating with two different and special pieces of apparatus say a special furnace and a pyrometer or an hydraulic press and new chemical substances are more powerful than their arithmetical sum These facts doubtless assist as assets of a research laboratory

When a central organization such as a laboratory has access to all parts of a large manufacturing plant and is forced sooner or later to come into contact with the various processes and problems the various possibilities and appliances it can hardly fail to apply in some degree the above law of powers

As a possible means of illustrating the almost certain assistance which one part of a manufacturing plant may give another when they are connected by experimenting departments or research laboratories and how one thread of work starts another I will briefly review part of a single fairly connected line of work in our laboratory In 1901 the meter department wanted electrically conducting rods of a million ohms resistance These were to be one-quarter inch diameter by one inch length In connection with this work we had to become fairly familiar with published attempts at making any type of such high resistances. Some kind of porcelain body containing a very little conducting material seemed a fair starting formula after the resistance of almost all kinds of materials had been considered Our own porcelain department was of great help in showing us how to get a good start We learned how and what to mix to get a fair porcelain and we found that small quantities of carborundum or of graphite would give us the desired resistance about once in a hundred trials The rods could be made but the variation of their resistance when taken from the porcelain kiln and when they were made as nearly alike as we could make them was often so many thousand fold that something new had to be done to make a practical success A small electric furnace was then devised for baking the rods and this was so arranged that the rate of rise of temperature the maximum temperature reached and the duration of heat at any temperature were under control and were also recorded The desired result was obtained and this work was thus finished It gave us a certain stock of knowledge and assurance

At that time a very similar problem was bothering one of the engineering departments Lightning arrester rods part of the apparatus for protecting power lines from lightning were needed Their dimensions were $\frac{3}{4} \times 6$ inches and they needed to have a definite but in this case *low* resistance and could apparently not be baked in a porcelain kiln The necessary variations in such a kiln are so great that in practice many thousand rods were repeatedly fired and afterward tested to yield a few hundred of satisfactory product All the cost of making an entire batch would have to be charged against the few units which might be found satisfactory and in many cases there were none good in a thousand tested It was evident that regulation and control of temperature was necessary This was found to be impracticable in case any considerable number were to be fired at one time as the heated mass was so great that the rods near the walls of the retort received a very different heat treatment from those near the middle and were consequently electrically different. This was still the case even when electrically heated muffles were used This difficulty led to experiments along the line of a heated pipe through which the rods could be automatically passed Some time was spent in trying to make a practical furnace out of a length of ordinary iron pipe which was so arranged as to carry enough electric current to be heated to the proper baking temperature Troubles here with oxidation of the iron finally led to substitution of carbon pipes. This resulted in a carbon tube furnace, which is merely a collection of 6-foot carbon pipes embedded in coke powder to prevent combustion and held at the ends in water-cooled copper clamps, which introduce the electric current By control of this current the temperature could be kept constant at any point desired. When this was combined with a constant rate of mechanical feed of the air-dried rods of porcelain mixture a good product was obtained For the past seven years this furnace has turned out all the arrester rods the number produced the last year being over 100 000 units

In this work we were also forced to get into close touch with the electroplating department. The rods had to be copper plated at the ends to insure good electrical contact The simple plating was not enough This introduced other problems which I will pass over as I wish to follow the line of continuous experiment brought about in part at least, by a single investigation The electric furnace consisting of the carbon tube packed in coke was a good tool for other work and among other things we heated the carbon filaments for incandescent lamps in it We were actuated by a theory that the high temperature thus obtainable would benefit the filament by removal of ash ingredients which we knew the ordinary firing methods left there While these were removed, the results did not prove the correctness of the theory but rather the usefulness of trying experiments It was found by experiment that the graphite coat on the ordinary lamp filament was so completely changed as to permit of a hundred per cent increase in the lamp life or of a twenty per cent increase in the efficiency of the lamp for the same life so that for the past four or five years a large part of the carbon lamps made in this country have been of this improved type This is the metallised or Gem lamp Naturally this work started a great deal of other work along the lines of incandescent lamp improvement At no time has such work been stopped but in addition to it, the new lines of metallic filament lamps were taken up In fact, during the past five or six years a very large proportion of our entire work has been done along the line of metallic tungsten incandescent lamps In this way we have been able to keep in the van of this line of manufacture The carbon tube furnace has been elaborated for other purposes so as to cover the action under high pressures and *in vacuo* Particularly in the latter case a great deal of experimental work has been carried out contributing to work such as that connected with rare metals In such a furnace materials which react with gases have been studied to advantage. Our experience with the metallised graphite led to production of a special carbon for contact surfaces in railway signal devices where ordinary carbon was inferior and suggested the possibility of our contributing to improvements in carbon motor generator brushes On the basis of our previous experience and by using the usual factory methods, we became acquainted with the difficulties in producing carbon and graphite motor brushes with the reliability and regularity demanded by the motor art.

Furnace firing was a prime difficulty Here again we resorted to special electrically heated muffles, where the temperatures even below redness could be carefully controlled and automatically recorded. This care aided by much experimentation along the line of composition of proportionality between the several kinds of carbon in the brush etc put us into shape to make really superior brushes. The company has now been manufacturing these for a couple of years, with especial reference to particularly severe requirements such as railway motors In such cases the question of selling price is so secondary that we can and do charge liberally for delicacy and care of operation in the manufacture

This carbon work naturally led to other applications of the identical processes or materials Circuit breakers, for example, are now equipped with a specially hard carbon contact, made somewhat as motor brushes are made

It is not my intention to connect all of the laboratory work to the thread which seemed to connect these particular pieces of work, but rather to show the possible effect in accumulating in a laboratory experiences which should show on an inventory.

Among other considerations which appeal to me is one which may be worth pointing out. Probably almost every manufacturing plant develops among its workmen from time to time [illegible]

---

*Presented before the [illegible] of Technology on the Fiftieth Anniversary of the Granting of the Charter of the Massachusetts Institute of Technology

[illegible] They are usually the inventors of the company They are often discovered in spite of opposition They are always trying new things. They are almost of necessity somewhat inefficient in the routine production. In many plants they are merely endured, in a few they are encouraged In my mind their proper utilization is a safe investment. A research laboratory assists in such a scheme Sooner or later such a laboratory becomes acquainted with this type of men in a plant and helps them in the development of their ideas.

It is not a perfectly simple matter to measure the value of a research laboratory at any one time In the minds of some, the proper estimate is based on the money already earned through its work which otherwise would not have been earned by the company This is a fair and conservative method which in our corporation ought to be satisfactory when applied not too early to the laboratories. It does not take into account what we may call the good will and inventory value, both of which should be more rapidly augmenting than any other part of a plant The experience and knowledge accumulated in a general research laboratory is a positive quantity In our own case we expended in the first year not far from $10 000 and had little more than expectations to show for it Our expenses rapidly rose and our tangible assets began to accrue Perhaps I can point to no better criterion of the value of a research laboratory to our company than the fact that its force was rapidly increased by a company which cannot be particularly interested in purely academic work Our annual expenditures passed the $100 000 mark several years ago My own estimate of the value would probably be greater than that of others for I am firmly convinced that proper scientific research is demanded by the existing conditions of our technical age

Without going into exact values which are always difficult to determine consider for a moment the changes which incandescent lighting has witnessed in the past ten years In this field our laboratory has been active in contributing to both carbon and to metallic filaments Moreover all of the improvements in this field have been the product of research laboratories of trained men In the case of our metallized carbon filament which has now been in use several years, the efficiency of the light was increased by about twenty per cent Among the carbon lamps of last year these were sold to the extent of over a million dollars

A broader but perhaps less accurate impression of changes recently produced may be gained by considering the economy now possible on the basis of our present incandescent lamp purchases in this country and that which would have resulted if the lamps of only ten years ago were used in their stead On the assumption that the present rate of lamp consumption is equivalent to about 80 000 000 25 watt tungsten lamps per year and on the basis of one and a quarter watts per candle power as against 3 1 of the earlier lamps and charging power at 10 cents per kilo watt hour we get as a result a saving of $240 000 000 per year or two-thirds million per day Naturally this is a saving which is to be distributed among producers, consumers and others but illustrates very well the possibilities It is interesting to note that we are still very far removed from a perfect incandescent illuminant when considered from the point of view of maximum theoretical light efficiency

I see from advertisements that 65 000 of the magnetite arc lamps originally a product of the laboratory are now in use These must have been sold for something near $2 000 000 The supplying of electrodes which we make and which are consumed in these lamps should amount to about $60 000 per year

Our study of the properties of the mercury arc produced our rectifier which has been commercially developed within the past few years Of these about 6 000 have been sold As they sell for not far from $200 per set it is safe to say that this also represents a sale of over a million dollars The advantage of these outfits over other available apparatus must also be recognized as not far from $200 for each hour through which those already sold are all operating

In such a complex field as insulations and molded materials there have been many changes produced As far back as 1906 we were using annually in a certain apparatus 20 000 specially drilled and machined soapstone plates which cost $1 10 each As the result of experiments on substitutes for such material it was found that they could be molded by us in the proper shape, with holes in place and of a material giving increased toughness at a greatly reduced cost As the result of this fact the price of the purchased material was reduced to us from $1 10 to 60 cents which in itself would have paid for the work But further developments proved that the new molded material could be made for 30 cents, which the foreign material could not equal, so we have since produced it ourselves. This caused a saving of approximately [illegible] annually for this one molded piece I have heard of other cases where prices to us have gone down, when we have obtained a little promise from our experimental researches

In considering the research laboratory as a financial asset there is another view which might not be visible at first sight. It is the question of the difference between the value of the useful discovery when purchased from competitors in the business and when made by one's own company It is not usually pleasant to have to purchase inventions after their value is known, no matter from whom but to have to pay a competitor for such a discovery is doubly irksome. One is naturally unduly fearful of its value to the competitor and he in turn is overestimating another's power to use it. The purchaser's profit is apparently limited to the differences between his efficiency of operating it and that of the original owner A business usually comprises processes of making and selling something at a profit and study of the making of the most modern most improved most efficient is about as essential as the study of the limits of safe business credits

I was recently informed by an officer of another large manufacturing company where much chemical work is done and which established a research laboratory several years ago that the most important value they got from their laboratory was the assurance that they were keeping ahead and are at least prepared for the new if they cannot always invent it themselves Incidentally he said that from one part of their research work they had produced processes etc which had saved $800 000 a year They are at present spending in their several research departments a total of about $300 000 a year

We hear frequent reference to the German research laboratories and a brief discussion may be in place For the past fifty years that country has been advancing industrially beyond other countries Not by newly opened territories new railroads new farm lands new water power sites but by new technical discoveries In fact this advance may be said to be largely traceable to their apparent over production of research men by well fitted universities and technical schools Every year a few hundred new doctors of science and philosophy were thrown on the market Most of them had been well trained to think and to experiment to work hard and to expect little The chemical manufactories began to be filled with this product and it overflowed into every other calling in Germany These well educated young men became the teachers the assistants and the professors of all the schools of the country They worked for $300 to $500 per year They were satisfied so long as they could experiment and study the laws of nature because of the interest in these laws instilled into them by splendid teachers This condition soon began to make itself manifest in the new making of things—all sorts of chemical compounds all kinds of physical and electrical devices I might say that pure organic chemistry at this time was academically most interesting Its laws were entrancing to the enthusiastic chemist and consequently very many more doctors were turned out who wrote organic theses than any other kind What more natural than that organic chemistry should have been the first to feel the stimulus? Hundreds and even thousands of new commercial organic products are to be credited to these men and to that time All the modern dye stuffs are in this class Did Germany alone possess the raw material for this line? No England and America had as much of that But Germany had the prepared men and made the start

It seems to me that America had made a start in preparing men for the research work of its industries For example it is no longer necessary to go abroad to get the particular training in physical chemistry and electro-chemistry which a few years ago was considered desirable Advanced teaching of science is little if any more advanced in Germany to-day than it is in this country In my opinion the quality of our research laboratories will improve as the supply of home trained men increases and that the laboratories of this kind will be increasingly valuable when analyzed as financial assets I am certain too that the industries will not be slow in recognizing the growing value of such assets They merely want to be shown

Probably in most industries there are what I may call spots particularly vulnerable to research For example, the efficiency of steam boilers based upon the heat energy of the coal used and the efficiency of the engine using the steam is continually being raised We may expect until the maximum calculable efficiency is reached that this advance will continue The reason is not far to seek It is a vulnerable spot Improvement is possible A small increase in efficiency of a power plant is an ever-continuing profit Great numbers of steam power plants exist and so inventors are influenced by the fact that new improvements may result in enormous total economies Every rule of the game encourages them I can make this clearer by illustrations

Artificial light is still produced at frightfully poor efficiency Electric light from incandescent lamps has been greatly improved in this respect, but there is still room for greater economies It is still a vulnerable spot.

In the case of iron used in transformers we have another such vulnerable spot A transformer is practically a mass of sheet iron wound about with copper wire The current must be carried around the iron a certain number of times and the copper is chosen because it does the work most economically No more suitable material than copper seems immediately probable nor is there any very promising way of increasing its efficiency but in the iron about which it is wound there is a vulnerable spot The size of the iron about which the copper is wound may possibly be still much further reducible by improvements in its quality In other words we do not yet know what determines the magnetic permeability or the hysteresis of the iron and yet we do know that it has been greatly improved in the past few years and that it can still be greatly improved

Let us make this vulnerable point a little clearer by considering the conditions here in Boston I assume there are approximately 50 000 kilowatts of alternating current energy used here Nearly all of this is subject to the losses of transformers If the transformers used with this system were made more than ten years ago they probably involve a total loss due to eddy and hysteresis of about $1 000 per day at the ten-cent rate Transformers as they are made to-day by using improved iron are saving nearly half of this loss but there still remains over $500 loss per day to serve as a subject for interesting research work

It should also be noted that Boston uses only a very small fraction of the alternating current energy of this country

Consider for a moment two references to the sciences and industries in Germany and England Dr O N Witt professor in the Berlin Royal Technical High School reporting to the German government in 1903 says What appears to me to be of far greater importance to the German chemical industry than its predominant appearance at the Columbian World's Fair is the fact which finds expression in the German exhibits alone that industry and science stand on the footing of mutual deepest appreciation one ever influencing the other etc As against this Prof H F Armstrong of entirely corresponding prominence and position in England says of England Our policy is the precise reverse of that followed in Germany Our manufacturers generally do not know what the word research means They place their business under the control of practical men—who as a rule actually resent the introduction into the work of the scientifically trained assistants If the English nation is to do even its fair share of the work of the world in the future its attitude must be entirely changed It must realize that steam and electricity have brought about a complete revolution that the application of scientific principles and methods is becoming so universal elsewhere that all here who wish to succeed must adopt them

So long as motors burn out so long as subways are tied up by defective apparatus so long as electric motors can run too hot so long as street cars can catch fire from so-called explosions of the current so long as the traffic of a whole city can be stopped by a defective insulation or a ten-cent motor brush there will probably be the equivalent of research laboratories somewhere connected with the electrical industries where attempts will be continually made to improve

Electrical Effects Accompanying the Fermentative Activity of Yeast

Prof. M C Potter at the recent soirée of the Royal Society exhibited an apparatus consisting of a glass jar containing a porous cylinder and into each of these are introduced solutions of glucose of equal concentration Two platinum electrodes are placed one in the jar and one in the porous cylinder and on the introduction of yeast into one of the solutions the whole constitutes a type of galvanic cell The leads from the electrodes are connected with a condenser and the condenser is discharged through a galvanometer by means of a Morse key By this method the E M F developed through the action of the yeast may be registered and compared with that derived from a standard cell

Perpetual Stamp Pads (Deiterich's)

Thirty-five parts of Japanese gelatine Tjen Tjan are boiled until dissolved with 3 000 parts of water passed boiling hot through flannel rinsed with 600 parts of glycerine and concentrated by evaporation to 1 000 parts One hundred parts of this mixture mixed with 6 parts of methyl violet 3B or 8 parts of eosine BBN or 8 parts of phenyline blue 2F or 5 parts of anilyne green D or 10 parts of nigrosine supplies the correspondingly colored stamp pad which is poured into a shallow tin box and covered with thin muslin (mull) If the surface becomes too dry it may be moistened with water or glycerine.

Diesel Marine Engines—III*

A Resume of Recent Performances

By Herr Th Saeuberlich of Osterholz-Scharmbach

Concluded from Supplement No 1847, page 334

The introduction of the crude oil motor especially the Diesel motor may be regarded as of epoch making significance in the fishing industry In other countries notably in Holland and Denmark there are already many small vessels working with motors but Germany has only a small number to show Generally speaking the fishing trade in Germany in recent years can only be described as bad and in face of this fact the introduction of the Diesel motor to-day must appear especially full of promise for it gives a new perspective to the herring fishery and it is to be hoped will have great influence in bringing about the fulfillment of the dream that Germany's requirements in the way of herrings may be met by Germany's own fisheries At present only a fraction of her needs is covered by her own production

The motor lugger Ewersand now to be described returned at the end of October from a five weeks fishing cruise on which she had been sent for trial purposes by the Frericks Company in conjunction with the Bricker Herring Fishery and not more than three tons of crude oil was used while steam luggers on the same work used twenty tons of coal The fuel consumption of three tons of oil can be still further reduced since on this cruise especially bad weather prevailed and by carelessness of the crew a portion of the oil was lost.

It was thought advisable to provide for a small auxiliary plant exactly similar to that usually employed on sailing luggers for hauling in the nets It would have been an easy matter to haul in by the motor but it was not considered advisable at first to have the safety of the net entirely dependent on the motor The motor has proved itself reliable in the worst weather and on the last return voyage from the fishing ground ran for about seventy-five hours in a high sea without interruption

The fuel is stored in a fixed tank in the engine room and takes comparatively little room in a position forward which has not been occupied previously

A further advantage gained from the employment of crude oil is that the cleansing of the herring casks in which generally speaking a part of the coal is stored is obviated

Trials have shown that in every respect crude oil can be relied upon for work at sea and that in consequence of the small space required and the low fuel consumption there can be no doubt that it will replace steam engines for herring fishing boats

In the construction of the motor equipment of the herring lugger now to be described it has again been kept in mind that everything should be as simple as possible Above all it was of importance because in uncustomary work this constitutes the chief difficulty that in bad weather extensive overhauling and repair should be rendered wholly unnecessary

The construction of the lugger motor is for the most part the same as that of the service boat engine already described A high-speed two-cylinder motor developing 80 to 90 effective horse power with 330 revolutions is used reversing being effected by a friction coupling and gearing From the constructional point of view special attention may be directed to the pedestals and the separate cylinders—see Figs 20 to 22 The peculiarity of the construction consists in the fact that the front column can be removed without taking the engine apart and therefore it is possible if required to take out the crank shaft from the front without much trouble Having regard to the limited space in craft of this sort it becomes an absolute necessity that every part should be readily accessible

With the reversing drive—Fig 23—it is possible to carry out three different evolutions the fly-wheel revolving constantly in one direction

(1) Friction coupling and brake blocks disengaged The propeller shaft remains stationary The small pair of wheels driven by the wheel keyed to the crank shaft on the large wheel on the propeller shaft, the casing and the friction coupling revolving in the same direction as the fly wheel but at half its speed In this state the engine runs light

(2) Ahead gear friction coupling and brake engaged The fly wheel brake ring and coupling form a rigid system with the wheel casing The direction of rotation and number of revolutions of the propeller shaft are the same as that of the crank shaft

(3) Astern gear coupling thrown out of gear brake blocks thrown into gear In this case the wheel casing is held fast and with it the arm B The wheels again revolve separately and the propeller shaft now revolves in a contrary direction to the crank shaft.

Reversing gears and reversing screws make exceedingly simple engine construction possible especially the employment of a small number of cylinders, and on this account are to be specially recommended for the rough work of the fishing industry

Comparisons—It may now be not uninteresting to draw a few comparisons between motor and steam ships but it stands to reason that in so doing only the most important points can be noticed and it would not be fair to generalize from these comparisons Such comparisons are influenced to a high degree by the size and especially by the kind of vessel and the purpose for which she is employed Moreover the efficiency of the screw has to be left out of account It is therefore only possible to show in broad lines the advantages of the Diesel engine for marine propulsion

If the service boat above described had been fitted up for steam an engine of only 100 indicated horse-power could have been employed and it would have given the vessel a speed lower by about 1½ knots and a towing power of no more than 1 320 kilos. Besides only a short cabin could have been accommodated In Table II are given the relative dimensions of three vessels for comparison

I —Motor service boat

Ia —Steam service boat of same dimensions and displacement as the motor service boat

* Abstract translation by *The Engineer* (London) from a paper read before the Schiffbautechnischen Gesellschaft and published in the *Journal* of the Society by Julius Springer Berlin.

III Steam service boat of the same towing power as the motor service boat.

The comparison between a steam trawler and a motor propelled trawler is even more favorable to the latter

A motor lugger of exactly the same body plan and of the same dimensions as a steam lugger is in consequence of the smaller space occupied by the engine and its lighter weight, in a position to take at least 160 more casks of herrings below decks than the steam lugger and can also carry at least 80 more nets Taking the value of the herrings at 30s per ton the Diesel boat is able to earn about £1 125 more per year

To this must be added a very notable economy in fuel

For the purpose of comparison particulars of three vessels are given in Table IV The first is a motor fishing vessel of the small type the second a steam vessel of the same dimensions and the third a steam boat of larger size

In conclusion two cargo ships of about 5 400 tons burden—one driven by oil the other by steam—are taken for comparison the former being under the disadvantage that it carries its own fuel for the return voyage while the latter does not.

The concluding pages of Herr Saeuberlich s paper are occupied with a discussion of the sources of Diesel oil throughout the world its cost and the ports at which supplies are purchasable Its price free on board at Hamburg is given as between M 45 and 50

Experiments with the Blind

IT is a well known fact that blind persons can perceive obstacles near them when walking either in front of them or at the side, or when standing still they perceive the approach of objects even when these objects approach very slowly and without noise This perception remains even when the person and the object are both quite at rest. Some claim that blind persons have a sixth sense called sense of obstacles or by various other names. Many opinions have been given by scientists as to the cause of the sensation and it is claimed that it is due to air pressure heat an unknown emanation or else to hearing. M Truschel inclines to the last claim, after making experiments at the Blind Institution of Paris in the presence of Dr Marage a prominent authority and other persons First the blind man is seated and the author holds out a large sheet of carboard hung from a cane bringing it near the person very slowly some times in front and at others from the top downward or making other movements Five blind persons one of them a professor were chosen First the subject has the head bare He perceives the object well on the two sides less so in front and never behind him Second he stops the ears as well as the nose with the fingers Here he never perceives the object before it touches him Third using 1½ inch rubber tubes put in the ears the effect is much less Fourth when his head is enveloped in stiff paper the distance at which he notices the effect is lessened When a wool hood is used the effect becomes better and the same is found for cloth of different thicknesses and colors However surrounding the head by a cardboard cylinder cuts off the effect entirely as the cardboard replaces the distant object and he perceives it alone When the floor is covered by carpet or the ground snow covered there is scarcely any effect given and when there is no noise in the room the person no longer feels the approaching object. On the contrary he feels it strongly when there are vehicles or tramways passing in the neighborhood or else there is the noise of a fountain a brisk fire or the like. It thus appears that sound plays the most prominent part in this supposed sixth sense It is recognized that blind persons can sometimes make use of other sensations such as air movement heat odors etc but these are always felt as such

TABLE V —*Cargo Vessels*

Type of ship	Motor	Steam
Dimensions, length m	108	108
beam m.	14 6	14 6
depth, m.	9 6	9 6
draught m.	6 55	6 57
coefficient of displacement	0 78	0 78

ENGINE AND REVERSING CLUTCH OF THE SWERSAND

Recent Advances and Problems in Chemistry

Inaugural Lecture Before the Kaiser Wilhelm Society

By Prof. Emil Fischer

This lecture was delivered by Prof Emil Fischer of the University of Berlin on the occasion of the inauguration of the Kaiser Wilhelm Society for the Advancement of Science on January 11th in the Ministry of Education at Berlin and is here reprinted from *Nature*

Prof Fischer traces the relations between science and scientific industries in Germany pointing out that by affording facilities for the prosecution of pure scientific research technical industry can only gain

At the present time more than at any other period we are inclined critically to examine the fundamental principles of all branches of knowledge and when necessary to introduce far reaching alterations in our original conclusions This state of mind applies also to the natural sciences During the last decades our actual knowledge has been extended to an extraordinary degree owing to new methods of research and in view of the more recent observations the older theories have proved in many cases to be far too narrow Even the fundamental principles of our knowledge appears to a certain extent to demand revision

Thus the progress in physical science forces us to adopt views which are incompatible with the older principles of mechanics in spite of the fact that these were regarded as unassailable by thinkers such as Hermann von Helmholtz Heinrich Hertz and Lord Kelvin

We stand in the same position with respect to the elements in chemistry Owing to the discovery of radium and similar bodies we have been forced to the conclusion that chemical elements are not unalterable and hence that their atoms are not indivisible

The same state of affairs obtains to even a greater degree in the biological sciences In comparative anatomy animal and vegetable physiology theory of evolution microbiology and almost all branches of medical science the rapid advance of experimental knowledge is accompanied by an equally rapid change in established theories Even the semi historical sciences such as geology palæontology anthropology and the venerable science of astronomy are taking active part in the general progress

Thus in these times of general scientific activity is founded the Kaiser Wilhelm Society for the Advancement of Science the primary object of which is the erection and maintenance of institutions of research

It need scarcely be said that we scientific investigators welcome this new and highly specialized creation with intense satisfaction and I regard it as a particular honor to be permitted to be the first to give expression of our profound gratitude

No one will be able to assert that experimental research in Germany has been neglected exactly the opposite conclusions must be drawn on contemplating the history of science during the nineteenth century This displays a long series of brilliant scientific discoveries made in this country The industries closely connected with science such as the chemical and electrotechnical industries fine mechanical engineering production of metals industries connected with fermentation and last but not least agriculture have also undergone in our hands a development envied on almost all sides by other nations

Should a criterion of the results of experimental research be desired this may perhaps be found in the distribution of the Nobel prizes which are awarded by absolutely independent corporations in Sweden

Only a month ago the Nobel prize for chemistry came for the sixth time to Germany this constitutes 60 per cent of all the Nobel prizes hitherto awarded for chemistry During the same period of time two and a half prizes were awarded to Germans for physics and three and a half for medicine Dr Alfred Nobel unfortunately did not provide for the remaining natural sciences

The majority of the investigations distinguished by the award of these prizes however belong to the nineteenth century Since that time matters are to some extent altered It is well known that the greater number of German scientific investigators are teachers at universities or polytechnics During the last ten years a scheme of practical education of the masses has developed which affords to all students the possibility of acquiring a thorough training in experimental science and which provides our industries with an army of scientifically educated workers. But this very education of the masses tends mentally to exhaust the teacher to a great extent certainly to a higher degree than is desirable or indeed compatible with the creative power of the investigator

There prevails in modern educational laboratories a condition of overstrained activity comparable with that existing in all but the smallest factories and commercial offices and in the harassing cares of the day the teacher loses far too readily that peace of mind and broad view of scientific matters necessary for attacking the larger problems of research This danger has been most keenly appreciated by teachers of chemistry to which body I myself belong It is therefore no mere accident that in our circles of recent years the cry for new laboratories should be at its loudest an appeal for laboratories which should permit of research in absolute tranquillity unencumbered by the duties of teaching

In place of the one State-supported chemical institute which we had planned chemists may now anticipate the immediate possession of two such institutes in which gifted men may conduct their original researches with ample means in freedom from any other duties It is anticipated that the younger generation of chemists will thereby derive special benefit By the younger generation I mean in particular those men who are at present acting as assistants or lecturers in university laboratories and who can carry on research in addition to the servile labor of teaching only by possession of an extraordinary capacity for work

That which applies to chemistry may *mutatis mutandis* be applied to the other sciences and is especially applicable to new branches of knowledge for the prosecution of which the laborious organization of educational laboratories leaves no possibility

The handicap under which we work in comparison with other nations in particular the United States of America in which similar institutes have recently been founded can thus be removed If the hopes which we all place in the new institutes are fulfilled Germany will in the future not lack recipients of Nobel prizes and we may then hope to maintain the honorable position which we hitherto have held in the domain of science

That this is however not only a matter of sentiment and honor but a palpable advantage in material respects is at once evident from the close relation between modern scientific progress and national well being I am not here to demonstrate this relation by means of statistics or political economical considerations On the contrary I would invite your attention to a cursory review of my own science I shall thus in considering the most recent achievements in this field be able to point out to you the diversity of the problems and their fertility with regard to the most varying branches of technical industry

As I have already remarked our conception of the nature of chemical elements has to some extent altered owing to the discovery of radium the first element to be discovered by a woman We are now acquainted with more than twenty four such substances—the so-called radio-active elements—and we recognize that they disintegrate spontaneously and that elementary transmutations are hence possible

Germany took at the outset only a small part in the notable researches connected with the discovery of these elements although the first stimulus leading to the discovery of radio-activity was given by the Rontgen rays The reason for this is that Germany possesses none of the raw materials necessary for the production of radium and that the majority of German investigators have not the means for the purchase of this costly element This lack of means was especially keenly felt when radium first found profitable application in the fields of medicine

We are therefore all the more delighted to record such an event as the recent discovery due to Prof Otto Hahn of the chemical laboratory of the University of Berlin[1] He has for several years been investigating the disintegration products of thorium which is employed in large quantities in the manufacture of incandescent mantles and has in the course of his work discovered several radio-active elements the most important of which he has designated mesothorium He has, moreover succeeded in devising a process for the isolation of this substance from the valueless waste products occurring in the manufacture of thorium Hahn's preparation is the bromide of mesothorium, a white salt, which evolves the same highly penetrating rays as the corresponding salt of radium For a given radio-active power this preparation costs only one-third as much as the radium salt. Nevertheless, it is not cheap, since for this small quantity of material $2,750 was paid. Thanks to an endowment from Dr von Böttinger of Elberfeld the Akademie der Wissenschaften in this city will in a few months be in possession of 250 milligrammes of this substance, and lend it out to German investigators It would be possible yearly to produce in Germany a quantity of this preparation of Dr Hahn's equivalent to more than 10 grammes of pure radium bromide from the valueless residues after the extraction of the thorium This is approximately equivalent to the world's stock of radium. By this discovery the radium famine hitherto prevalent in Germany may be said to be relieved

The field of chemical experimentation has in the last decade been widened to an extraordinary degree by the ease with which it is possible to obtain very high and very low temperatures. High temperatures can now be obtained by means of electric furnaces with which temperatures up to 3 000 degrees are easily produced Low temperatures may be obtained by means of liquid air This commodity can now be purchased in Berlin at the comparatively low price of 43 cents per liter For this we are indebted to His Majesty the Kaiser who invited Prof. von Linde, of Munich to erect here one of his large machines for the liquefaction of air[2] You will understand how indispensable this liquid has become when I tell you that in the laboratories of the University of Berlin several liters are daily consumed for scientific purposes

Far more effective is liquid hydrogen which affords a temperature lying 60 deg C below that of liquid air The boiling point is as low as —252 6 deg C only 20 4 degrees above the absolute zero ' The lecturer here explained that liquid hydrogen could not at the present time he obtained in Berlin but that he was nevertheless able to show it to his audience as he had received a shipment of the liquid prepared that morning from the University of Leipsic He went on to show how the extreme lowness of the temperature of the liquid can be demonstrated by transferring a small quantity from its container into a transparent glass vessel and immersing in it a glass tube sealed at the bottom On removing the tube it is seen to be filled with a white solid resembling snow this is solid air when once removed from the cooling liquid the solid melts after a few moments

Referring to the main stock of the liquid from which he had drawn his sample for the experiment Prof Fischer went on

'The remainder of the liquid hydrogen in the containing vessel is to serve to-day for scientific purposes At the end of my lecture it will find its way to the physico-chemical laboratory of the university there to be employed this evening and during the night by Prof Nernst for his important researches on the specific heat of the elements at temperatures in the vicinity of the absolute zero

When the Kaiser Wilhelm Institutes for Chemistry are once in full swing we shall I hope no longer be obliged to travel to Leipzig every time we want some liquid hydrogen.

Liquid hydrogen was prepared for the first time about twelve years ago by Prof Dewar in the famous laboratory at the Royal Institution in London But the costly experiments necessary for its production were rendered possible only by the liberal means which Dr Ludwig Mond the great benefactor of chemistry, placed at his disposal Dr Mond, moreover has not forgotten his German Fatherland and German science He bequeathed to the University of Heidelberg, where he had studied the sum of $250 000 for chemical and physical research and several years ago he endowed the State-supported chemical institute which he had planned, with the sum of $50 000.

Inorganic chemistry, in which, thirty years ago advance was scarcely considered possible, has, owing to the new aids to research—as for example, high temperatures and powerful electric currents, etc.—undergone absolutely unexpected developments. I will merely give you some idea of this development by indicating a few processes of technical importance, beginning with the attempts to prepare valuable nitrogenous compounds from the nitrogen of the atmosphere.

"The direct production of nitric acid from air[3] by means of a powerful electric discharge has reached

[1] Dr Hahn made the discovery of the mesothorium in the laboratory of University College, London, while investigating some thorianite residues given to him by Sir William Ramsay.

[2] A similar apparatus was independently devised and simultaneously patented by Dr. William Hampson in London.

[3] First carried out on a [illegible]

the [illegible] of large-scale manufacture In Norway at the present moment a gigantic works, by the side of a mighty water-fall, is in course of erection by German factories in conjunction with Norwegian engineers, and supported by German and French capital.

Synthetical saltpeter is already on the market, since German dye factories derive a considerable portion of the nitrites necessary for their work from the same source.

The strikingly original process devised by Prof A. Frank and Dr N Caro in Charlottenburg for the preparation of calcium cyanamide from calcium carbide and atmospheric nitrogen came somewhat earlier into practice

And now a third process, based upon the direct combination of atmospheric nitrogen with hydrogen to form ammonia, has been announced Prof Haber of Karlsruhe by means of an ingenious application of the laws of physical chemistry has succeeded in obviating the difficulties which hitherto have rendered this synthesis impracticable The well known Badische Anilin und Sodafabrik at Ludwigshafen am Rhein has taken over his patents and technically perfected the process to such a degree that synthetical ammonia will in all probability shortly be placed on the market

"The greater the number of such processes and the keener the competition which they excite the greater is the benefit to the consumer In the case I have just mentioned this has an especial significance as the bulk of technical nitrogenous substances are employed in agriculture for artificial manures

In the opinion of high authorities German agriculture could easily consume twice nay thrice the amount of nitrogenous material at present employed for this purpose were only the price to fall to a corresponding degree In such a case it is possible that the crops would increase to such an extent that Germany could be independent of foreign countries with respect to agricultural produce A task of great national importance has thus been set to chemical industry

This last process the synthesis of ammonia possesses the advantage that no electricity merely heat is involved In other words all that is necessary is fuel a commodity of which Germany has ample store Furthermore it is to be noted that the cost of production depends only on the price of hydrogen which together with the inexpensive atmospheric nitrogen serves as raw material The problem of producing hydrogen at a moderate cost has already been solved by chemical industry owing to the great interest recently taken in airships In this way the truth of the old saying is established that all industries affect one another and that improvements in one field may occasion fertile results in totally remote spheres of activity

Such a relation of mutual stimulus obtains also between theoretical chemistry and the production of metals The production of gold silver and copper has gained in simplicity to an extraordinary degree by the introduction of electrochemical methods The study moreover of alloys and the perfecting of inexpensive methods of preparing metals hitherto obtainable only with difficulty such as chromium tungsten manganese vanadium and tantalum has been of immense benefit to the steel and electrotechnical industries"

As an example of the latest production of these industries, the lecturer at this point exhibited to his audience some samples of a new modification of iron so-called electrolytic iron This material is prepared at the Langbein Pfannhauser factory in Leipsic by a process devised by Prof Franz Fischer in the laboratories of the University of Berlin the iron being deposited from a solution of an iron salt by an electric current The material can be readily rolled or drawn into wire The samples had the form of extremely tough plates reaching a thickness of five millimeters and showed a bright surface which is not due to any polishing the metal being detached in that state from the electrode. Among the samples exhibited was a seamless iron tube coiled in serpentine fashion which had been deposited upon a leaden core

This electrolytic iron is distinguished from all other commercial varieties by its extraordinary purity, in consequence of which it possesses distinctive physical properties. In particular it is much more readily magnetized and loses its magnetism far more rapidly than other kinds of iron this property rendering it especially suitable for electromagnets. To illustrate this point, the lecturer here exhibited an electromotor of ordinary design which had originally developed one-half horse-power but which, on replacing the original electromagnets by others constructed of electrolytic iron, had its performance raised to 1¼ horse-power This iron should prove of the greatest importance in the construction of electromotors.

Referring to the much discussed question of the husbanding of our natural resources, Prof Fischer went on

Our present-day material civilization is to a great extent founded on the rapid utilization of the fossilized combustibles anthracite and brown coal But posterity will not fail to reproach us with having grievously squandered this valuable material for in the conversion of the heat of combustion of coal into energy in the ordinary way by means of steam engines more than 85 per cent of the work potentially contained in the coal is lost This loss however may be appreciably lessened by suitable chemical treatment of the coal If the coal be first converted into combustible gas—so-called power gas—and this then consumed in a gas engine the output of useful power is treble that developed in a steam engine Valuable by products—ammonia and tar—can moreover be recovered and indeed the methods hitherto employed for the production of power gas are in many respects capable of improvement I therefore deem it possible that at some time special institutes will be founded in the centers of the coal districts—perhaps under the auspices of the Kaiser Wilhelm Society—where these important problems can be investigated with the aid of all the methods known to science

Fossilized combustibles which owe their origin to the vegetable kingdom form a connecting link between mineral and organic substances Organic chemistry surpasses inorganic chemistry in variety of methods and products to the highest degree Small wonder for it embraces all those complicated chemical bodies which occur in animal and vegetable life The number of organic substances accurately investigated may to-day be estimated at the high figure of 150 000 and every year eight or nine thousand more are added to the list We may therefore reckon that at the close of this century organic chemistry will comprise the entire gamut of substances found in the animal and vegetable kingdoms

This rapid increase is wholly due to organic synthesis From the few elements occurring in organic chemistry of which carbon predominates all these compounds are built up much as an architect produces the most diverse edifices from the same form of brick

Synthesis in organic chemistry is an offspring of Berlin It was born eighty two years ago in the Niederwallstrasse by the synthetical production of urea by Friedrich Wohler It has moreover found its greatest field of activity in Germany It stands no longer in fear and trembling of the complicated constituents of the living organism I shall demonstrate this fact by discussing the three classes of substance predominating in organic life the fats the carbohydrates and the proteins The synthesis of fats was effected so far back as two generations ago by Mr Berthelot in Paris The first synthetical carbohydrates—grape sugar fruit sugar etc—saw the light twenty years ago in Würzburg and the methods for the synthetical building up of albuminous substances have been worked out during the last ten years in the laboratory of the university of this city

Through such things as these proteins carbohydrates, and fats organic chemistry is brought into close touch with the biological sciences for the entire metabolism in the living organism is merely a sequence of chemical transformations which these substances undergo Chemistry is thus called upon to partake in the solution of the great riddles of life Nourishment growth reproduction heredity age and the manifold pathological disturbances of the normal state It is not surprising that the keenest activity exists in these interesting fields of work and we may safely hope that provision will be made for biological research in the new Kaiser Wilhelm Institutes

The example given by the magnificent institute here in Berlin for the study of the problems of the industries connected with fermentation in which the results of scientific research meet the practical requirements of brewers and distillers serves to show how fruitful can be the collaboration of biologists and chemists

Moreover chemical and many other industries have derived great benefit from organic chemistry A few examples from recent times will illustrate this fact.

The most widely distributed of all the carbohydrates is cellulose of which cotton and linen are entirely composed and which is the chief constituent of wood and plant fibers And what a variety of articles is nowadays manufactured from cellulose! Paper collodion, celluloid photographic films smokeless powder artificial silk artificial hair artificial leather"

In illustration of the cellulose industries the lecturer displayed before the audience samples of artificial silk and horse hair and films in great variety All these products, he said had been prepared by ingenious combinations of chemical and mechanical processes. Artificial silk and hair in spite of their striking similarity to the natural products, Prof Fischer explained, were of totally different composition from these, which are not derived from cellulose but belong to the class of proteins The lecturer further pointed out that the magnificent colors with which the artificial textures were dyed were the work of organic chemistry They belong he said to the family of synthetic coal tar dyes This subject is to day so large that complete half yearly courses of lectures are delivered upon it at the universities. Hundreds of such dyes are on the market and the value of the dye stuffs produced in Germany the majority of which are exported approximates to fifteen millions of pounds sterling

Of all these dyes I shall only mention synthetical indigo because this substance was the most difficult of all to synthesize and on the other hand was a great commercial success

This synthetical product is not only much purer in composition and color than the natural dye stuff but also considerably less expensive On this account the cultivation of the indigo plant in India has diminished to one sixth of the original extent and will to all appearances soon disappear altogether[1] Woolen and cotton goods are now dyed with German indigo even in Asia to which continent a quantity of indigo worth no less than $9 500 000 was exported in the year 1909

While on this subject I may refer to the two most important coloring matters of animal and vegetable life chlorophyll and hæmoglobin The former plays an important part in the chemical process upon which all life depends—I refer to the conversion of the atmospheric carbon dioxide into sugar which takes place in green leaves under the influence of sunlight The red pigment in the blood fulfills in our own bodies the important function of transporting the oxygen from our lungs to the tissues thus rendering possible that process of combustion which forms the basis of our bodily and mental strength

The lecturer here showed two specimens of pure chlorophyll of which one was crystalline He remarked I owe these rare preparations to Prof R Willstätter of Zurich who of recent years has been studying this coloring matter with remarkably successful results Hæmoglobin has also lately been thoroughly investigated in Stuttgart and in Munich and the remarkable conclusion has been drawn from these investigations that chlorophyll and hæmoglobin are closely related This fact thus denotes a species of consanguinity between the animal and vegetable kingdoms This must however be of great antiquity—that is to say to date from remote times when the animal and vegetable kingdoms were as yet not distinct

Of greater commercial importance than the coal tar dyes is India rubber Its consumption is continually increasing, and is estimated at some 70 000 tons yearly an amount corresponding in price to about one hundred and seventy five millions of dollars You can therefore readily understand that this subject has attracted the attention of synthetic chemists and for the last nine months one has heard even in public of attempts to prepare synthetical India rubber In fact in August 1909 Dr F Hofmann and Dr C Coutelle chemists to the Elberfelder Farbenfabrik succeeded in devising a practical process for its synthesis The starting material is a volatile mobile and colorless liquid termed isoprene[2] which in turn can be readily synthesized from even simpler substances

This liquid is converted into India rubber merely on heating in closed vessels The lecturer here exhibited a sealed glass tube which had been originally filled with a mobile liquid isoprene but which after heating contained a jelly like mass of synthetical India rubber Pointing to this he said When thus prepared on a large scale the substance is somewhat denser and of a light yellow color That this product is really India rubber has been definitely established by the scientific investigations of Prof Harries in Kiel a high authority on this subject who has since independently devised another process for the same purpose

When synthetic chemistry has once taken possession of such a field it is not confined to the particular product occurring in nature but can bring forth a whole series of similar substances Other rubber like substances have been prepared not from isoprene but from similar liquids such as dimethylbutadiene Such products are termed homologues They possess properties closely resembling those of India rubber but differ slightly in chemical constitution It is as yet not decided which of these synthetical substances forms the most suitable substitute for India rubber The same applies to the far more important question of cost of production But when one considers the fate of natural indigo of madder and of other natural products one may hope to see synthetical India

[1] The recent work of Bloxam and his collaborators has demonstrated the possibility of recovering from the leaf a yield of indigo increased to such a degree that the cost of production is certainly no more than that of the synthetical product Furthermore the natural indigo is stated by some authorities to possess certain benign impurities which render it more suitable for dying purposes.

[2] First shown to yield India rubber in 1892 by Sir William Tilden (*Chem. News*, lxv., 265)

rubber gradually enter into successful competition with the naturally occurring commodity

Camphor which may be placed in the same chemical category as India rubber is also prepared artificially on a large scale The first firm to manufacture synthetical camphor was the Chemische Fabrik auf Aktien (formerly Schering) of Berlin but other firms are now following suit By this the camphor monopoly which the Japanese government was able to establish after the annexation of Formosa was broken down

Passing on to a somewhat different field the lecturer now showed to his audience samples of an artificial resin closely resembling amber in its external characteristics and capable of serving as a substitute for that substance in the production of such articles as necklaces combs cigar holders etc Samples of such articles were submitted which had been placed at the disposal of Prof Fischer by the Bakelite Company Bakelite being the trade name of the material which is prepared by a process recently worked out on a technical basis by the American chemist Baekeland

Referring next to the association of synthetic chemistry with medicine the lecturer remarked that workers in this field were actively engaged in the pursuit of the discovery of new medicaments and that the great amplitude of this subject compelled him to mention only a few instances. Thus he showed to the audience a bottle containing a white powder—veronal—which is a hypnotic largely employed at the present day It is in no way connected with the older vegetable narcotics such as opium etc. but is entirely a synthetical product. He then pursued his subject.

Organic synthesis is not limited to vegetable products only but embraces equally fearlessly substances of animal origin An instructive example of this may be found in a remarkable compound (adrenalin) which is formed in our own bodies in the suprarenal glands and which plays an important part in the regulation of the blood pressure Shortly after its isolation in a pure condition from these glands Dr F Stolz chemist to the dye factory at Höchst was able to synthesize it from constituents of coal tar This synthetical product has now been placed on the market by the Höchst firm under the name of Suprarenin A very dilute solution of this substance causes a powerful contraction of the blood vessels and consequent dispersal of blood from the tissues A skin surface well charged with blood—as for instance a red nose—is instantly rendered quite pale on painting it with such a solution Unfortunately, the color is not evenly discharged owing to the varying permeability of the epidermis and as the action of the drug soon ceases with return of the original redness adrenalin is not suitable as a cosmetic On the other hand it finds most useful application in surgery as by its means certain incisions can be made without loss of blood this is found particularly convenient for operations on the eye mouth and nose

Flora's fairest children the sweet-scented flowers must also submit to competition with synthetic chemistry The scent industry has received a powerful impetus from synthesis and yearly turns out in Germany alone goods of the value of more than ten million dollars Among the products of this industry may be mentioned ionone an artificial violet scent discovered in the laboratory of this university by the late Prof F Tiemann and manufactured by Messrs Haarmann and Reimer in Holzminden The contents of this bottle would be sufficient to envelop not only the Ministry of Education but the entire avenue Unter den Linden in an atmosphere of violet perfume for the osmophoric value of these substances is extraordinarily high

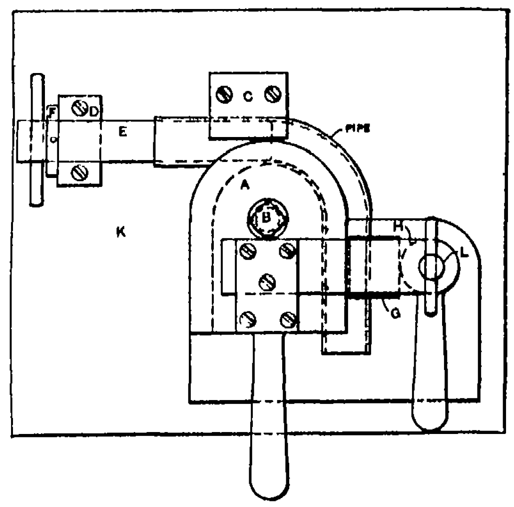
In contradistinction to the simple ionone the majority of the natural odors of flowers are due to complex mixtures of different scents These nevertheless have been successfully reproduced Among scents so prepared are lily of the valley mock orange lilac tuberose and finally the greatest achievement synthetical attar of roses Although the natural oil from roses contains about twenty different odorous substances the chemists of the scent factories at Leipzig (Heine & Co Schimmel & Co) have succeeded after laborious research in isolating all the components synthesizing those or preparing them from less costly oils and then reuniting them in the proper proportions It now requires a most sensitive nose indeed to distinguish the synthetical attar of roses from the natural product

These examples show the success which has followed the encroachment of synthetic organic chemistry in nature's domain What I have already said is sufficient to prove that chemistry as well as all natural sciences is the true field of unlimited possibility The Kaiser Wilhelm Institutes are henceforth to take part in the expansion of this field and the appropriation of the treasures hidden therein

"It is, of course not to be expected that they will entirely supplant all the older scientific institutions. We of the older institutions do not feel by any means so weak as willingly to allow such an event to occur On the contrary we shall exert our best energies to maintain a keen competition with the younger institutes. This will serve to keep both sides fresh and active

Pipe-Bending Device

The illustration shows a pipe-bending device which will be of value to anyone wishing to bend pipe with out the trouble of filling it with sand or other materials The mandrel E is held on base K by the steel block D Stop collar F is set and pinned on the mandrel in such a position as to allow the end of



PIPE-BENDING DEVICE

the mandrel to project slightly past the center line of swivel block A which is pivoted at B and rounded out for the pipe The backing block C which also fits the pipe is set so as to allow the pipe to slide over the mandrel E and keeps it from buckling while it is being drawn off the mandrel

The pipe is shown in the illustration after having been bent at right angles Before making the bend the swivel block A is set in a position parallel with the mandrel E and the end of the pipe is then placed on the mandrel It is held to the swivel block by means of a sliding block G which is locked by the eccentric lock lever H After making the bend the lock pin L is pulled out, after which the block G and the eccentric lever H can be removed the pipe may then be pulled off the end of the mandrel —*Machinery*

The Ferry Total Reflectometer

The name total reflectometer' is given to an instrument designed for the measurement of the optical refractive index of a liquid by means of the phenomenon of total reflection A recent issue of *Prometheus* describes a new form of the instrument invented by the French physicist Ferry

If AB (Fig 1) represents the surface of separation

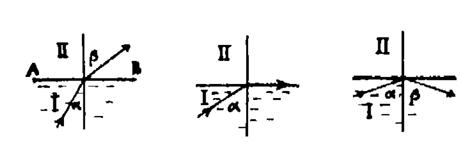


Fig 1 Fig 2 Fig 3

between water I and air II a ray of light directed upward through the water at a small angle of incidence α is reflected at the surface and emerges at a larger angle β such that the ratio $\frac{\sin \beta}{\sin \alpha}$ is equal to the ratio of the velocities of the ray in air and in water and is therefore constant for all angles of incidence (so long as any refraction occurs) This ratio is called the refractive index from water to air,

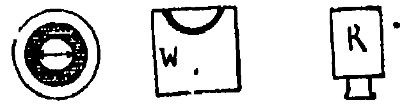

Fig 4

for light of the particular wave length employed If the angle of incidence α is gradually increased the angle of refraction β increases correspondingly until it becomes a right angle and the refracted ray coincides with the surface (Fig 2) In this case $\sin \beta = 1$, so that the refractive index is equal to $\frac{1}{\sin \alpha}$ This value of the angle of incidence is called the critical angle, for if the ray, in the water, makes a still larger angle with the normal to the [illegible] it cannot emerge, but is totally reflected at an [illegible] equal to its angle of incidence α (Fig 3)

Kohlrausch's total reflectometer the inst[illegible] most commonly used for measuring the ref[illegible] index of a liquid by means of total reflection, r[illegible] two settings and two readings for each measur[illegible], but Ferry's apparatus requires only one readi[illegible] no accurate adjustment.

A hemispherical cavity in a cubical block o[illegible] (W Fig. 4) contains a concentric glass hemisph[illegible] slightly shorter radius and the space betwe[illegible] the hemisphere and the wall of the cavity is fille[illegible] the liquid When the cube of glass is viewed [illegible] a telescope R, a dark ring, caused by the to[illegible] reflection of some of the incident rays, is seen. [illegible] internal diameter of the dark ring varies acco[illegible] to the refractive index of the liquid. This dia[illegible] is measured with a micrometer eyepiece. From [illegible] result of the measurement it is possible to calc[illegible] the index of refraction from the liquid to the [illegible], and hence, the index of refraction from the liqu[illegible] to air or vacuum, when the index of the glass is kn[illegible] The use of the instrument, however, is simplifie[illegible] graduating the head of the micrometer screw in u[illegible] of refractive index, so that the refractive index [illegible] the liquid is obtained by direct reading, without [illegible]culation.

Short Cuts in Multiplication

It is ridiculous how much unnecessary trouble s[illegible] people—let me say most people—take when they h[illegible] a bit of multiplication to do Take the three exam[illegible] here given. In the first, by the long way, there [illegible] sixteen figures and four operations but by sim[illegible] multiplying by the factors 4 8 and 4 the product [illegible] there without any addition

In the second example, which is done in two lo[illegible] and hence wrong ways of which the second is th[illegible] quicker there are still by either of these ways twelv[illegible] intermediate figures and four operations, wherea[illegible], if one would only add three ciphers and then subtra[illegible] the multiplicand the answer would be there with only six figures and two operations.

In the third example, by setting three ciphers a[illegible] before to the multiplicand and subtracting twelv[illegible] times itself the answer is obtained by writing only ten intermediate figures and performing two operations In the last two examples writing the ciphers is really not necessary Why take so much trouble? One can just imagine them there

An Improved Electric Steel Furnace

By Dr Alfred Gradenwitz.

In designing the electrical steel furnace described below Dr H Nathusius has endeavored to combine the individual advantages of the Héroult and Girod furnaces while avoiding the drawbacks of either

In this furnace which is of the combined arc and resistance type there are three surface carbon electrodes penetrating vertically into the hearth compartment at the angles of an equilateral triangle These electrodes are connected up to the outside terminals of a three-phase current generator or transformer whereas three steel electrodes enchased in the bottom (which are likewise arranged at the angles of an equilateral triangle) are joined to the inside terminals of the same three-phase current generator or transformer These inside terminals are obtained by dissolving the neutral point of the machine and transferring it into the charge As accordingly the surface electrodes as well as the bottom electrodes are of mutually alternating polarities the current passes from one surface electrode to another from one bottom electrode to another and from each surface electrode to one of the bottom electrodes In fact there is inside of the charge a perfect compensation of currents, in opposition to the surface currents of the Héroult and the cross currents of the Girod furnace. This heating process, according to which the whole of the charge is traversed and encircled by heating currents obviously is as economical as can be desired

Again the fact that the current is distributed to the whole cross section of the bath that is both to its surface and bottom is bound to result in another beneficial effect by forming rotary fields which similarly as in the case of a three-phase current motor will set the surrounding iron parts rotating

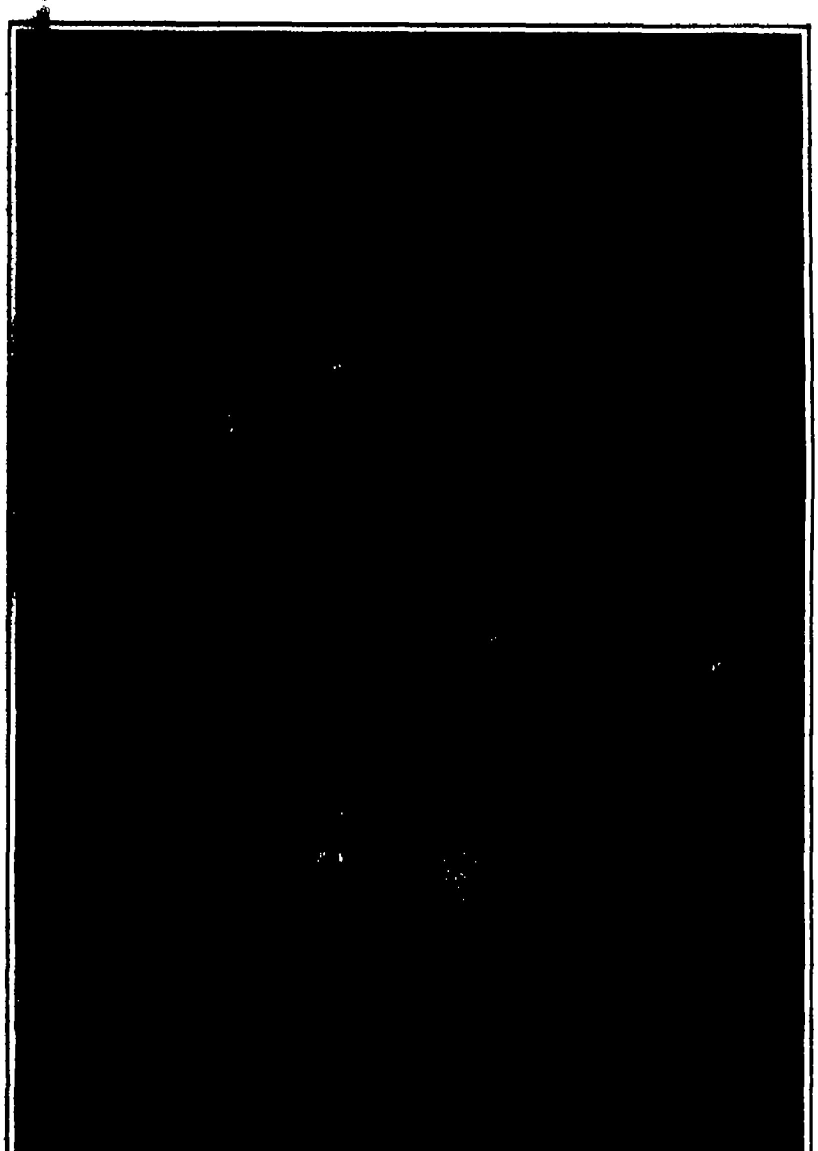
It further will be readily understood that in the Nathusius furnace with its six heating focuses located at the issue of the current from the various electrodes the bath can be heated and throughout its mass much more rapidly than in furnaces only comprising two heating centers As furthermore the surface electrodes are placed as close to one another as feasible the electric arcs will repel each other by virtue of the electro-dynamic forces exerted on one another by currents of equal direction

Apart from this advantageous heating effect, the *electrical arrangement of the Nathusius furnace* is exceedingly favorable As three phase currents are used in practically all large metallurgical works the use of this type of current is doubtless advantageous while the problem of including the charge in the circuit is solved most ingeniously by locating the neutral point in the bath itself, thus accurately prescribing the path of the current independently of any resistances As the circuit comprises not only the electric arc which is bound to vary continually but the slag layer, the steel bath and the mass rammed upon the bottom electrode any shocks produced by short-circuits in the electric arc are compensated as it were by an electric buffer thus dispensing with any furnace regulation in the case of normal operation

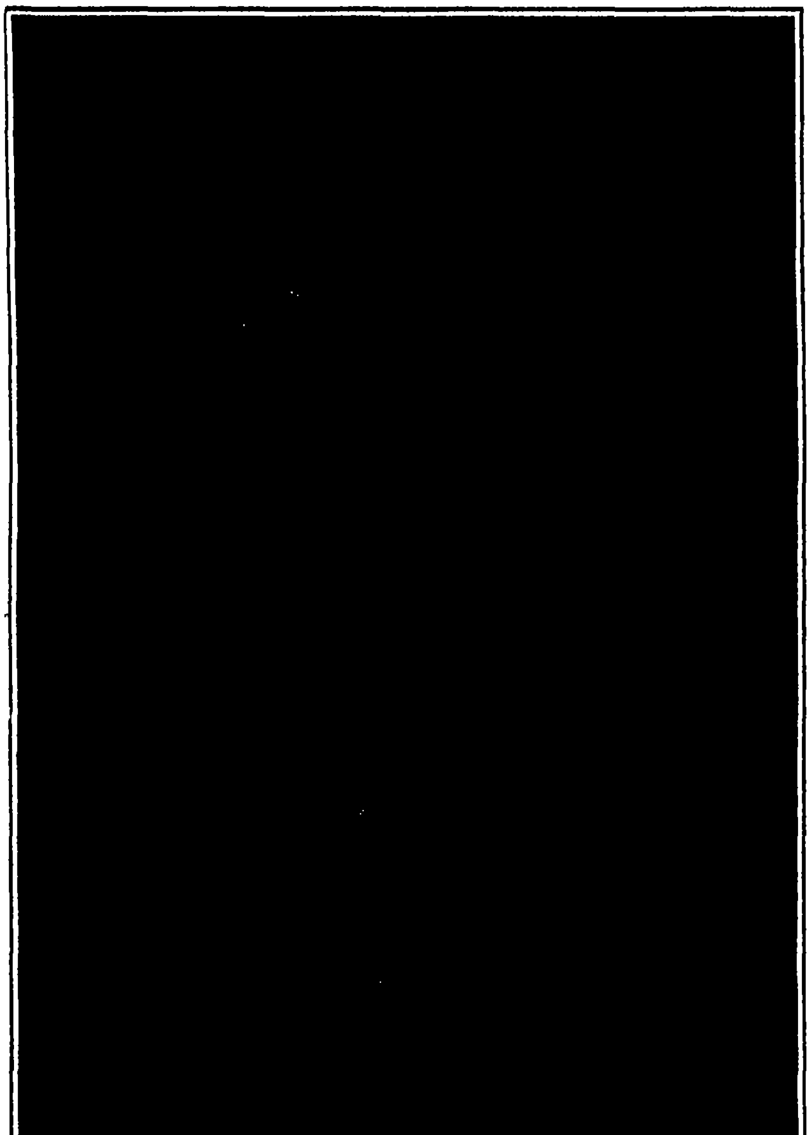
A further advantage *from the electrical point of view* is that the current flowing from one bottom electrode to the other is readily transformed to any intensity by the aid of a special generator with adjustable neutral conductor or else by means of a booster transformer As this current only flows between the bottom electrodes viz through relatively small resistances its intensity can be increased without any necessity of using machinery of excessive dimensions which obviously renders it possible to obtain very strong effects

While during the first stage of operation (the refining stage) an effective heating of the slag (the only refining agent) by intense arcs is of much importance it should not be overlooked that during the ensuing deoxidizing stage the slag acts only as a protective cover and accordingly requires no strong heating During this second stage the whole of the bath should therefore be heated as effectually as possible which in the Nathusius furnace is done by using a booster transformer and thus deriving from the electric arc a considerable amount of energy concentrated in the bath or the bottom

After once preparing the charge it is often desirable to allow the bath to rest for some time, during which stage the amount of heat to be added only



POURING OUT THE CHARGE



THE OPERATION OF TAPPING

AN IMPROVED ELECTRIC STEEL FURNACE

corresponds to the heat lost by radiation and conduction This in the Nathusius furnace is effected most advantageously by cutting out entirely the surface electrodes allowing current only to flow between the bottom electrodes and thus doing away with arc heating

Being of a round shape the furnace is pivoted in the same way as a converter upon two uprights the tilting device being operated electrically or hydraulically The bottom electrodes which are made of cast steel are fitted into the bottom from underneath they do not penetrate into the steel bath and are covered by a layer consisting of the same material as the furnace bottom The whole of the furnace except the lid consists of a rammed dolomite mass and is very durable as is also the lid which is made of argillaceous materials quartz slate and the like

A furnace constructed on the above lines by the Bergmann Elektrizitäts-Werke Ltd of Berlin which has been in operation for more than a year at the Friedenshütte Steel Works was recently tested by Dr B Neumann of Darmstadt This furnace derives its electrical energy from a three phase current transformer the high tension end of which wound for 6 000 volts is connected up to the circuit of the power house supplying the steel works The low tension winding is so designed that both ends of each of the three coils issue out of the transformer each of the three windings being connected at one end with a surface electrode and at the other with a corresponding bottom electrode The rails which are made of flat copper are designed for a permanent current intensity of 2 500 amperes The transformer is able permanently to yield 550 kilowatts and at the low tension end gives an interlinked tension of 110 volts The phase tension thus is 63 volts which disregarding tension losses in the conductors is the tension between the surface and bottom electrodes Into the conductors leading to the surface electrodes is inserted a switch which short circuits these three conductors and thus allows the bottom electrodes to be used alone for current supply

The furnace transformer is fed from the three phase current system of the local power house no unfavorable influence having ever been noticed Into the high tension circuit of the transformer are inserted a voltmeter and an ammeter and each of the three conductors leading to the surface electrodes comprises an ammeter A (Fig 1) Between the three surface electrodes are inserted three voltmeters V and three other voltmeters V indicate the voltage between each of the surface electrodes and the corresponding bottom electrode Finally the tension between the bottom electrodes can be checked by three voltmeters V Each phase of the low tension circuit comprises a wattmeter

The booster transformer having an output of 150 kilowatts is in its primary circuit likewise connected up to the 6,000 volts three phase current system of the power house As the current intensity at the low tension end depends on the variable resistance of the bottom (floor) material and the temperature of the bath the booster transformer is designed for two

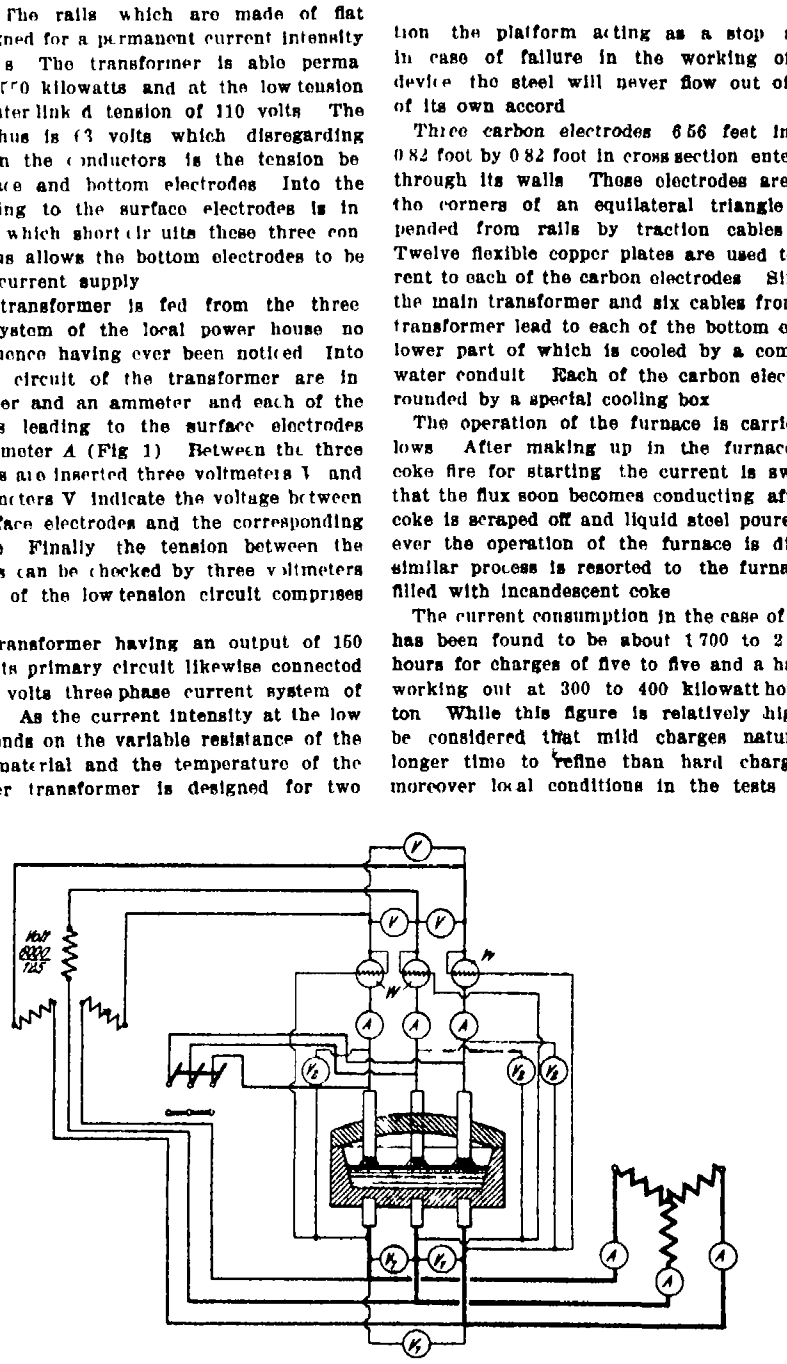


FIG 1 DIAGRAM OF CONNECTIONS

tappings for each low tension phase and is adapted to be connected up in triangle or star arrangement for each of these tappings thus allowing 16 2 19 22 28 33 or 38 volts secondary tension to be derived with a primary tension of 6 000 volts An ammeter is fitted into each conductor leading from the booster transformer to a bottom electrode

As regards next the furnace itself this is designed for a capacity of five to five and a half tons of liquid steel It is extremely simple in construction, and is tilted by hydraulic means The furnace proper consists of two parts, the hearth and a removable lid, both of which are surrounded by a sheet metal sleeve The outside diameter is 8 96 feet, and the height 3 20 feet.

The furnace comprises three doors (two arranged laterally and one at the discharge opening) which insure a ready view of the whole bath surface, thus facilitating the introducing of flux material discharging of slag etc These doors are distributed over the spaces between the electrodes. The three cast steel bottom electrodes are fitted into the floor from underneath while the whole of the furnace body otherwise is entirely disengaged Its center of gravity is so arranged that the furnace may tilt of its own accord only in a backward direction the platform acting as a stop so that even in case of failure in the working of the tilting device the steel will never flow out of the furnace of its own accord

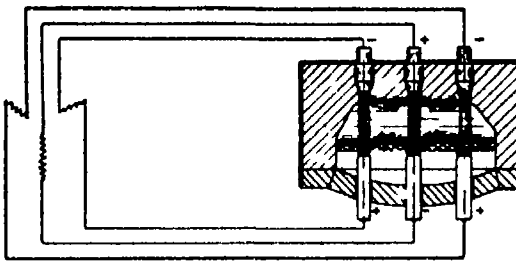

FIG 2—DIAGRAM SHOWING ARRANGEMENT OF ELECTRODES IN THE THREE PHASE CIRCUIT

Three carbon electrodes 6 56 feet in length and 0 82 foot by 0 82 foot in cross section enter the furnace through its walls These electrodes are arranged at the corners of an equilateral triangle being suspended from rails by traction cables and rollers Twelve flexible copper plates are used to supply current to each of the carbon electrodes Six cables from the main transformer and six cables from the booster transformer lead to each of the bottom electrodes the lower part of which is cooled by a common cooling water conduit Each of the carbon electrodes is surrounded by a special cooling box

The operation of the furnace is carried on as follows After making up in the furnace a wood or coke fire for starting the current is switched on so that the flux soon becomes conducting after which the coke is scraped off and liquid steel poured in Whenever the operation of the furnace is discontinued a similar process is resorted to the furnace being left filled with incandescent coke

The current consumption in the case of mild charges has been found to be about 1 700 to 2 000 kilowatt-hours for charges of five to five and a half tons thus working out at 300 to 400 kilowatt hours for each ton While this figure is relatively high it should be considered that mild charges naturally take a longer time to refine than hard charges Though moreover local conditions in the tests were as unfavorable as could be such charges have frequently been made with less than 300 kilowatt hours to the ton

No definite idea of the working expenses can so far be formed The first cost of the five-ton furnace was found to be about 12 000 marks, and that of the electrical equipment, exclusive of the transformer or generator but inclusive of cables, pole pieces, etc, about 15 000 marks A chief smelter, a smelter a boy and a man for regulating the electrodes were required to keep up operation The life of the lid was found to be six weeks.

* Stahl und Eisen, No. 38 1910.

The World's Lead Supply

After having passed in review the world's production in reserves in coal, iron and copper, Prof. J. F. Kemp, in his paper, "Geology and Economy," goes on to treat in the same way the case of lead We quote him in his own words

'Among the nations of the world the United States has become the chief contributor of lead and yields year by year proportions varying from 27 to 30 per cent of the total The next country is Spain with about two-thirds as much and Germany follows with three fifths

In this country the State of Missouri is the heaviest contributor and is responsible for practically 40 per cent of the total Idaho is next with about 30 per cent and Utah follows with 13 to 14 The Western lead all carries silver The precious metal is an important factor in the value of the product When we come to forecast the future it is not possible to see more than a few years in advance or to speak in more than a general way The miners would be glad to be assured of reserves of ore for a goodly period of years but it is seldom possible or practicable to demonstrate their presence Operations necessarily continue with a few years supply blocked out in advance of the actual mining and the hope is maintained that more will be found Very often the expectations prove justified We may therefore in a measure forecast future experience somewhat by the past In the Missouri lead region mines have been operated for forty or fifty years not on so large a scale at the outset as now but continuously For some years at least no change may be anticipated In Idaho the lead ores are now known to continue to depths of nearly 2 000 feet beneath the overlying surface and to be holding out without essential change in character. In Missouri however the mines never have been very deep that is over three or four hundred feet, and the compensation comes in wide horizontal extent.

Some of the old time heavy producers have greatly declined Nevada once an extremely important source of lead is now a comparatively small contributor. Colorado in former years our chief source has dropped to only a third of its one time yield and yet the total of the country has gone quite steadily on The fall in the price of silver was a hard blow to the Western lead miners and naturally not only cut off their profits but raised the necessary percentage of metal in the ore.

If we look ahead for a century or some such long period we may not feel assured that production can be maintained at present rates There may of course be new discoveries in lands not as yet fully explored Being distant from present centers of consumption as they necessarily would be their entry into the markets would imply higher prices so as to meet the charges of freight

On the other hand lead is a metal which oxidizes or changes very slowly In its applications in the metallic state it tends thus to accumulate unless lost in use as in the case of shot and bullets. It is extensively employed in the manufacture of paint and in this form is of course never recovered About 2 per cent of the entire output is destroyed to give us white and red pigments

It behooves us on the whole to be careful in the use of lead and to avoid when possible, its unnecessary sacrifice

Ionization in the Electric Furnace

An interesting apparatus was exhibited at the recent soiree of the Royal Society by Dr J A. Harker and Mr C G Eden In some experiments involving the treating of refractory oxides in the electric furnace some curious effects were noticed indicating pronounced differences in the chemical activity at high temperatures of the atmospheres of two different electric furnaces A miniature furnace of simple construction suitable for temperatures to 3 000 deg C, was shown working It consists of a tube of arc lamp carbon 14 millimeters external diameter, surrounded by a protecting sheath of pure lamp black, and heated by alternating current, passed through it from a small transformer Entering the interior of the tube at each end, and insulated from it, is an electrode of carbon One electrode is hollow so that an optical pyrometer can be sighted upon it the other is movable on a graduated scale A battery of variable E M.F and electric measuring appliances serve to measure the amount of current sent across the gap at any temperature In the larger furnace used, the resistance of the gap varies from infinity at ordinary temperature to an apparent value of less than an ohm at 2,200 degrees. At low temperatures such as 1,400 degrees a few volts give a "saturation current." At high temperatures the saturation current reaches 8 or 10 amperes. The phenomena are not those of an arc, and are unaltered by passing an indifferent gas through the furnace.

The Wastes of a Blast Furnace*

How They are Utilized

By Edward M Hagar, President, Universal Portland Cement Company Chicago

Until the last decade, practically the only utilization of the wastes or by products of a blast furnace was the use of a portion of the waste gases to raise the temperature of the incoming blast through heat ing the brick work in so-called hot stoves and in some cases a small portion of the power value of the gases was obtained by burning them under boilers to generate steam for driving the blowing engines

At the present time the calorific value of the waste gases is being utilized directly in gas engines for blowing purposes and for generation of electric power a considerable portion of the slag is used in the manufacture of Portland cement and the flue dust consisting of the finest ore and coke particles is being collected and converted so as to be rechargeable into the furnaces.

The aggregate saving or profits resulting from these three developments is a matter of millions of dollars per annum and in a modern blast furnace plant it would almost seem that pig iron was the by product and indeed the investment in the equipment to utilize those former wastes exceeds that of the blast furnace itself

The writer in his work has come in contact with these evolutions with plants in operation or under construction of a capacity to produce twelve million barrels of Portland cement per annum from slag and limestone using over one million three hundred thousand tons of slag in a year these plants being driven entirely by electric current generated by gas engines directly from the waste blast furnace gases the power requirements being forty thousand horse-power for twenty four hours every working day In one of the cement plants the first commercial method for reclaiming flue dust was discovered

By using the blast furnace gases directly in combustion engines after suitable washing to remove the grit, the power obtained from a given amount of gas is equal to at least two and one-half times that obtainable by burning the gas under boilers for generating steam for use in steam engines.

A modern blast furnace of the usual size with gas blowing engines and gas engines driving electric generators will provide sufficient gas to furnish seven thousand kilowatts electric power in addition to driving its own blowing engines

This permits the most modern steel works such as those at Gary Indiana to practically do away with the use of coal for power purposes operating the rolling mills by electric power from the surplus gases

The United States Steel Corporation of which the Universal Portland Cement Co is a subsidiary has already installed two hundred and fifty thousand horse power gas blowing and gas electric units which it can easily be figured displaces or saves the consumption of approximately a million tons of coal per annum as compared to the old fashioned method

With the modern high blast pressures and the use of fine Missabe ore the finest of the particles together with the coke dust, are blown out through the top of the furnaces and are caught in the flues dust catchers and gas washers

The iron ore in this dust amounts to fully three per cent of the total ore charged which aggregates the large amount of approximately a million and a quarter tons per annum in this country Until within a few years this dust has been thrown away or used as filling although containing about forty per cent metallic iron

For many years efforts were made to use this material by compressing it into briquettes but the cost of the operation together with the fact that the briquettes disintegrated and the dust was again blown out, led to an abandonment of the briquetting plants

The first commercially successful method of utilizing the dust was discovered by passing the material through the cement kilns at South Chicago Experiments showed that with the proper heat treatment, the coke dust could be burned off and the iron ore conglomerated into nodules or nuggets averaging over sixty per cent iron content. These nodules, when fed to the blast furnace, were easily and completely reduced. The fact that the sinter of the flue dust contains such a high percentage of iron and that all of the sinter is reduced, together with its physical shape assisting the steady movement of the charge downward in the blast furnaces, thereby preventing so-called slips, makes the sinter more valuable per ton than any ore.

It was necessary to derive mechanical means for preventing the accumulation of the sinter on the walls of the kiln Plants have been in operation for some years using this process with endless chains carrying scrapers constantly passing forward through the kiln and cooled in water on their return outside of the kiln

Recently other methods of utilizing dust have been devised which may prove successful commercially and the indications are that within a short time the greater portion of this former waste will be prevented

The development of the Portland cement industry in this country and the extension of its uses have been marvelous and the following table shows a remarkable increase in the production of Portland cement in the United States every year since 1895 when this country first reached the production of approximately one million barrels

Year	Production of Portland Cement in the United States	Production of Universal Portland Cement	Percentage of Universal to Total Amount of Portland Cement
	Barrels	Barrels	Per Cent
1895	990 324	——	
1896	1 543 023		
1897	2 677 775		
1898	3 692 284		
1899	5 652 266		
1900	8 482 020	32 443	0 38
1901	12 711 225	164 316	1 29
1902	17 230 644	318 710	1 85
1903	22 342 973	465 930	2 08
1904	26 505 881	471 294	1 78
1905	35 264 812	1 735 343	4 92
1906	46 463 424	2 076 000	4 55
1907	48 785 390	2 129 000	4 36
1908	51 072 612	4 535 000	8 88
1909	62 508 461	5 786 000	9 27
1910	73 500 000*	7 001 500	9 52

* Government estimate

It may be of interest to note the increasing percentage of the total American production shown by Universal Portland cement which is the only Portland cement manufactured in this country using slag as one of the raw materials With the new plant now approaching completion the aggregate production of Universal Portland cement in the Chicago and Pittsburg districts will amount to over one-eighth of the country's total Expressed in weight the output of the finished product will be over two million gross tons per annum Our plants in the Chicago district will consume all the available slag that is suitable for the purpose from an aggregate of nineteen blast furnaces in the South Chicago works of the Illinois Steel Company and in the Gary works of the Indiana Steel Company

Comparing the pig iron production and Portland cement production of this country in figures of long tons the percentage of Portland cement to pig iron in 1890 was six tenths of one per cent in 1900 ten and three-tenths per cent and in 1910 forty seven per cent The continuation of any such relative growth would mean that before 1920 the tonnage of Portland cement would considerably exceed that of pig iron I would hesitate however to predict that such would be the case

Portland cement is defined by the United States government as the product obtained from the heating or calcining up to incipient fushion of intimate mixtures either natural or artificial of argillaceous with calcareous substances the calcined product to contain at least one and seven tenths times as much of lime by weight, as of the materials which give the lime its hydraulic properties and to be finely pulverized after said calcination and thereafter additions or substitutions for the purpose only of regulating certain properties of technical importance to be allowable to not exceeding two per cent of the calcined product

From this definition it will be seen that the raw material for Portland cement is not limited to any particular form of material it may be made from any combination of materials that together furnish the proper elements In this country Portland cement is manufactured from a number of raw materials which, with a few exceptions, may be classed under four heads.

First. Argillaceous limestone (cement rock) and pure limestone.

Second. Clay or shale and limestone

Third Clay or shale and marl

Fourth Slag and limestone

In all cases the raw mixture is a combination of some form of clay and some form of lime and in the first and fourth classifications the clay materials contain some lime This simply reduces the proportion of lime material necessary for a proper mixture

In the manufacture of Portland cement from slag and limestone the molten slag flowing from the furnaces is granulated by a stream of water loaded into cars and transported to the cement plants where it is dried in rotary driers and receives the first grinding It is then mixed in automatic weighing machines with the proper proportion of ground and dried calcite limestone These are then ground together and burnt to a hard clinker at a temperature of nearly 3000 deg F in rotary kilns using pulverized coal for fuel

This clinker after seasoning is crushed and ground and mixed with a small percentage of gypsum to regulate the setting time The cement is ground to such fineness that ninety six per cent passes through a sieve having ten thousand meshes and eighty per cent passes a sieve with forty thousand meshes to the square inch It is then conveyed to the stock house for storage prior to shipment

It is necessary to use a flux in furnaces supplying slag for cement manufacture a pure calcite limestone The limestone burnt with the slag must also be a pure calcite stone It is also essential that the ores be of a uniform and proper character

Inasmuch as Lake Superior ores are noted for their remarkable uniformity of analysis the resultant slag obtained from the use of these ores and a pure calcite limestone is more uniform in its analysis than any form of natural clay deposit used in the manufacture of Portland cement and the variation in the proportions of the two raw materials used in the manufacture of Portland cement from slag is less than those of any other materials mentioned above

In addition the opportunity for analysis and selection of the proper ingredients through the use of an artificial material is a great advantage as compared to the necessitous use of natural materials just as they are found with their variations in analysis at different depths

In the intense heat of the kiln under the influence of the oxidizing flame any sulphides in the slag are completely burned out.

The rotary kiln commonly used ten years ago was sixty feet long and six feet in diameter This has gradually been increased in length and diameter until the modern kiln is one hundred and forty to one hundred and fifty feet long and eight to ten feet in diameter and there are a few even larger kilns in use Kilns are usually set at an incline of three quarters of an inch to the foot With the lining and contents the modern kiln weighs one hundred and fifty tons and in revolving upon two bearings presents interesting constructional features

In the case of the plant at Buffington Indiana using twenty six thousand horse power situated between South Chicago and Gary Indiana electric power is supplied at twenty two thousand volts from the steel works at these points Each piece of machinery is driven by its individual motor supplied with alternating current at four hundred and forty volts The high tension line is connected through the cement plants and the gas engines at these two steel works fourteen miles apart operate continually in parallel This enables the cement plant to draw its power from either source or from both sources at the same time as may be desirable It has happened that one of these works has supplied power to operate the cement plant and furnished additional power at the same time to the steel works at the other end of the line

The method of manufacture above described is the standard method of manufacturing Portland cement from natural deposits and the finished product differs in no way from other Portland cements in chemical analysis fineness specific gravity color nor in the operation in practical work It has no peculiarities whatever and has no limitations as to its applications There is no difference from the chemist's point of view between the manufacture of Portland cement from natural deposits such as limestone and clay or shale and its manufacture from limestone and slag Slag is really a mixture of the clay from the ore with the lime content of the stone used as a flux in the furnace

Our method of manufacture of Universal Portland

* Presented before the Congress of Technology at the fiftieth anniversary of the granting of the charter of the Massachusetts Institute of Technology.

cement does not embody any real invention nor is it based on any patents It is simply an adaptation to an artificial raw material of the regular Portland cement process formerly applied only to natural deposits

True Portland cement in which slag is used as one of the raw materials should not be confused with Puzzolan or so-called slag cements which are simply mechanical mixtures of slag and slaked lime ground together without burning Such cements are suitable only for use under ground and in moist locations

The manufacture of Puzzolan cements in this country has practically been abandoned

The remarkable growth of the Portland cement industry is not equalled by any other manufactured article This is due to the economy durability and plasticity of cement and concrete work While large engineering work, such as dams, bridges, and heavy reinforced concrete buildings, consume large quantities of cement the bulk of consumption at the present day is in a multitude of small uses It takes an average shipment of only five barrels a day to take care of the average customer of a large cement company

For example, there is a steady increase in the application of cement to new uses on the farm, such as silos, fence posts, barn floors feeding floors watering troughs corn cribs etc There as elsewhere concrete is rapidly displacing all forms of wood construction this process being hastened by the continually advancing cost of lumber

Beautiful effects are now being obtained in concrete surface finishes and its use in decorative work is advancing rapidly

The use of Portland cement will continue to increase until the campaign of education of the small user has reached its finality In this direction a great work is being done to educate the general public in the proper use of cement by individual manufacturers, by the Association of American Portland Cement Manufacturers, and by the cement shows which are given in several of the largest cities every year

In conclusion it will be seen from the foregoing that most of the problems of utilization of wastes or by-products of the blast furnace have been solved and that these solutions in addition to being highly profitable, are powerful factors toward the conservation of our natural resources

Portland cement manufactured from slag, to a large extent, replaces wood the waste gases displace coal, and reclamation of the flue dust conserves the deposits of iron ore

Determining Aeroplane Altitudes*

How a Machine's Height is Measured

By Henry Harrison Suplee

MEASUREMENTS of altitude are usually more difficult of precise determination than those made at or near the surface of a comparatively level country This is evident in connection with the frequent revisions which have to be made of the altitudes of mountain peaks and it becomes especially apparent when the true height attained by an aeroplane is to be determined

The early performances of flying machines were comparatively limited so far as altitude was concerned the height above the surface being little more than was necessary to insure safe clearance above trees buildings and similar obstructions It is only within the past year that altitudes of several thousand feet have been attained but since the aviators have succeeded in acquiring greater control over their machines and have themselves discovered that no serious difficulty attends the conduct of flights in the upper air there has arisen a competition among sporting airmen to secure the record altitude which demands some reliable method for measurement of the true position above the surface of the earth Apart from the desirability of determining the correct height attained in any such competition it is also extremely important to be able to measure the correct position of an enemy in the air as soon as the aeroplane enters the domain of warfare The range must be obtained if the special aerial guns are to do effective work while knowledge of the true altitude is also most desirable in connection with the work of the scouting aviator

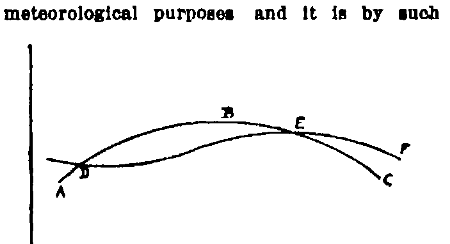
Several requirements must be met in considering satisfactory solutions of the problems connected with aerial altitude measurements Broadly two fundamental methods have to be considered one in which the apparatus employed is carried in the aeroplane itself the other in which the measurements are made by the use of instruments observing the flying machine from the ground These again may be divided into methods which enable the altitude to be determined immediately and continuously and those which require subsequent computations to be made from the observed data

The older aeronauts usually depended upon the barometer as an indicator of altitude and with the sustaining power of a large balloon and the opportunity afforded of consulting such an instrument carefully a certain degree of precision was obtained especially when a high grade mercurial barometer was carried and simultaneous readings were taken on the surface of the earth Even with a carefully calibrated aneroid compared with a standard instrument immediately before and after the trip the altitude attained might be fairly well determined provided the rate of ascent and descent of the balloon was not too rapid

PHOTOGRAPH OF ISLE ST LOUIS TAKEN FROM BALLOON

The known distance between river banks and the known focus of lens enable altitude to be computed

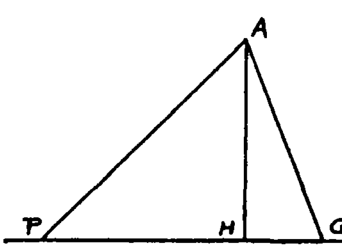
In the case of the aeroplane however the conditions render it impracticable to use a mercurial barometer while the demands upon the operator's attention preclude the possibility of visual readings and records Reliance therefore has to be placed upon the recording aneroid barometer similar in general construction to the instruments generally employed for meteorological purposes and it is by such apparatus that most of the published altitudes attained by aeroplanes have been determined



CURVES SHOWING LAG OF BAROGRAPH RECORD

Records of this kind however, must be accepted with caution and should be carefully checked, whenever possible, because of the conditions under which the instruments are obliged to act are hardly conducive to a very high degree of precision.

A brief examination of the construction and action of the aneroid barometer will show why this is so The aneroid barometer is really a special form of pressure gage, intended to measure external pressures generally less than the ordinary atmospheric pressure at sea level The pressure gage as usually employed in engineering work is employed to determine pressures maintained in closed vessels such as steam boilers reservoirs of compressed air or of water under pressure and the like and it is not difficult to make suitable connection and lead the pressure fluid into some kind of a closed chamber in the instrument and utilize the dilatation or other movement of the walls of the chamber to indicate the variations in pressure In the case of the barometer however the pressure fluid is the external air and the arrangement of parts must be practically reversed This is effected by employing a small chamber usually cylindrical in form, somewhat like a short drum the top and bottom being corrugated in order to permit a certain amount of movement If the air be exhausted from such a chamber the tendency will be for these corrugated ends to collapse together under the external pressure of the air and if this tendency is opposed by a spring of sufficient strength to hold the ends apart the apparatus will be in equilibrium so long as the pressure of the external atmosphere remains constant If the external pressure increases the corrugated ends will move together while if the pressure decreases the force of the spring will pull them further apart. The combination



TRIANGULATION METHOD FOR DETERMINATION OF ALTITUDE

therefore will respond at all times to the variations in atmospheric pressure It is evident that the amount of movement permissible is limited by the elasticity of the metal and by constructive details and that it is in all cases very small

It is necessary therefore to use some method of multiplying the motion in the vacuum box as it is termed In the ordinary dial barometers of the Naudet type this multiplication of motion is effected by the combination of levers and of watch-chain, often visible through the opening in the front, while in the recording barometers of the Richard design recourse is had to the use of several vacuum boxes built up together in such a manner as to secure the accumulated movement of all, this increased movement being also multiplied by leverage A pencil attached to the end of the lever enables the vertical movement to be recorded upon ruled paper, and if this paper is kept in motion at right angles to the pencil movement by means of clockwork a curve of pressures will be automatically described It is an instrument of the latter type which has been used in most of the recent altitude flights of aeroplanes.

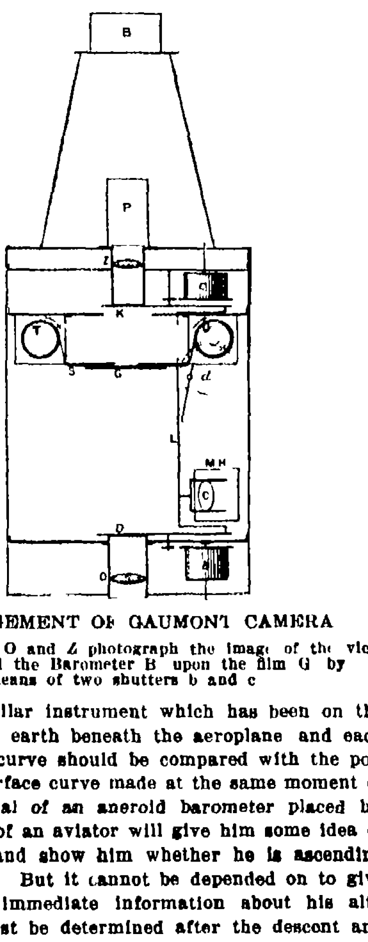
The great difficulty in obtaining reliable records with such a barometer lies in what may be termed its "lag." As will be perceived from its construction a certain amount of time is required for the mechanism to respond to changes in external pressure. This lag is due not only to the movement of the vacuum box itself, but also to the frictional resistance and inertia of the multiplying mechanism—and, indeed, it is principally caused by the latter The result is that the instrument does not respond quickly enough to follow

* Reprinted from Cassier's Magazine

rapid changes in altitude. This may readily be demonstrated by carrying an aneroid barometer in the hand while making a rapid ascent in the express elevator of a tall building. The pointer will be seen to fall for some little time after the elevator has reached the top of its run showing that an immediate reading would have been erroneous. In mountain ascents and similar measurements this error is eliminated by giving sufficient time for the instrument to catch up with the pressure changes and under such conditions very precise altitude determinations may be made, but this is impracticable in the case of the aeroplane.

The extent to which this lag may affect the indications of a recording aneroid barometer is seen in the diagram. If the curve *A B C* indicates the actual pressures of the atmosphere and the transition be rapid the recording barometer which may be correct at the point *D* will not rise quickly enough to trace the true curve and will still be rising when the correct curve has begun to fall so that the record on the paper of the instrument will be something like *D E F* different both in form and position from what it should be. Such a deviation from the truth will be greater or less according to the rapidity in the change of altitude. In general it may be accepted that the recording barometer as at present constructed may show the correct height of the aeroplane by which it is carried if the machine soars at a fairly constant height for a moderate time—probably half an hour would be ample—but that under more rapid altitude changes it will indicate a lower altitude than the true one.

In any case it is impracticable to obtain a reliable determination by the direct reading of the instrument alone. The reading should always be compared with



ARRANGEMENT OF GAUMONT CAMERA

The two lenses O and Z photograph the image of the view beneath and the Barometer B upon the film G by means of two shutters b and c

that of a similar instrument which has been on the surface of the earth beneath the aeroplane and each point on the curve should be compared with the portion of the surface curve made at the same moment of time. The dial of an aneroid barometer placed before the face of an aviator will give him some idea of his altitude and show him whether he is ascending or descending. But it cannot be depended on to give positive and immediate information about his altitude; this must be determined after the descent and comparison with the station barometer.

It is true that there are certain types of aneroid barometers notably the improved instruments of the Goldschmidt pattern, which are notably free from lag owing to the direct connection between the vacuum box and the indicating arm but these instruments have as yet, not been made in the recording form and require careful and precise ocular readings to be taken and the altitude subsequently computed. While especially well adapted for mountain service and for the measurement of altitude determinations upon the surface of the earth they have not as yet been adapted to aeronautical purposes. It is probable that a barograph combining the accurate indications of the Goldschmidt barometer and the convenience of the well known disk recording pressure gage may be constructed for this purpose.

The suspension of a barograph when carried in an aeroplane is a matter which demands attention. Vibrations in themselves are rather beneficial than otherwise in the use of an aneroid barometer and it is desirable that the ordinary instrument should be tapped before a reading is taken, in order that the frictional resistance of the pivots and other working parts may be overcome. The continual trembling of the aeroplane motor, however, introduces vibrations into the record curve, which may become periodical and excessive unless the instrument is carefully suspended. M Latham suspends his barometer from his neck but a better plan is that devised many years ago by the late Col Renard the case of the barograph being placed within a bamboo cage and held suspended in space by a number of rubber bands. It

PHOTOGRAPH TAKEN IN GAUMONT CAMERA, SHOWING BAROMETER DIAL UPON VIEW

has been shown that an instrument thus suspended may be allowed to drop from a height of 10 or 15 feet to the ground without injury. Barographs fitted in this manner have been successfully used upon the *ballons-sondes* or free exploration balloons sent out for meteorological investigations.

Optical methods employed from the aeroplane itself are necessarily limited since they usually demand more attention than can be given by the operator himself and require the service of an independent passenger. The principle is that of the well known artillery range-finder the observer in the aeroplane sighting upon two points on the ground and reading the corresponding distance on the scale of the instrument whence the proportionality of similar triangles gives the altitude or the scale of the instrument may be so graduated as to enable the altitude to be read directly.

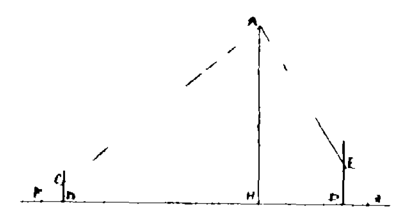
This principle however may be still further extended by the use of the apparatus already fully developed for the operations of photogrammetry or photographic surveying.

The idea of taking photographs from a balloon appears to have originated with Nadar as long ago as 1855 but it was not until the perfection of the gelatino bromide dry plate and the consequent possibilities of instantaneous photography that practical results were obtained. Attempts were made in France in 1878 by Dragon and by Triboulet and in 1880 by Desmarets while in 1883 some very successful photographs were taken in England by Shadbolt. Photography from balloons thus became recognized as a valuable adjunct especially in connection with military observations and its possibilities have by no means yet been exhausted.

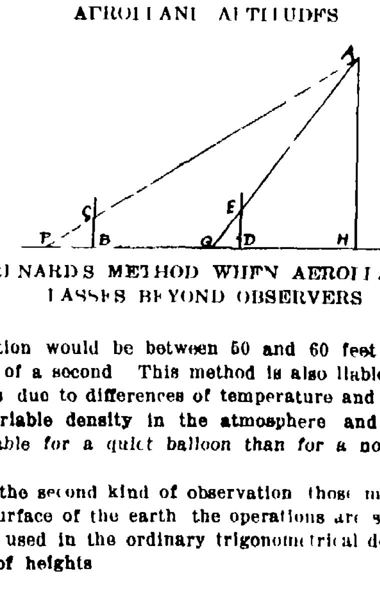
The excellent work which has been done by French topographers notably by Col A Laussedat using cameras of special design arranged so as to enable several correct perspective views to be combined into

clearly marked monuments on the field furnishes the necessary information and the proportion between the true distance between two stripes on the field and their distance on the photograph will give the relation between the focus of the lens and its height above the ground. When no predetermined base is visible it may still be possible to find out subsequently the dimensions of some building or other object in the picture and thus enable the altitude to be computed. Several years ago M Gaumont devised an ingenious combination of camera and aneroid barometer so arranged that the dial of the barometer was photographed upon each picture thus furnishing a record of the altitude at which each negative was taken. This method involves the general objections to the use of the aneroid which have already been mentioned but the plan has wide possibilities in connection with probable improvements in barometers for this purpose.

An ingenious plan which has been suggested for measuring the altitude of an aeroplane and which while it requires the services of an independent operator demands no other apparatus than an accurate stop watch is the acoustic method. Any sharp sound such as a quick whistle or a report which may be differentiated from the noise of the machine itself will be returned to the ear of the operator in the form of an echo from the surface of the earth. If therefore the time elapsing between the sound and the echo be noted the corresponding distance may be estimated from the known velocity of sound. Taking the velocity of sound at 1 100 feet per second or a little more than 100 feet for a tenth of a second and remembering that it is the double distance going and returning which is thus computed the error of ob



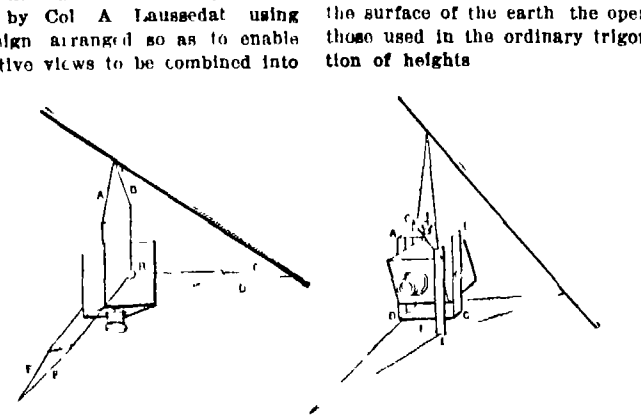
RENARDS METHOD FOR DETERMINING AEROPLANE ALTITUDES



RENARDS METHOD WHEN AEROPLANE PASSES BEYOND OBSERVERS

servation would be between 50 and 60 feet for one-tenth of a second. This method is also liable to variations due to differences of temperature and of layers of variable density in the atmosphere and is more available for a quiet balloon than for a noisy aeroplane.

In the second kind of observation those made from the surface of the earth the operations are similar to those used in the ordinary trigonometrical determination of heights.



METHODS OF SUSPENSION OF CAMERA FROM AEROPLANE

a single topographical map shows what may be done when a direct plan can be photographed from above. Already the camera has been arranged to permit photographs to be taken from observation kites and a similar apparatus is adaptable to the aeroplane.

By having a ruled screen placed within the instrument so that the lines are photographed upon the film at the same time as the surface of the earth beneath the scale of the picture may readily be determined in connection with the known focal length of the lens and thus the only element required to be known is the true dimensions of some object in the picture. In the case of the altitude record trials the use of certain

Thus if an aeroplane be situated at *A* and two observers at *P* and *Q* at the extremities of a base line of known length and simultaneous observations are made of the angles *A P Q* and *A Q P* the triangle will be completely determined and the height *A H* may be computed. If the observers are directly beneath the aeroplane the altitude will be obtained very simply but this is rarely the case. It will therefore usually be necessary to make three simultaneous observations from as many known points from which the true height may be obtained.

At the Harvard Boston Aero Meet in September 1910 trigonometric measurements were made with a

base line of somewhat more than 6 000 feet. The operators were provided with standardized watches to enable tally to be kept of the observations and with head and breast attached telephones to enable the word to be passed for the moment of the simultaneous observations. Since transit instruments were employed it was possible to measure both vertical and horizontal angles and thus the results were obtained with but two observing stations. For ordinary angular measurements of this sort the sextant has also been employed but the precision is necessarily lower than with the transit.

Another method suggested by Commander Paul Renard may be applied under certain conditions. Two observers are placed at points P and Q the distance P Q between them being known and it is also being known that the flight of the aeroplane will pass over some point vertically over the line between P and Q. The two observers are furnished with instruments which enable them to measure the apparent height. In the absence of sextants or other instruments of precision a simple substitute may be found in the form of rods placed at B C and D E these being erected as nearly vertical as possible and at points at which the distances B–P and D–Q are known. These rods should be graduated so distinctly as to be easily read by the observers and it is essential that P B and D Q should be on the same alignment. The observers are to be instructed to watch for the passage of the aeroplane and to read the apparent point at which it crosses the graduated rods at the moment when it passes over the base line. With these readings and the knowledge of the distance between the two observers the altitude of the aeroplane may be computed as follows. From the two sets of right angled triangles we have

$$\frac{P\,B}{C\,B} = \frac{P\,H}{A\,H}$$

and also

$$\frac{Q\,D}{E\,D} = \frac{Q\,H}{A\,H}$$

By adding these two equations together we get

$$\frac{P\,B}{C\,B} + \frac{Q\,D}{E\,D} = \frac{P\,H + Q\,H}{A\,H} = \frac{P\,Q}{A\,H}$$

In this formula we have the quantities P B Q D and P Q already known while the single unknown which may thus be determined is the altitude A H. This method it will be observed is independent of the particular values of the horizontal distances H P and H Q—that is the aeroplane may pass anywhere over the line between the two observers provided the corresponding readings on the two graduated rods are correctly taken. It is desirable however that the aeroplane pass between the observers although readings may be taken if it should pass beyond them as shown in the figure. With experienced observers this will give fairly good results since the men will secure approximately simultaneous readings. The principal defect is that it gives the height over some undetermined point H and hence it is well if possible to have the whole system arranged upon a fairly level plain.

When a trial for an altitude record is made upon this plan the aeroplane may circle above the base line and its height taken every time it cuts across the line the observations being numbered to enable the proper ones to be paired.

In many cases especially in warfare it is the distance between the observer on the earth and the machine in the air which is desired. This is really a problem in range finding, and the principles are [illegible] known.

At the camp of Chalons the Boushier telemeter [illegible] used with a fair measure of success. The instrument consists of two telescopes, of which the objectives are fixed at one meter apart and the images brought together by reflectors, so that measurement is made of a very acute triangle the aeroplane being at the sharp apex opposite the base of one meter.

It will be seen that at the present time there is no method which is entirely satisfactory for general use. Trigonometrical observations from the ground, while the most accurate require much previous preparation practicable only during some exhibition or sporting event and possibly capable of permanent installation in important fortresses liable to attack, but otherwise inapplicable for lack of time and need of suitable apparatus.

The photographic methods require in general the services of an additional operator although it is possible that an automatic device may be produced. In any case it does not furnish its report until after the flight is over and the film developed and hence its usefulness is limited to the production of a subsequent record of the trip. It may well be investigated however in connection with the substantiation and verification of altitude records made by other methods.

There remains the barometrical method and, while this is at present lacking in precision it offers the greatest opportunities for improvement and development. In view of the high degree of precision attained in the determination of mountain altitudes by aneroid barometers of the Goldschmidt type it seems altogether possible that some improved variety of barograph will be produced in response to the demand which the aeroplane is making.

Sugar Refining*

The Processes of Manufacture

By W D Horne

Just as sugar made from the cane appears first to have been used in the Orient and to have followed a westerly path so we find the art of refining had its origin in the East and progressively traveled westward. Although the sugar cane was in use in India as early as the fifth century B C we learn of refining having been practiced first about 500 A D in Mesopotamia. A large trade in refined sugar gradually developed between the Orient and Europe and in 1470 a certain Venetian was awarded a government payment of 100 000 crowns for discovering a process of refining sugar which was from that time extensively carried on in Venice. In the sixteenth century Antwerp led in the sugar trade in Europe and in the refining industry. England began refining sugar in 1544 and gradually gained the supremacy over the other European countries in the industry. With the development of refining in Europe the price fell from two shillings per pound in the thirteenth century to four pence per pound in the sixteenth century. This undoubtedly was partly due to the general introduction of the sugar cane into the West Indies from 1510 to 1650 and the consequent enormous production of sugar and its ever growing commerce.

As early as 168[illegible] there was a refinery in New York city and by 17[illegible] New York Philadelphia and Boston refined about 1 [illegible]00 000 pounds of sugar yearly out of the 60 000 000 pounds which was annually consumed being about two per cent of the entire amount. Refined sugar was heavily protected by duty and sold at [illegible]0 cents per pound. By 1860 there were forty one refineries in the United States producing $42 000 000 worth of sugar annually. Now there are about half as many refineries turning out three million tons of sugar annually worth about $ [illegible]00 000 000.

In 174[illegible] Marggraf succeeded in obtaining 6.2 per cent of sugar from beets and Achard established the first beet sugar factory in Austria in 1769. Napoleon to encourage the industry on account of the difficulty in obtaining sugar because of the blockade of the French ports during the wars heavily subsidized the industry in France about the beginning of the last century. It gradually spread over Europe. The first experiments in beet sugar manufacture in the United States were made in 1830 and again some beet sugar was made in California Illinois and Wisconsin during the period from 1863 to 1876. Claus Spreckles built a factory in 18[illegible]0 at Alvarado Cal which was the first to meet with pronounced success. The industry has developed considerably since then until there are now sixty four factories located principally in the western States and Michigan with a total output last year of 457 000 tons being 13.92 per cent of the consumption of the country. By 1900 the production of beet sugar had so increased that it had grown to be 60 per cent of the world's sugar supply.

In 1910 11 the world's sugar supply will be 17 000 000 tons—50 per cent cane and 50 per cent beet. Sugar is produced also in small quantities from the sap of the date palm in some eastern countries. Prolonged attempts were made in this country some fifteen or twenty years ago to produce sugar from sorghum but without success as the dextrinous bodies in the sorghum juice prevent large quantities of the sucrose from crystallizing and this plant is now used exclusively for the manufacture of syrup. The annual production of maple sugar in this country amounts to 6 000 tons but as maple sugar owes its principal value to its pleasant flavor rather than to its sweetness it is always sold in its raw state as refining it would rob it of half its present value and render it impossible of competition with cane or beet sugar. Milk sugar is produced to some extent and used always refined for medical purposes principally.

Sugar refining consists essentially in the purification of the crude crystalline material through the well known process of recrystallization. To this we can add the second process of absorption of impurities by means of bone black first introduced by Derosne in 1812. By this means is affected a direct separation of impurities from the sugar solution and a large removal of the coloring matters allowing of the more easy production of perfectly white crystals. While the process is relatively a simple one and perhaps more mechanical than chemical in its nature the enormous consumption of sugar in the country and keen competition in manufacture have led to the establishment of very large and elaborately equipped plants for the conduct of operations where every economy of procedure is carefully observed. The great amount of capital involved in erection and maintenance of such plants together with the highly developed technique required for their operation has tended to keep the business in relatively few hands and to render it a dangerous enterprise for any but the most thoroughly equipped to venture upon. The sugar refineries of the country are in a few spots—New York Philadelphia Boston New Orleans, San Francisco and Baltimore containing practically all of them. In 1910 the country consumed 3,350,355 long tons of sugar practically all being refined. Of this amount 333 006 tons were cane sugar raised in Louisiana and neighboring States. 457 000 tons were beet sugar raised and refined during the process of manufacture in our western factories. 2 472 756 tons came from our insular possessions and Cuba and 73 393 tons came from other foreign countries. We imported practically no beet sugar and we exported practically no sugar at all. With the exception of Great Britain the United States leads the world in the consumption per capita of sugar this being 81.6 pounds per person. Most of this goes into direct use for household purposes and yet enormous quantities are consumed by manufacturers of confections preserves condensed milk as well as by canners of fruit ice cream makers soda water fountains and many other users.

As will be seen the natural location for a sugar refinery is on the water front where it can more economically receive and unload the great cargoes of sugar and of coal which come to it almost daily for a modern refinery melts from a million to three or four million pounds of sugar per day. The economical handling of this vast amount of raw material and the successful guidance of so much organic matter in solution at high temperatures through long and complicated processes without fermentation, decomposition discoloring or waste is no mean accomplishment, but as in every other instance of manufacture the whole matter has been worked into a routine which once properly installed, almost takes care of itself. As the sugar whether in solution or later in granular form has to pass through many operations in a continuous stream as it were, it is thus found advantageous to have the units of a sugar refinery many stories high so as to take advantage of gravity to pass these solutions from place to place or in delivering the dryer material from one department to another. This holds true equally of the bone-black and we find the char house is usually a tall building in close proximity to the sugar house itself. In many instances the boiler house also has its coal bunkers in the upper story, allowing the fuel to feed by gravitation into the fire room or even upon the grates themselves. The high cost of real estate in cities also makes it advisable to extend upward rather than laterally. Each sugar refining plant will be found to have a large dock department for the receiving, weighing and storage of raw sugar; a boiler house for the generation of steam for power and evaporation, a wash house for the so-called washing of raw sugars, the pan house for boiling grain-

* Yale Scientific Quarterly

[illegible] and other processes of manufacture of dry sugars a char house for the accommodation of the bone-black filters kilns for the re-burning of the char etc., and usually a warehouse for the storage and shipment of refined products. These departments are not always built separately and frequently more than one of them will be found in the same building

Somewhat different processes are used for the refining of beet and of cane sugar but the difference consists principally in the method of defecation or clarifying the original raw sugar solution of its suspended impurities and part of its coloring matter In either case the first operation is the unloading weighing and storage of the raw sugar whether in bags baskets mats, hogsheads or in other packages in proximity to the melting department A portion of the sugar is usually taken direct from the scales to the wash house, where the sugar is raised by a bucket elevator to an upper story and mixed with a low grade syrup while passing through a conveyor to the raw sugar mixer The magma of raw sugar and syrup is fed from the mixing tank containing revolving arms into centrifugal machines which purge the syrup from the sugar in a few minutes Water sprinkled on effects the final washing giving a sugar of high purity and a low syrup This sugar is dissolved in a round melting tank with revolving arms in hot water to a density of about 30 Beaumé pumped into blow ups treated with a very small amount of acid calcium phosphate and made slightly alkaline with milk of lime Such a solution would boil at about 217.5 deg F and its temperature is next raised to something under 200 deg F whereby tricalcic phosphate is precipitated entangling the suspended impurities and also removing possibly by precipitation some of the coloring matter The lime has the effect of precipitating some of the gums and the heat at the relatively slight alkalinity precipitates most of the albuminoids. This process is applicable to cane or beet sugar or to a mixture but in defecating beet sugar alone it is sometimes customary to add a few tenths of a per cent of caustic lime precipitating this with carbon dioxide which precipitates suspended matters and largely removes the color In either case the solution must be mechanically filtered This is commonly done through cotton twill bags inclosed in woven sheaths These are called Taylor filters *In the case of beet solutions the* filter press is sometimes used but this is not applicable to cane sugars which are gummy and sticky and clot the filter press Beet sugar solutions are sometimes treated with sulphur dioxide after this preliminary alkaline defecation and again filtered in presses in a very faintly alkaline or neutral condition The filter bags after becoming nearly exhausted are allowed to drain during several hours are washed with hot water several times allowing to drain between times and are removed from the closed iron tanks in which they hang for washing They are turned inside out and rinsed in several waters passing through wringers between them The muddy water thus obtained still contains some sugar and is pumped through filter presses the sugar of the clear filtrate being recovered The press cake containing very little sugar is discarded

The clarified solutions are next filtered through bone-black contained in cylindrical filters or cisterns The liquor gives up the greater part of its color and a less per cent of its ash and organic impurities to the bone black and is collected in storage tanks according to color and purity Lower grade solutions of greater color follow the washed sugar solution on the char so that the last filtrate from the char is pretty dark in color and much lower in purity

The char filtered liquors pass to the vacuum pan holding about 1 000 to 2 000 cubic feet where it is boiled to grain and concentrated to a low water content.

This magma is dropped into the mixers or crystallizers from which it passes to the centrifugal machines, where it is purged and washed with a spray of clear water sometimes followed by a spray of blue water *formerly colored* by ultramarine which of late years has been replaced by harmless aniline colors prescribed by the government since the pure food law put its ban on ultramarine as a mineral substance not to be allowed in sugar products The syrups can again be boiled in the vacuum pan to produce granulated sugar and when the impurities and color accumulate enough the syrups are used for yellow sugars

The moist sugar from the centrifugal machines containing a small per cent of water is passed through nearly horizontal revolving drums containing longitudinal shelves projecting inward which have the effect of picking up the sugar and sprinkling it through the current of warm air which is drawn through the opposite direction

The sugar thus dried next passes through revolving screens which separate it into different grades according to the size of the crystals giving rise to granulated sugar to be bagged or barreled

In making cube sugar some of this moist granulated sugar from the centrifugal is pressed into cubical blocks by an ingenious machine and gently dried in ovens during a few hours Cut cube sugar was originally made by draining the magma or boiled mass of sugar in conical molds for about two weeks with occasional washing by means of pure sugar solution sawing the dried cones into disks and cutting these across into cubes A modified process of this kind is in use in Europe and to some extent in this country in which the conical molds are supplanted by rectangular frames which are purged in centrifugal machines in minutes instead of weeks

Yellow sugars are made from low testing syrups which are boiled in a vacuum pan and contain smaller softer crystals than higher grades of sugar with considerable amounts of adherent mother liquor

To return to the bone-black this is washed down by hot water after the last sugar solution sinks below its surface and is thus freed from the sugar Certain mixing of the water with the sugar solution is inevitable *giving rise to a zone of sweet water* As the water begins immediately to dissolve the impurities which the char had just absorbed *from the impure* sugar solution passed through it this sweet water contains impurities along with the sugar and has to be separated from the main filtrate and treated by itself The sugar washes out faster than the impurities however and when most of the sugar has been removed the stream of outgoing water is turned to the sewer and continued until the char is pretty nearly free of what water can remove The bone black is then drained emptied from the filter by gravity upon a dryer on the floor beneath through which it passes to the kilns These are furnaces provided with internal iron pipes through which the char passes *By proper regulation of the flow of the* char through these retorts its temperature is kept at a point which subjects the impurities still *remaining* in it to destructive distillation Moisture ammonia carbon dioxide and other gases are given off some of which are highly inflammable leaving in the char a small residual amount of carbon The char after cooling is then ready for use again and this entire cycle of operations is repeated

When the carbon accumulates to such an extent as to choke the pores of the bone black the decolorizing power of the char diminishes so that finally it must be discarded Of late years this trouble has been *obviated by the introduction of the* Weinrich system of de carbonization in which the char is passed through a roaster very much like the granulator before described and heated on the outside by direct fire to a suitable temperature The air admitted suffices to burn off the impurities without attacking the carbon of the char itself in any marked degree By this means char can be kept at a high point of efficiency for a considerably longer time

The large amount of heat passing away from the char filters in the hot wash water is recovered by passing this water through tubulated heat economizers in which the incoming city water passes in the opposite direction absorbing the heat of the outgoing water

Water for sugar refining should be as soft as possible and as free from sulphates iron color and suspended matter as can be

The sweet waters from the char are evaporated in multiple effect evaporators and usually mixed with other low grade solutions

Fuel is an important matter in sugar refining large quantities being used to generate steam for *power purposes evaporation and heating* This in large part explains why sugar is not refined where the raw product is made the fuel cost being prohibitive

The laboratory organization in a sugar refinery is a matter of great importance It is the laboratory's function to keep track of the quality not only of the raw and finished material but also of the material in process of refining not only to show the efficiency of each process but to enable the most economical and expedient combination of the various liquors syrups and other solutions throughout the process of refining so as to prevent unnecessary work and to indicate the most advisable method of handling All raw sugars have to be analyzed in considerable detail a close watch is kept on fuel variations in the water supply must be noted finished products must be kept up to the mark and waste products must be carefully checked up to avoid excessive loss New processes have to be devised to meet varying condition and experimental work must always be pursued to keep up with the latest improvements and discoveries in the art

The routine must go on day and night without cessation and all chemicals apparatus and other appliances must be properly standardized and those standards maintained *Analytical processes* have to be investigated and tests devised for new needs *many materials entering into use in a large factory* have also to be subjected to occasional tests or analyses and competent advice has to be given as to the desirability of new methods or processes suggested from whatever source

All this calls for an elaborate competent and smooth running chemical organization The routine tests principally of purities are conducted by young men carefully trained in this work and provided with every possible facility for its accurate and speedy accomplishment In the laboratory many tests are made on char samples and wash water daily all raw materials and waste products all miscellaneous sugar samples *as those involved in stock taking* and so on

The laboratory also keeps careful statistical records of all its various work and compiles elaborate monthly and yearly statements covering all these tests The laboratory should be provided further with a good general chemical library and ample files of sugar journals as well as those of more general nature A good laboratory should lead the work of the house rather than follow it by showing the way over difficulties that are from time to time bound to spring up by inventing and elaborating new processes of more economical work by keeping in touch *with the outside world and in general by assisting* a smooth running of the entire enterprise

A Graphical Solution of the Quadratic Equation*

By Albertus Darnell

Prof Carl Runge of Göttingen among other applications of graphical methods, mentions a very interesting solution of the quadratic equation Prof Runge it will be remembered was Kaiser Wilhelm Exchange Professor at Columbia University during the past year

First consider the following graphical calculation for determining a line which shall represent the value of $f(x) = a_0 + a_1x + a_2x^2$ for some particular value of x.

Lay off $AB = a_0$, BC perpendicular to AB and equal to a_1, CD perpendicular to BC and equal to a_2. Now make DE equal to the unit of measure, EF perpendicular to DE and equal to the value of x for which we wish to compute the value of $f(x)$ Draw GH perpendicular to DF AH is the linear representation of $f(x)$ when x equals EF

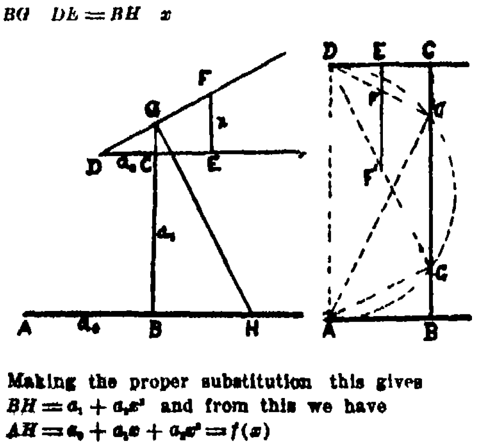
It is obvious that the triangles of the figure are similar. Therefore we have

x $CG = DE$ a_2

Remembering that DE is the unit this gives $CG = a_2x$ and from this we have

$BG = a_1 + a_2x$

BG $DE = BH$ x



Making the proper substitution this gives $BH = a_1 + a_2x^2$ and from this we have $AH = a_0 + a_1x + a_2x^2 = f(x)$

If the value of x had been so chosen that the point H had fallen at A we should evidently have had a value of x satisfying the equation $f(x) = 0$ This reduces the solution of the quadratic to the problem of constructing a right triangle on AD as hypotenuse with the vertex of the right angle on BC

The next figure shows the application of this method to the equation $2 + 5x + 2x^2 = 0$

EF and EF are respectively the roots $-\frac{1}{2}$ and -2 DE being the unit

The variations of the figure resulting from changes in the signs of the coefficients present no difficulty

An account of the literature on the subject can be found in Encyklopädie der Mathematischen Wissenschaften

* School Science and Mathematics.

Shoe-sole Dressing – Mix over a slow fire 6 000 to 10 000 parts of linseed oil 30 parts spermaceti 15 parts of ceresine 30 parts of resin and 30 parts of turpentine apply the mixture warm to the soles of the shoes and the seams rub off with a rag and dry at the stove

How Exporters Should Pack

Suggestions from United States Consuls and Foreign Business Men

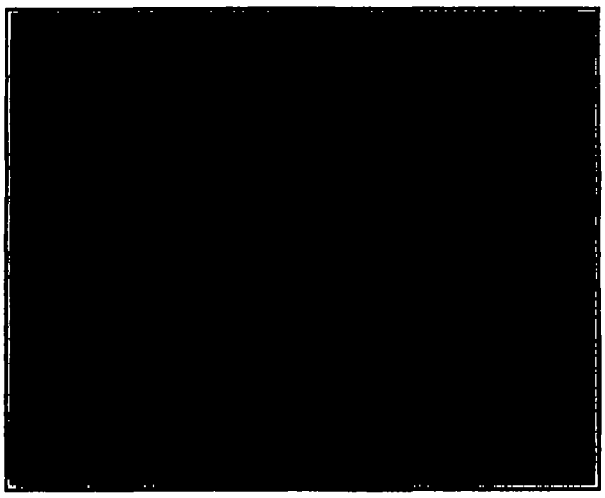
The Bureau of Manufacturers of the Department of Commerce and Labor has in course of preparation and almost ready for the press a monograph on Packing for Export which from the viewpoint of the exporter whether he be shipper of manufactured articles or of natural products is one of the most important publi

What is good packing for shipments to one country may be bad packing for another '

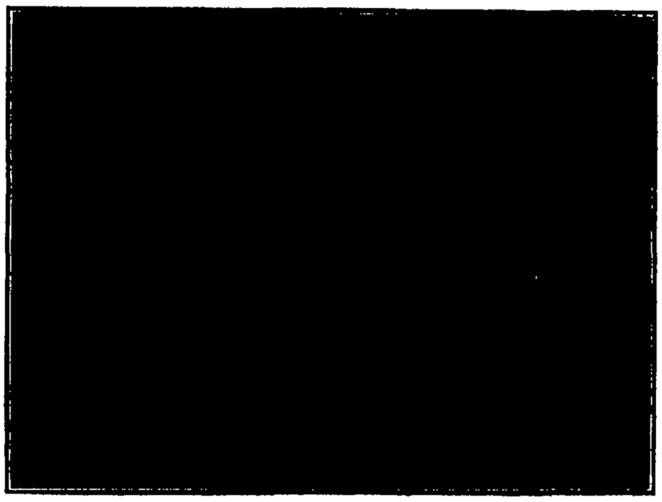
The volume therefore comprises letters from consular officers including criticisms and advice in the effort to help the American exporter

The matter in the following and the accompany

The government bulletin treats at length of the various methods of transportation, rail water rail and water pack animals and man carriers and the style of packing demanded in each instance It also considers the climatic conditions port conditions, danger of pilfering consular regulations marking of shipments



WELL-PACKED SHIPMENT OF PAPER



AMERICAN COTTON PROPERLY PACKED FOR EXPORT

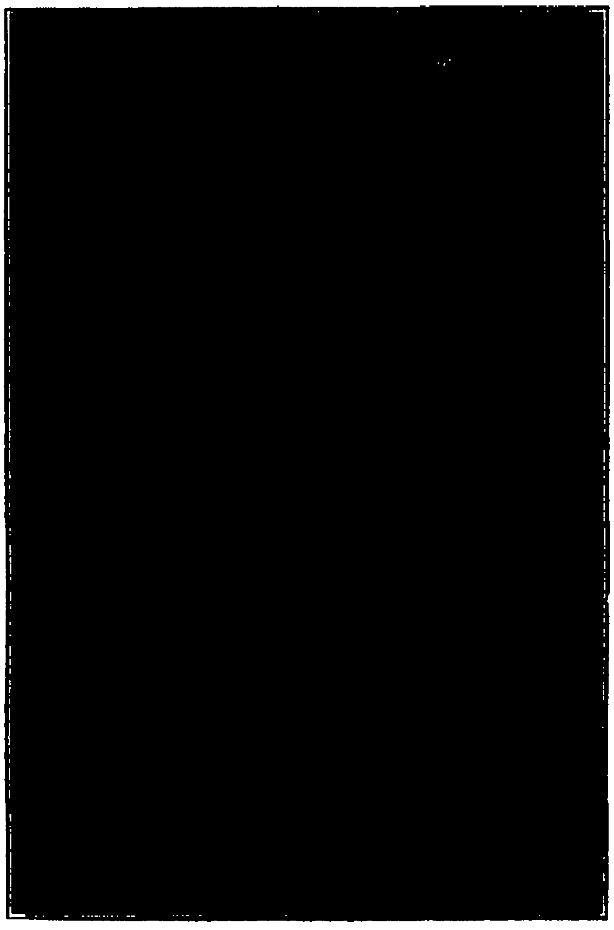
cations over issued for it marks the inauguration of a new propaganda the preachment of the gospel of good packing not from the standpoint of the shipper but from that of the consignee based on the consignee s knowledge of all the conditions at his end of the line which will affect the goods or the materials in which they may be packed The purpose of the monograph will be to tell the shipper just how the consignee wishes the goods packed The consignee from his experience knows what style of packing will

ing illustrations are extracts from the proposed publication

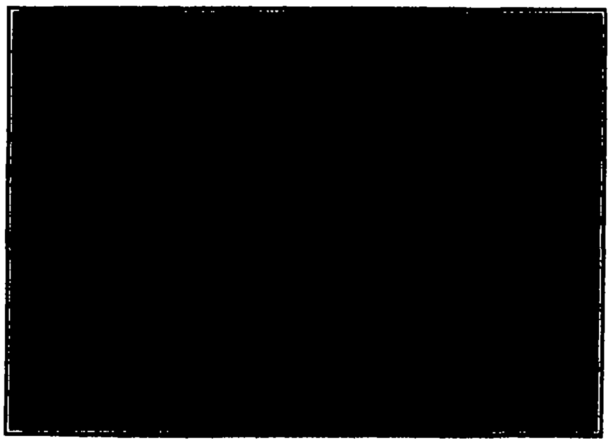
It is said that flagrant cases of defective packing due to the ignorance by Americans of business methods abroad and to the dependence of exporters on their own judgment in such matters have undoubtedly resulted in loss of foreign trade in many instances No doubt the American manufacturer fails to realize that while he may sometimes save a few dollars at this end on a shipment the buyer in foreign markets by rea

and difficulties arising from the use of second hand containers bearing old marks

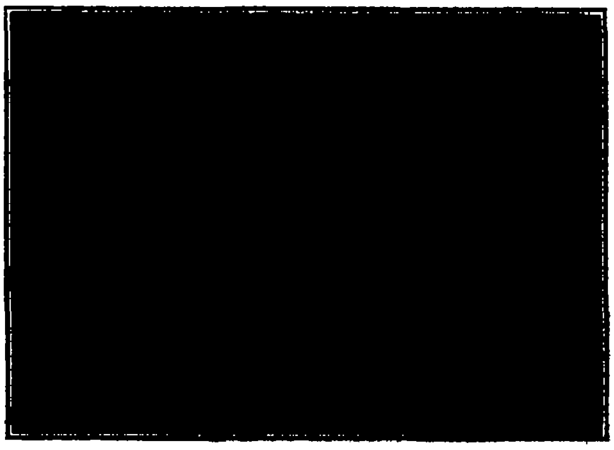
In Ireland certain shipments of American cotton seed meal were received in bags which bore tags showing a guarantee below that called for in the contract Evidently the bags had been previously used for domestic shipments in America and when refilled the tags had not been removed Although the meal held up in analysis to contract quality the tags were a source of annoyance to the Irish importer since many



SHIPPING CASES STRAPPED WITH STEEL BANDS



COTTON CLOTH BALE WITH INADEQUATE WRAPPER



CLOTH CUT BY STEEL BANDS

HOW EXPORTERS SHOULD PACK

stand the handling the goods must receive before reaching his particular point He knows also the packing that will not reach his market in good condition

As Mr A H Baldwin Chief of Bureau of Manufacturers says in his letter submitting the monograph to the secretary

son of lack of facilities to replace broken parts readily and cheaply often has to pay out five or ten times what would have been the original cost in this country or failing to be able to duplicate, there is loss of time and interest on the value of the shipment for several months until parts can be brought from this country "

of his customers complained about them and he was obliged at much expense to have tested samples from each lot sold to show his buyer that the meal ran higher in analysis than the tags indicated. No American cottonseed meal should be exported in bags that have been previously used for such shipments."

The packing of machinery, always an important and

frequently a difficult problem is discussed at length in a very comprehensive article prepared for an English journal by an engineer correspondent and transmitted by Consul Benjamin F Chase of Leeds

The responsibility for poor packing is not always as easily determined as where the manufacturer exports directly for if he ships through an export agent or commission house one party may seek to shift the responsibility to the other Along this line Consul General William H Michael of Calcutta (for many years Chief Clerk of the State Department at Washington) writes

"The goods were packed poorly for foreign trade because the manufacturers packed at the factory for shipment to their export agents in New York or other ports and the export agents instead of repacking simply forwarded the goods in the original cases While the original cases were strong enough and entirely suitable for transportation from the factory to the shipping port, the packing was utterly unsuited to the long and severe strain of transit from point of shipment to India

Frequently much expense can be saved for freight ing by properly proportioning the packages This is well illustrated by Commercial Agent W A Graham Clark of Honduras who tells how a mule can carry 150 or 250 pounds according to the size of the package He says

"It should be noted that if a package weighs as much as 150 pounds a mule can carry only one and as this rests on his backbone he cannot carry much above this weight but he can carry two 125 pound packages strapped one on each side

The information from consuls includes reports from two consuls in Canada three consuls in Mexico one consul each in Central America Costa Rica and Guatemala two in Honduras and so on throughout the world

The definite character of the instructions is illustrated in the report by Consul William W Canada of Vera Cruz who says

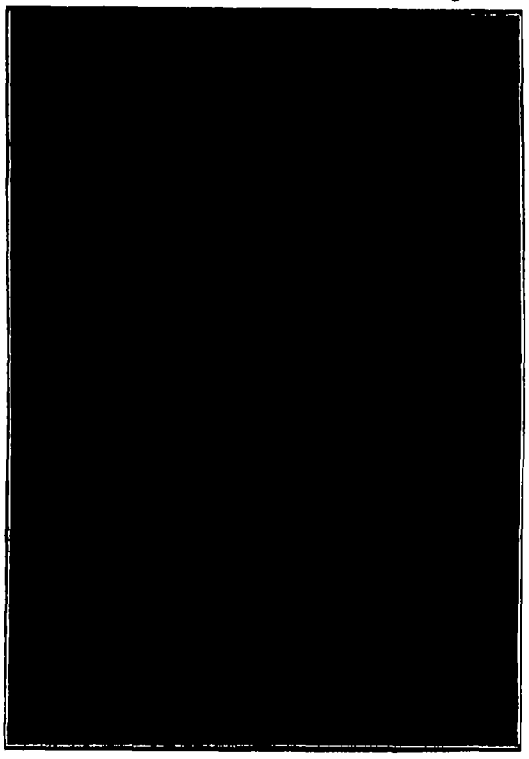
Apparently the campaign inaugurated against faulty packing of merchandise coming from the United States has borne fruit and its good effects are being seen in this port Recently there arrived in Vera Cruz a shipment of 180 kegs of railroad spikes from Pittsburg and of this entire lot only two kegs were in bad condition though their contents were not lost This shipment was put up in first class order as all kegs were hooped with iron and a piece of batten was itted into the tops and bottoms securely nailed and then a piece of strap iron was nailed over these and down the sides of the package

Many ice-cream freezers have been received recently at this port and the methods of packing them should be changed to prevent damage This class of merchandise should be crated in such a manner that there will be no projections outside the crate The articles inside ought to be secure and immovable All detachable parts such as constitute movable mechanism should be secured firmly by wiring The crates in addition to being well and strongly made, should be strapped and wired on the ends"

Consul General Thomas Ewing Dabney of San Salvador says

"Local agents of typewriters have requested that machines be packed in double boxes—one box within

CASE BEARING TOO MANY MARKS



WELL-MADE BOX LINED WITH TIN AND CLOTH

the other—with straw between This will avoid their breaking loose in the cases and being smashed by rough handling

Consul Philip E Holland of Puerto Plata Dominican Republic says

Shippers of tallow should perforate the barrels and recork the holes to avoid leakage By doing this heavy duty would be saved the importer as water tight barrels pay a duty of $1 50 to $3 each regardless of the fact that they are mere coverings

Commercial Agent John M Turner of Argentina and Paraguay says

It is preferable to mark packages on four sides as then a mark will always be in sight On delicate ware the word fragile is suggested as being better than any other as it means the same in a number of languages Stencil marking is better than hand marking with a brush Care should be taken that the mark is distinct before shipping as packages rub together in a ship's hold and marks are liable to be erased or rendered indistinct.

Consul General Maxwell Blake of Colombia says

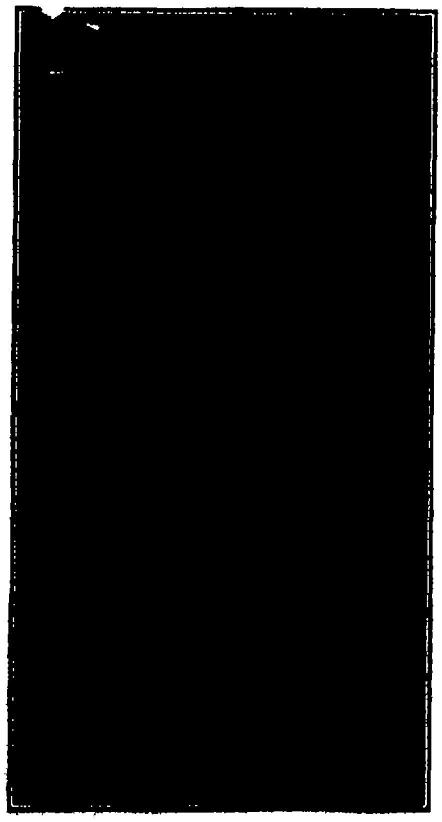
Hacienda proprietors in this country consult each other and manifest a great curiosity with reference to the delivery as to the successful operation of each others new machinery purchased abroad A reputation for unsafe packing is always sufficient to prevent the repetition of such an experience however satisfactory a shipment might otherwise be

As to the This side up with care sign so commonly used in this country Consul General Frank H Mason writing from Paris says

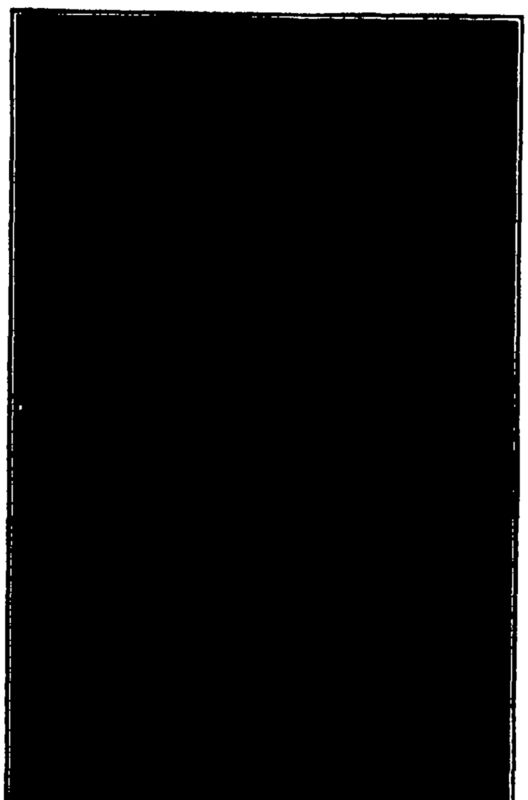
The first general mistake of many American shippers is to pack machinery furniture automobiles etc so that the goods rest on the bottom of the case and they are reasonably safe so long as the case is kept in an upright position They mark the top of the case This side up and take the chance that it will be kept so But in unloading from cars drays and lighters such cases are frequently rolled over and over In the hold of the vessel they are packed so as to secure the greatest economy of space resting on the side or end or even bottom upward At some European ports steam or electric cranes are used which lift the goods out of the hold swing them around and land them more or less gently on the dock At other places the merchandise has to be hoisted on the deck by the vessel's winch and then slid down a long slip slide to the dock striking the bottom with a shock that frequently breaks packages and gives a serious shaking up to the contents

In many of the reports from the consular officers in Europe we find complaint as to the packing of cotton and some point out errors in the packing of apples and other fresh fruits dry fruits lard shoe blacking and other commodities of various kinds

Consul Rufus Fleming of Edinburgh sends an extended report including specific directions for the shipment of a list of over 100 articles comprehending almost all kinds of merchandise and presenting the Scotch idea of the requirements of the trade with great particularity

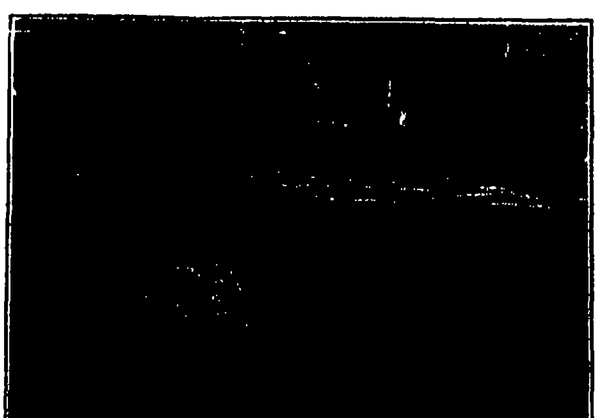


STOVE POORLY PACKED



BOLIVIAN INDIAN FREIGHT CARRIER

BOX AND BALE SHOWING EXCELLENT PACKING



OLD FLOUR BARRELS IN WHICH IRON FITTINGS HAVE BEEN PACKED

HOW EXPORTERS SHOULD PACK

There is hardly a foreign point of the globe from Canada to South Africa the Society Islands, Australia, India or Asiatic Turkey that is not reported in the proposed publication

The illustrations we have given are most interesting and graphically present bad as well as good packing some disastrous results of bad packing and sundry of the freight carriers met with in some of the corners of the world

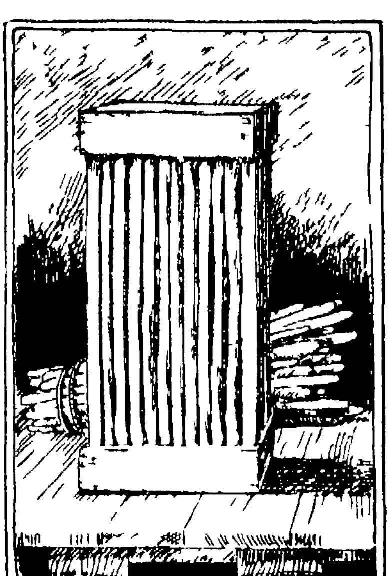
The Bolivian Indian freighter is of special interest Commercial Agent W A Graham Clark of Bolivia says of him

STRAPPED REINFORCED WOODEN PAIL

The Indian himself can carry heavy loads He always carries everything on his back never on his head or in his hands It is curious to see him loading He kneels with his back to the load throws around it two or three coils of a rope which he knots across his chest and then bending over on his face he *staggers to his feet* and *moves off* with a load that two men can hardly lift from the ground with their hands

Of the llamas shown in another illustration it is said that while they are slow in their movements and weak carrying only about 100 pounds each they are prized as beasts of burden in the mountainous sections because they forage for themselves and are not affected by the highest altitudes

The bulletin being a Government publication naturally refrains from any official indorsement of patented devices It is evident however that with the interest that must develop in effective packing a field is afforded for the exercise of invention in the product of some standard package adapted to the conditions and supplying the requisite features demanded by many of the points throughout the world to which our products find their way



STOKES IN CRATE

HOW EXPORTERS SHOULD PACK

Gyroscopes for Stabilizing Aeroplanes

In a paper by C[illegible]rdville in the *Comptes Rendus* some valuable information is contained on the use of gyroscopes as a mean of balancing aeroplanes The gyroscopes used weighed about five kilogrammes and rotated at 6 000 revolutions per minute The gyrostatic action was used to cause rudders to work automatically Experiments with a fixed apparatus were made in a uniform air current and also in variable winds at the top of the Eiffel Tower It was found that the gyroscope with its pivoted frame tended to acquire an oscillatory movement this was overcome by the use of damping planes immersed in water This difficulty was not experienced when the apparatus was applied to gliders 12 square meters in area, the planes themselves being sufficient to damp the *oscillations* This *gyroscopic* governor successfully compensated for disturbances of balance due to distribution of load and to variable winds and was afterward used with advantage in a motor-driven aeroplane Rotation was first obtained by means of flexible transmission and friction gearing at present the driving power is obtained from a small fan exposed to the draught from the propeller

LLAMAS USED AS PACK ANIMALS

Corrosion of Aluminium

Messrs E Heyn and O Bauer, of the Koenigl Materialpurefungsamt have made some investigations on the decay of aluminium About fifty samples of Al in the form of sheet and various utensils have been tested in water and various solutions of salts with a view to elucidating the cause of corrosion of and the nature of the accompanying efflorescent growth on aluminium cooking utensils The results show that Al may be subject to two kinds of decay (a) uniform attack of the whole surface owing to conversion of Al into hydrated oxide and (b) local attack accompanied by scaling and the formation of a comparatively small amount of aluminium hydroxide results in considerable decay Exposure of sheet Al to the atmosphere alone or air free water alone results in no corrosion the simultaneous presence of water and air being necessary as is the case with iron The hardness of the metal determines to a large extent the nature of the corrosion soft Al is usually attacked uniformly but hard-drawn Al blisters and exfoliates in lines agreeing with the direction of rolling the pressing from a circular sheet resulting in these lines being straight on the bottom and curvilinear on the sides of a pressed cylindrical vessel The harder the Al the more liable it is to local attack and annealing at 450 deg C entirely removes this tendency, the corrosion of annealed sheets being quite uniform. [illegible] water and solutions of several salts such as [illegible] and calcium chloride produce uniform cor[illegible]. The concentration of the salt solution has a gr[illegible] effect on the amount of action, in every case a c[illegible] definite concentration producing the most dele[illegible] effect. The composition of the Al has little or [illegible] effect on the degree of corrosion Greasing the [illegible] with vaseline decreased the tendency to corrode [illegible] diminish the corrosion the authors propose th[illegible] Al should either be less severely cold-worked o[illegible] it should be subsequently annealed at 400 to 45[illegible] C to reduce its hardness, but at the same time point out that this reduces the mechanical strengh of the material.

Building Materials and Noise

A German scientist named Nussbaum has for a long time been studying the question of the suppression of noise in dwelling houses He has experimented both in the laboratory and in private houses One point he has ascertained is that the more solid and tough and strong the building material is the more quickly and loudly it conveys sound and its conductivity can best be tested by strokes with a piece of metal The higher the tone the greater the conductivity

Nussbaum has made many experiments with partition walls He has found that those of tiles and cement transmit sound most and those of solid clay least Between the two comes the wall of ordinary brick, and the more the brick is burned the more noise it transmits A quickly hardening lime mortar is to be preferred to a clay mortar One experiment showed that when a floor was covered with sand and cork mats spread over it hardly any noise penetrated to the room below but that when the cork mats were joined together by any material underneath noises were at once perceptible

To the question How are the sounds of the piano or the violin in the neighboring apartments to be excluded? Nussbaum has returned the suggestion that the ceilings be treated as he successfully treated his telephone cell namely to line them with a layer of zinc or lead

New Zealand's Sulphur Island

One of the most extraordinary islands in the world lies in the Bay of Plenty New Zealand It is called White Island and consists mainly of sulphur mixed with gypsum and a few other minerals Over the island which is about three miles in circumference, and rises between 800 and 900 feet above the sea, there continually floats an immense cloud of vapor attaining an elevation of 10 000 feet

In the center is a boiling lake of acid-charged water covering fifty acres and surrounded with blow holes from which steam and sulphurous fumes are emitted with great force and noise With care a boat can be navigated on the lake. The sulphur from White Island is very pure, but little effort has yet been made to procure it systematically

The Alps Could Run the Railways

Engineers in Zurich report after careful examination that sufficient electric power could be developed from the waterfalls of the Alps to run all the railways of Switzerland. There would be little or no reduction of cost it is said but the time may come when the change from steam to electricity may be desirable, because Switzerland has to import all the coal she uses

From twenty-one waterfalls, some of which are already partially utilized for industrial purposes, [illegible] horse-power could be developed but only 60,000 horse-power would be required to replace the steam power now used on the railroads.

Radiant Energy and Matter—I*

Sir J J Thomson's Royal Institution Lectures

For this course of lectures at the Royal Institution this year Prof Sir J J Thomson of Cambridge has selected the subject of "Radiant Energy and Matter"

In commencing his first lecture Sir J J Thomson said that he thought no apology was needed for his selection of a subject, since as he was informed by Sir James Dewar the last set at the Royal Institution on the subject of radiation were delivered by Prof Tyndall, and formed the basis of his book on "Radiant Heat and Light"

To every inhabitant of the solar system whether of the earth or of Mars the question he continued was one of vital importance The planets did not live on their own resources of energy but were dependent from day to day almost from minute to minute on the supplies received from the sun The solar system in short was equivalent to a system of power distribution on an enormous scale The power house was the sun and the method of distribution was practically one of wireless telegraphy since there was every reason to believe that radiant energy traveled through the ether in a form mechanically equivalent to electric waves The power expended in various ways on the earth was practically wholly received from the sun Thus the energy available in coal was actually solar energy transformed into the energy of chemical separation Water powers again were dependent on the raising of the water to a high level by heat received from the sun The magnitude of the energy thus sent us from that body was far larger than most people realized Actual measurement showed that shining in a clear sky the sun transmitted to the earth energy at the rate of 7 000 horse power per acre

At present this energy was practically all wasted being expended for the most part merely in making the earth a little warmer than it otherwise would be and this effect was most pronounced in regions where any addition to the temperature might well be dispensed with If we knew how to harness this energy we could obtain from it all the power necessary to run the works of the world Various attempts had indeed been made to do this and at the late meeting of the British Association at Sheffield Mr Fessenden had described an installation then in course of construction in one of the hotter States of the Union In this instance it was proposed to use low pressure steam turbines and it was claimed that the cost of the energy thus obtained would be less than half that of the cheapest hitherto available However this might be there was here the speaker continued a great resource for us to fall back upon when coal became scarce and dear and the water powers available had all been taken up

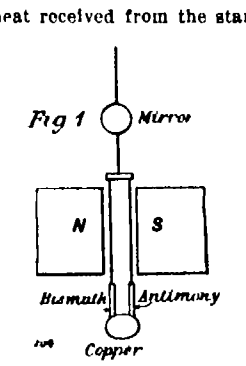
In the present course of lectures he proposed he went on to discuss the manner in which radiant energy was propagated and how the intensity of radiation depended upon the temperature of the body from which it came On this afternoon he would he said confine his discourse to questions concerning the total amount of energy coming out of a radiating body at various temperatures and would reserve for the next lecture questions as to the distribution of the energy in the spectrum according to the color of the light For the study of radiant energy it was necessary to have other means of measurement than the eye Bodies gave out radiant energy at all temperatures above the absolute zero but this energy did not affect the eye unless the temperature of the emitting body was 500 deg F to 600 deg F at least Even then by far the larger proportion of the total energy existed in a form which did not affect the eye and would not be perceived were no other means of detection available Even in the case of the sun three fifths of the energy we received from this body produced no impression on the eye Were however the temperature of the sun doubled only about one fifth of the total energy would escape perception as light while if the sun were still hotter practically the whole of the energy would be received in a visible form With the temperatures actually at our disposal we had means of investigation which would serve where optical methods were not available and these almost all depended upon the conversion of radiant energy into heat

The term "radiant heat" was sometimes used but was rather a misnomer since the energy in question did not become heat, as we now understood the term till it fell upon, and was absorbed by some body It would be better indeed, to call this "radiant heat" electricity as there was every reason to believe that radiation was essentially an electrical phenomenon

* The report here given of Sir J J Thomson's lecture is taken from Engineering.

In measuring the amount of radiant energy the radiation was absorbed and transformed into heat

A very delicate instrument for measuring heat radiation was the bolometer which consisted simply of a strip of platinum on which the radiation was allowed to fall heating the strip and changing its resistance Our means of measuring electrical resistance were the speaker said so delicate that temperature changes almost inconceivably small could thus be detected With this instrument Langley had made his discoveries on the amount of heat the earth received from the sun The bolometer was followed by the radio micrometer of Prof Boys This consisted of a small thermopile (see Fig 1) formed out of a rod of bismuth and another of antimony suspended from a quartz fiber as indicated On heating the junction a current traversed the wires which completed the circuit This circuit lay between the poles of a magnet and the wires tended when the current passed to set themselves square with the lines of magnetic force With this instrument it was possible to measure the radiation received from a candle a mile away Even this instrument was the speaker added surpassed in delicacy by the radiometer of Prof Nicols which was an adaptation of the well known radiometer of Crookes With this instrument Prof Nicols had been able to measure the heat received from the stars



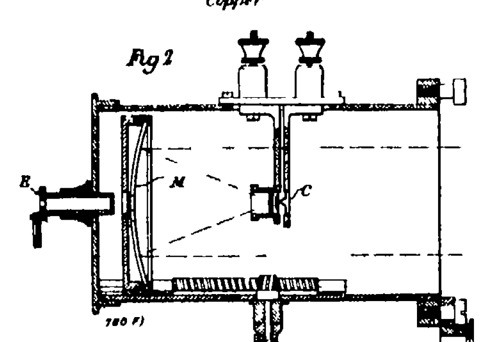


Fig 1 Prof Boys Radiometer consisting of a small circuit suspended between the poles (N S) of a magnet and comprising a thermocouple Fig 2 The Féry Pyrometer The rays of light and heat radiation enter the instrument along the dotted lines from the right strike the mirror *M* and are reflected to the focus at *C* where they fall upon a thermopile This is connected to a galvanometer the deflection of which indicates the temperature of the thermopile and hence of the source The eye piece *E* is used for sighting the instrument on the source whose temperature is to be measured

For his experiment this afternoon the lecturer proceeded he would use a Féry pyrometer of the construction shown in section in Fig 2 The radiant energy entered at the right and falling on the concave mirror *M* was reflected on to a little thermopile at *C* This was connected up to some form of current measurer In the industrial use of the instrument this was an ammeter graduated to give temperature readings direct Though primarily intended for measuring furnace temperatures the instrument could also be applied to measure the amount of radiation from much colder bodies but then more delicate means of detecting the current generated were required and he would himself therefore make use of a galvanometer suspended from the roof of the building so as to be less liable to vibration

Before making use of this instrument however he would he proceeded show another method of detecting radiation which did not affect the eye This was due to the elder Becquerel who found that if a phosphorescent body such as zinc blende were rendered phosphorescent by exposure to a bright light and then afterwards exposed to radiant energy of a different kind the part exposed to certain descriptions of black light became almost as black as if painted with a brush This observation could be used as the basis of a method of detecting radiant energy not perceptible by the eye The range of radiation which produced the effect was not however very great lying just a little on the infra-red side of the spectrum

Exposing a plate covered with zinc blende and rendered phosphorescent to the spectrum of an arc lamp the lecturer showed that the portion which caught the infra red rays became quite black Similarly, if a sheet of ebonite were placed between the phosphorescent sheet and the light of an arc lamp the rays which got through this opaque sheet again extinguished the phosphorescence and a similar effect was shown to be produced by the radiation which traversed a solution of iodine in bisulphide of carbon Methods of detection based on these phenomena were Sir Joseph continued available with radiation of a certain kind but for most purposes it was necessary to fall back on the methods already mentioned in which the radiation was absorbed and transformed into heat

A vital question he proceeded was the relation between the temperature of a body and the total amount of radiation given out by it Newton thought that the amount of energy radiated from a body was proportional to the difference between the temperature of the body and that of its surroundings This was true for small temperature differences whatever the true law of radiation but it did not give us much help when dealing with widely different temperatures Applying Newton's law Watson had estimated the temperature of the sun as 7 000 000 deg C which was about 1 000 times its proper value The true law connecting radiation with temperature had been known for several years and its discovery originated in some experiments by Tyndall who measured the radiation from a piece of platinum at different temperatures Thus at 1 200 deg C he found that the amount of radiation was 11 7 times as much as at 525 deg C Taking these figures Stefan tried to find a relation between the two absolute temperatures and the amount of the radiation emitted In the first case the absolute temperature was 1 473 deg and in the second 798 deg F Then Stefan found that the ratio $\left(\frac{1473}{798}\right)^4$ was about equal to 11 7 and this suggested to him that the energy of radiation from a body was proportional to the fourth power of the absolute temperature Thus if the absolute temperature were doubled the energy radiated out would be 16 times as great

This was Prof Thomson continued perhaps the most important law as to radiant energy yet discovered and it was known as the fourth power law Originally discovered by Stefan as stated it had been abundantly verified since and it had further been found to have a strong basis in thermodynamics A discussion of this he would however defer until he had in a subsequent lecture shown the existence of a pressure due to radiation as this pressure was the basis on which Boltzmann and others had shown from thermodynamic considerations that the radiation must vary with the fourth power of the temperature

The fourth power law the lecturer continued had been extended and physicists were able to say not merely the rate at which radiation varied with the temperature but also the actual amount of energy emitted by a body at any temperature

Thus according to Kaulbars the radiation emitted per second from 1 square centimeter of the surface of a blackened body was equal to $\sigma\theta^4$ where $\sigma = 5.72 \times 10^{-5}$ ergs and θ denoted the absolute temperature

If a body had a temperature of 1 000 degrees therefore it emitted from each square centimeter of its surface 5.5×10^7 ergs per second or in other words gave out energy at the rate of about 1/200 horse power per square centimeter This radiation moreover came out from a very thin layer Assuming this layer to be even as much as 1/100 millimeter thick then a cubic centimeter of the surface of a body at 1000 degrees transformed energy at the rate of 7 horse power This which was really an underestimate well illustrated the speaker said the compactness of the mechanism by which heat was transformed into radiation Since the amount of energy coming out was so large it was easy to understand the rapid extinction of light from small particles such as sparks

One very interesting application of the equation just given was he said to the determination of the temperature of the sun Though somewhat difficult owing to the effects of atmospheric absorption it was possible to measure the intensity of the radiation received from each square centimeter of the sun's surface and from this to deduce the temperature of the latter The most accurate results appeared to make this about 6 000 degrees absolute which was much lower than was at one time thought At 6 000 degrees absolute the rate at which energy was radiated per square foot of surface was formidable, being about 15,000 horse-power How

then did the sun keep on radiating at this rate without getting appreciably colder? Nowadays we always tried to see if radioactivity would not suffice in such cases In the case of the sun the energy could not be supplied by radium as the life of the latter was too short being quite insignificant compared with geological time In this respect uranium being very much longer lived fitted in all right, but it remained to be seen whether the possession of a good supply of uranium would be enough to supply energy at the rate required Unfortunately on making the calculation it turned out that even if the sun consisted wholly of uranium the rate of energy supply would still be insufficient. The sun's surface radiated energy at the rate of 1.2×10^{11} ergs per second, while uranium liberated energy at the rate of 1 erg per second per gramme Hence the number of grammes of uranium below each square centimeter of the sun's surface would need to be 1.2×10^{11} and the whole mass below 1 square centimeter of the sun's surface was actually nothing like as great. Hence it was necessary to give up radioactivity as a sufficient source of the sun's energy and in consequence almost the only hypothesis at present tenable was that at first put forward by Helmholtz An influx of meteors into the sun had been suggested by some as the source of the solar energy The objection to this was that in that case the earth must act, to a certain extent, as an umbrella, and calculation showed that, if it received a corresponding proportion of the assumed meteoric shower, the number received would be enough to make the earth red hot. Helmholtz had in consequence suggested that the energy was supplied by the sun's attraction on itself This hypothesis implied that the sun was shrinking at the rate of about 200 feet per year and with existing means of measurement there was at present nothing to be said against this conclusion

(To be continued.)

Carbureters and Vaporizers*

How They Should be Designed

By T A Borthwick

An analysis at all approaching completeness of even one tenth of the carbureters for vaporizing gasoline or kerosene that are now being manufactured either as belonging to a definite machine or being placed on the market as an accessory would be a work extending to several volumes The scope of this field may be gaged by a glance at the patents review of the technical journals where two or three specifications of newly patented designs may be found almost every week It is therefore not intended here to deal with them fully as regards their mechanical arrangement but to consider the conditions most favorable for the economical and satisfactory production of a combustible fuel and to trace its path from the entry into the float chamber until it reaches the combustion chamber

It may be taken primarily that the use of a jet of which the effective level is regulated by a float chamber as originated by Maybach is almost universally adopted in all cases in which gasoline is the fuel This type is also used to a very large extent in engines using refined and semi refined kerosene It is with devices of this kind that this article will deal

It is a matter for surprise that the use of such a delicate and uncertain piece of apparatus has not been avoided In fact the float chamber has received very little attention beyond the arrangement of the balance weights or in attempts to dispense with them altogether

The arrangements shown in Figs 1 2 and 3 are those most commonly adopted in current practice Fig 1 is arranged so as to admit the lightest possible working parts and thus minimize the troubles due to inertia when traveling over uneven roads It has the further merit that any surplus of gasoline escaping on account of vibrations of the needle valve causes the float to press more heavily on the balance weight and thus to close the valve more tightly on its seat

The arrangement shown in Fig 2 requires the needle and its fittings to be somewhat heavier than in Fig 1 since the pressure due to the weight alone acts to keep the valve on its seat The design shown in Fig 3 has the merit of simplicity and has also the same advantages as Fig 1 but it is open to the objection that the gasoline pipe has to be uncoupled every time the float chamber is opened an occurrence which happens not infrequently especially with kerosene

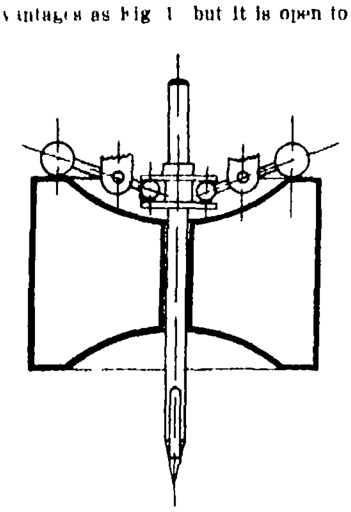

Fig 1 DIRECT NEEDLE VALVE

Among improvements relating to the float chamber that known as the Gillet Schwarz device is one of the more important This consists of a through connection between the mixture pipe and the space above the fuel pipe in the float chamber by means of a branch pipe to which is attached a cock making the effective area of the through connection adjustable The resultant effect of this device is to tend to produce a constant ratio between the pressure in the float chamber and that over the jet or in other words to produce a constant effective height for the jet and therefore on the wider opening of the throttle to give a weaker mixture It may perhaps be satisfactory to

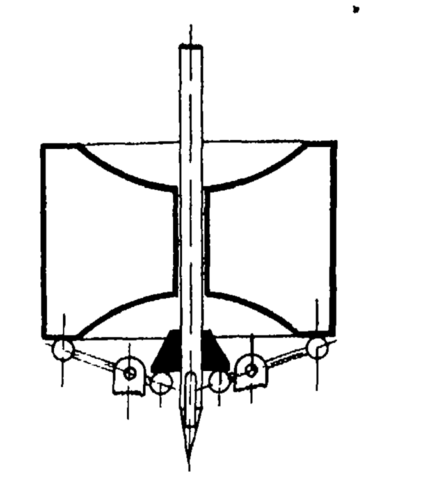

Fig 2 INVERTED NEEDLE VALVE

explain the desirability of this weakening of the mixture with the opening of the throttle by reminding the reader that with a partially closed throttle the cylinder is only partially filled consequently the compression pressure is lowered and a richer mixture is required to enable it to be ignited The best pressure ratio is obtained experimentally by opening or closing the cock in the by pass as may be required Another and perhaps more valuable quality in the Gillet-Schwarz device is that in multi cylinder engines it discriminates between the supplies of mixture to each cylinder e g in four and more particularly in six cylinder engines it will frequently be found that the mixtures are required of different strengths for the different cylinders as shown by the fact that some of the cylinders will fire weakly or miss altogether while the remainder will fire well This is partially due to variations in the volumes of the combustion chambers but more largely because of leaking past valves and valve covers and perhaps it is also due to a still larger extent to the timing of the valves not being uniform throughout the cylinders This device assists in partially neutralizing the last two faults since the effective height of the jet being approximately constant the cylinder with the stronger suction will draw the moist air and as it will have nearly a uniformly higher compression the ignition of the charge is assured On the other hand the cylinder with the weaker suction and consequently weaker compression will draw less air thus forming a richer and more readily fired mixture

After mentioning the above device we may add that the same principle has been utilized in a carbureter brought out by Messrs Cravens Ltd of Sheffield

Little else need be said with regard to the float chamber except perhaps a note about the position of the hole between the float chamber and the jet One frequently finds that this is situated at the bottom of the chamber where it draws any grit or sediment which may find its way inward The hole should be at least a quarter of an inch from the bottom or preferably more since even if a gasoline filter is provided one finds that dirt still finds its way in by some mysterious means It must also be remembered that it is not safe to assume that adequate precautions are taken to exclude all dirt when the gasoline pipe is uncoupled or when the float chamber cover is removed.

A final item to be noted is the needle valve It is frequently found that this is made of mild steel, and, therefore exceedingly liable to become rusted in the presence of gasoline It should, therefore be made of a high percentage nickel steel, or of silver steel.

Before dealing with the details of the mixed chamber it is desirable to consider the general disposition of the mechanism of the carbureter For purposes of comparison we may divide all carbureters into two classes—vertical and horizontal Referring to the former class it may be noted that the vertical carbureter usually gives a more direct flow for the gases, has fewer bends is more economical in fuel consumption than the horizontal type and is furthermore, not so liable to become choked As an offset to these good qualities the horizontal carbureter is undoubtedly easier to be started since the incoming air rushes directly across the top of the jet instead of flowing along it

We will now consider some of the very simplest forms of carburetors being those without any kind of automatic controlling device for the auxiliary air inlet and hence without any means of discrimination between requirements of a full throttle at low speeds and the same at high speeds This class of carburetors is by no means the largest but, speaking generally they give singularly satisfactory results very nearly equaling those attained by carbureters provided with the most accurate adjustments Under these circumstances one is almost inclined to wonder whether for practical purposes the extra complications and delicate parts of the more refined devices are warranted

Taking a few typical examples of this class we will first examine the White & Poppe carbureter which is well to the fore in its line The general arrangement is shown diagrammatically in Fig 4 from which it will be seen that a vertical rotary throttle is placed in the path of the inlet gases and that the throttle casting forms a shroud over the jet a gasoline tight joint being formed between it and the conical top of the jet and the shroud being kept on its seating by means of the spring *A* The hole in the jet and the shroud is disposed eccentrically in such a way that the jet the air inlet and the mixture outlet are all cut off simultaneously and in a definite, predetermined proportion A simpler and more satisfactory way of effecting this three-fold function could hardly be imagined The only adjustment of any kind is that for the air outlet, by means of the sleeve interposed between the throttle and the casing. This is operated by moving two stops on the chamber cover,

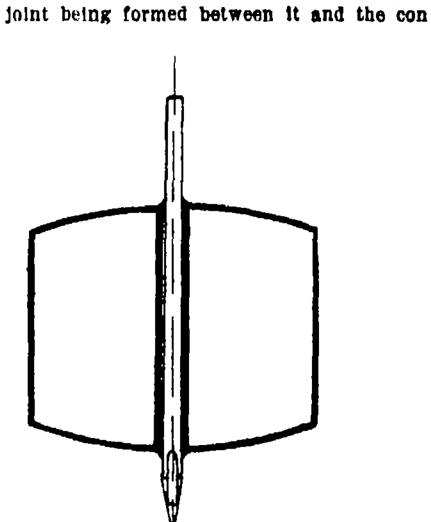

Fig 3—FLOAT AND NEEDLE VALVE

* Reprinted from *Cassier's Magazine*

and compensates for varying atmospheric conditions, and also for different qualities of gasoline.

The remaining portion of the White & Poppe carbureter is a short trunk placed between the mixture outlet and the engine inlet pipe, it serves the purpose of removing any heavy particles of gasoline therefore making the mixture more homogeneous. We believe, however, that this atomising chamber has been omitted in the latest designs of this carbureter.

An approximately similar carbureter but of the vertical type is the Claudel Holson which however has a different kind of jet and one which is both ingenious and interesting. Referring to Fig 5 the hair line circle represents the throttle and it will be seen that the jet outlet and also the holes in the sleeve surrounding the jet, are inclosed by the throttle while the holes at the bottom of the sleeve are outside the jet. The function of the sleeve may be explained as follows. Assuming a partially closed throttle the holes at the top of the sleeve will be in a partial vacuum caused by the suction of the engine while the holes at the bottom will be approximately at atmospheric pressure. A current of air will therefore pass upward inside the sleeve and draw upon the jet. If, however the throttle were fully open the top holes would be nearer atmospheric pressure and the pressure difference between the top and bottom holes would be less and therefore there would be less suction on the jet from this source.

By these means the requirements of proportionately richer mixtures for the lighter throttles are effectively and simply met. It may be added that the Claudel Holson is an exceedingly well constructed and designed carbureter affording a specially smooth and straight forward flow for the gases.

Another example of this type of carbureter is one which has been fitted on the Belsize cars. It is of the vertical type and is so arranged that a throat of con

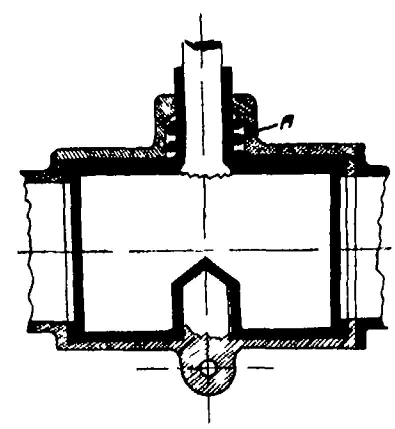

FIG 4—WHITE AND POPPE CARBURETER

stant size is maintained but that simultaneously with the rotation of the throttle a screw of quick pitch is also rotated and by its means a sleeve is lifted in a circular chamber coned inward and therefore the effective air inlet is increased and the mixture is atomized higher up in the carbureter prior to reaching the throttle. Further examples of this type of carbureter are the Trier & Martin triple jet the Craven already mentioned under the heading of float chamber and the H P carbureter. This last has a simple means by which if desired air only may be drawn into the engine after the complete closing of the throttle.

As regards the jet it may be mentioned that it should be kept as large as possible in order to lessen the disturbing and fluctuating influence of friction. Since however for slow running with no load the quantity required is almost infinitesimal the idea of providing a separate jet or a variable jet to serve this purpose may be worthy of consideration. The former method, of a separate jet is probably the better one of the two unless some method is adopted similar to that used in the White & Poppe carbureter in which the jet is cut off eccentrically. The earlier method adopted by a number of makers of lowering a taper needle into the jet, is not nearly so good since capillary attraction and jet friction combine to make the supply very variable. It should be emphasized however that the secondary jet is to be used solely for the purpose stated, and should be neutralized or preferably cut off positively for working positions under load.

It may be recalled that a year or two ago several triple and quadruple jet carbureters were brought out but these have for the most part since been abandoned. These would obviously have an abnormal amount of jet friction and therefore be sluggish in action. For reasons already stated, they would not give uniform results, as the friction even under uniform atmospheric conditions does not remain a constant quantity.

A form of jet, as fitted to the Itala and other vertical carbureters, may here be mentioned, it is shown in Fig 6. It will be seen that the gasoline is compelled to leave the jet head radially the object is to integrate it with the incoming air, but it is somewhat questionable whether it penetrates any further into the stream of air than that which immediately surrounds the jet.

In considering the subject of the throat of a carbureter several features should be taken into account.

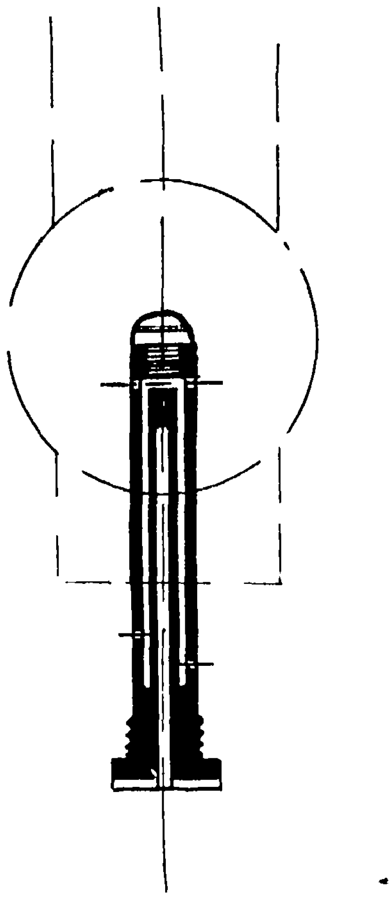

FIG 5—CLAUDEL-HOLSON CARBURETER

So far as the surfaces are concerned one has only to compare the action of a rough and a machined throat of similar dimensions to appreciate the influence of the nature of surface upon performance. We may also add that we have found engines to run appreciably better with inlet pipes made of solid drawn copper tubing than when made of castings of similar shape and size.

When a carbureter for gasoline is fitted with a throat of constant diameter it will be found that the most satisfactory size is that which gives the air a velocity of about 100 feet per second for a horizontal throat or 120 feet per second for a vertical throat.

Taking as an example an engine of four inches bore and five inches stroke and capable of being throttled down to 160 revolutions per minute the carbureters assuming the cylinders to be properly filled should have a throat area of 0.358 square inch corresponding to about 11/16 inch diameter when of the horizontal pattern and 0.298 square inch or 5/8 inch diameter if of the vertical pattern.

It is however more than probable that when the engine is idly rotating at that speed the throttle aperture does not allow the cylinders to become more than one third full. To cover this condition and also to get the best mean for general working it is advisable to fit a cut off for the throat although this is not generally provided. On the White & Poppe carbureter the throat is mechanically enlarged and it is found that an engine of the size given above will run very light when in good condition at 160 revolutions per minute with an effective throat area equivalent to a diameter of 3/16 of an inch.

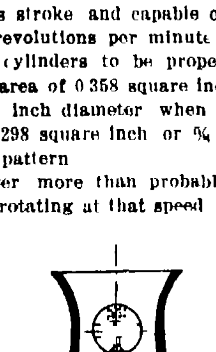

FIG 6—ITALA CARBURETER

This throat reduction is done in a very ingenious manner in the Trier & Martin carbureter. In the earlier patterns a vertical shutter was hung across the throat and cut off all but a small portion until the suction of the engine became powerful enough to lift it out of the way. More recently the same makers have used a device shown in Fig 7 which is self explanatory the suction of the engine pulls the spring and allows additional air to pass between the coils. A similar spring device has been used to operate an auxiliary air inlet.

In many carbureters of the horizontal pattern there is no reason why a much greater application of the *vena contracta* should not be made and the throat enlarged accordingly. Taking the case which we have already considered that is a throat 11/16 inch diameter and also take the *vena contracta* constant as 0.6 we might enlarge the throat to 0.37 ÷ 0.6 square inch or 0.601 square inch or 7/8 inch diameter and place the jet where the contradiction occurs. This plan could of course be quite logically adopted with vertical carbureters but the application of it would present some difficulties in the arrangement of the parts.

Regarding the use of other spirits than gasoline it may be mentioned that benzol methylated spirits and also benzine may all be used without alteration to the gasoline carbureter other than the change in the size of the jet. Benzine is somewhat slow and heavy in its working but methylated spirit gives an exceedingly lively engine and also very good results from the point of view of power output but it also makes an engine which is somewhat too hard in working for general use.

The use of fuels of the kerosene type such as the American White Rose or Royal Daylight the Russian Russolene Scottish Lighthouse Burma Victoria or refined Borneo and the numerous other oils of approximately the same nature also the heavier and more sluggish spirits such as the usual commercial grades of naphtha presents no very great difficulties after the few necessary modifications have been made in the design of the carbureter.

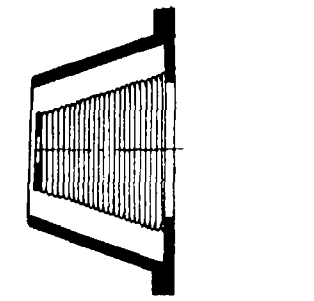

FIG 7—TRIER AND MARTIN NOZZLE

It is necessary primarily to provide a vaporizer which may be heated by the exhaust gases of the engine or by other means such as a blowlamp. This vaporizer should be so designed that as large a surface as possible is presented to the incoming mixture in order to prevent the formation of a core of unvaporized mixture this latter condition being apt to occur if tubes of at all large diameter are used.

The method of drawing in the air is different from that used with the gasoline carbureter. With the carbureter for kerosene the amount of air passing through the throat must be only sufficient to lift the oil out of the jet and carry it onward so that the unvaporized mixture is not sufficiently rich in oxygen to become ignited in the vaporizer.

The additional air required to form the explosive mixture is taken in by means of a separate valve between the vaporizer and the engine inlet valve. There are a few carbureters for kerosene on the market as a specialty the majority being the exclusive designs adapted to and confined to the engines of the makers.

Wireless Railroad Signals

For some time past the Prussian and Bavarian authorities have been experimenting with a system of wireless telegraph signals for railroads which is said to promise good results. An aerial transmitter wire is carried on the telegraph poles at the side of the road with transmitting stations in the signal bell towers and a wire loop antenna is placed on the top of one of the cars of the train. By this means signal to stop go ahead go slow and so on can be transmitted to moving trains over an effective range of 12 kilometers nearly 7½ miles. The average distance between the bell towers on German railroads is only 18 kilometers so that the range of the signals is amply sufficient.

The Lost Arts of Chemistry*

The Origin and Reason for Some Widespread Beliefs

By W D Richardson

IN addition to chronicling past and present events merely it pleases the historian from time to time to ascertain as nearly as he can by a comparison of present with past conditions and present knowledge and practise with past knowledge and practise the present condition of mankind of any particular society in comparison with past conditions Thus are compared present systems of government with past systems new religious beliefs with old modern science with ancient science present day arts and manufactures with those of old

Progress never takes a straight course for any considerable length of time Nor does it even follow an undulating course in one general direction But there are advancements and retrogressions repeated endlessly And again progress as recorded by history does not represent necessarily the progress of the whole human race On the contrary it does not represent even a large part of the human race but at most an isolated portion of it and in this isolated portion the progress is recorded not of the whole but of the most advanced individuals only When we say that the present age is one of great business scientific and manufacturing or artistic achievements in comparison with the fourteenth century for example we mean that a few individuals very few in fact compared with the total number have contrived to bring about great results in those fields of human activity But we must remember at the same time that the majority of individuals may not have been directly concerned in the advance or may not have contributed directly to it at all Indeed it seems as though the lowest members of the human race to day are no farther advanced mentally than were their progenitors in recent geologic times Even with rapid progress of the most favored or most enterprising individuals there may be little progress or none in the case of the average of mankind It is not unlikely that at the present day the intellectual gap between the mentally highest and lowest of mankind is greater than at any previous time

In spite of the high intellectual and practical stand ard reached by the leading men of to day from another point of view (called by some the pessimistic) the outlook to-day is far from satisfactory in politics religion manufacture or science Whether we consider our all but failing efforts at democracy in the United States or the vacillating and undirected religious tendencies of the people (as shown by Mormonism Seventh Day Adventism Dowieism Christian Science the old theologies or the strange oriental doctrines and ideals of the majority of our people which fortunately are scarcely put into practise) or if we consider the slow conservatism and plodding course of manufacture and business including our great untouched problem of the economic distribution of goods we can not fail to be impressed with the length of the journey which we must sooner or later take on the road of development

But we may turn from the rather unsatisfactory consideration of politics religion and business to the consideration of modern science with a rare degree of satisfaction and enthusiasm There at least progress is visible tangible or even obtrusive There at least the forward movement does not take the slow conservative timid pace of business nor follow the meandering uncertain sentimental path of religion or the crude meaningless way of politics In that field at least the way is certain the methods positive the results satisfying the application secure and the progress lively Considered by itself science and the scientific method are the most satisfactory and satisfying things in the possession of the human mind The unfortunate thing—it can not be classed as a criticism—about science is that it has left the multitude untouched With the results of science and the scientific method on every hand forming so large a part of our splendid materialistic civilization nevertheless the great the overwhelming majority of people are ignorant of the methods the aims and the results of scientific inquiry in daily use and of daily necessity Of even greater import the scientific method of thought is not a part of their mental equipment.

Science and the scientific method have their critics no less than other excellent things Science is unmoral cold heartless pessimistic hopeless often cruel in method say they The scientific inquirer can well afford to let most of such accusations as these go unchallenged But there is one statement which has been sown broadcast which springs up in a thousand unexpected places and which it is worth while to devote some attention to in order to refute it. It is the statement that ancient peoples have been possessed of knowledge and of arts unknown to modern times and indeed people would have us believe that this knowledge and these arts are recoverable by us if at all only with extreme difficulty The lost arts is the cry In so far as these so-called lost arts concern applied chemistry let us examine into them and ascertain if possible whether or not there is truth in the assertions alluded to

In the first place we may well inquire into the origin of the widespread belief that the knowledge of various mechanical and chemical arts has been lost to mankind Probably first among the causes is that universal veneration of antiquity which makes gods and saints out of heroes and martyrs of the past leads to ancestor worship and in general exaggerates the virtues the crafts and the deeds of valor of olden times Secondly the delight of many persons in mystery their tendency toward belief in the mysterious occult and miraculous against their better judgment and the facts in the case have great influence in originating and perpetuating the belief in lost arts Thirdly among the more general causes we may place vague statements or sentences which we cannot accurately translate in ancient manuscripts Fourthly the natural reaction against an egotistical age Fifthly the use by ancient peoples for certain purposes of materials which we would not use to-day on account of their unsuitability This leads to the conclusion that the ancients knew of different and better methods of preparing the material Sixth it has pleased certain writers and lecturers to insist strongly upon the point that there have been at various times in existence arts no longer known and used One finds brief statements in various books of such import as they knew how to harden copper Their mortar outlasted the stone it cemented The degree of perfection they reached in enameling has never since been attained etc In America the man who has had probably more effect than others in this respect was Wendell Phillips His lecture entitled The Lost Arts was first delivered in the American Lyceum course in the winter of 1838 During succeeding years the lecture was repeated about 2 000 times and was heard by all sorts of audiences throughout the country and at the time and subsequently made a great impression Many persons now living still remember the famous lecture It is difficult to read this lecture to day and believe that it was seriously intended in certain places by Wendell Phillips yet I am assured by several individuals who heard it that, although illumined by humor in places it was as a whole seriously intended and received In various lectures Phillips committed many sins against accuracy and truth but in none more than in the Lost Arts He misquoted Pliny in regard to his statements about the origin of glass manufacture—a tale familiar to you all and hardly rising to the dignity of a first class fable And of all authors Pliny can least afford to be misquoted being already overburdened with inaccuracy and unreliability Let me present a few brief quotations from this remarkable lecture

The chemistry of the most ancient period had reached a point which we have never even approached and which we in vain struggle to reach to-day In deed the whole management of the effect of light on glass is still a matter of profound study

The second story of half a dozen—certainly five—related to the age of Tiberius the time of Saint Paul and tells of a Roman who had been banished and who returned to Rome bringing a wonderful cup This cup he dashed upon the marble pavement and it was crushed, not broken by the fall It was dented some, and with a hammer he easily brought it into shape again It was brilliant transparent but not brittle I had a wineglass when I made this talk in New Haven and among the audience was the owner Prof Silliman He was kind enough to come to the platform when I had ended and say that he was familiar with most of my facts but speaking of malleable glass he had this to say—that it was nearly a natural impossibility and that no amount of evidence which could be brought would make him credit it. Well the Romans got their chemistry from the Arabians, they brought it into Spain eight centuries ago, and in their books of that age they claim that they got from the Arabians malleable glass There is a kind of glass spoken of there that, if supported by one end, by its own weight in twenty hours would dwindle down to a fine line and that you could curve it around your wrist.

Cicero said that he had seen the entire Iliad, which is a poem as large as the New Testament, written on a skin so that it could be rolled up in the compass of a nut-shell Now this is imperceptible to the ordinary eye You have seen the Declaration of Independence in the compass of a quarter of a dollar written with glasses I have to-day a paper at home as long as half my hand, on which was photographed the whole contents of a London newspaper It was put under a doves wing and sent into Paris, where they enlarged it and read the news This copy of the Iliad must have been made by some such process

Pliny says that Nero the tyrant had a ring with a gem in it which he looked through and watched the sword play of the gladiators—men who killed each other to amuse the people—more clearly than with the naked eye So Nero had an opera-glass

So Mauritius the Sicilian stood on the promontory of his island and could sweep over the entire sea to the coast of Africa with his nauscopite which is a word derived from two Greek words meaning 'to see a ship Evidently Mauritius who was a pirate had a marine telescope

The French who went to Egypt with Napoleon said that all the colors were perfect except the greenish white which is the hardest for us They had no difficulty with the Tyrian blue The burned city of Pompeii was a city of stucco All the houses are stucco outside and it is stained with Tyrian blue the royal color of antiquity

But you never can rely on the name of a color after a thousand years So the Tyrian blue is almost a red—about the color of these curtains This is a city all of red It had been buried seventeen hundred years and if you take a shovel now and clear away the ashes this color flames up upon you a great deal richer than anything we can produce

I feel reasonably sure from what I know of the history of science that the main points made in this lecture were not true in Wendell Phillips's time I know they are not true to-day

To recapitulate The causes of a belief in lost arts appear to be the veneration of antiquity, the belief in the mysterious and occult inaccuracies in and in accurate readings of ancient texts reaction against present-day egotism the use of unsuitable materials by ancient peoples and the emphasis laid upon ancient skill by half accurate writers

No one could wish to detract from the great, the skilful and the beautiful works of the ancients All we can desire is a proper and clear understanding of their accomplishments

Long before the way was prepared for an approach to chemistry as a science many were the chemical facts known and used, and many the chemical arts and manufactures which arose and flourished The foundations of many of our greatest chemical industries were securely laid long before the science of chemistry lent its aid The industries of cement and plaster, glass, ceramics pigments oils and fats, varnishes and lacquers, sugar fermentation textiles, paper dyeing leather glue and various metallurgical industries are some of those which were very well developed before the advent of scientific chemistry Indeed the science of chemistry has found and still finds some of its richest materials in these very industries. What can be accomplished by patient manual skill and dexterity is amazing and it must be conceded that the adoption of exact mechanical processes in our times has lessened the necessity for such skill in many directions It is true also that many ancient peoples and many of the less mechanical modern ones have applied manual dexterity to their arts in such a way that we marvel at the results. But it is difficult to find a case where similar application to-day would not yield a similar result. Nothing can be considered lost unless it be the demand for and desire to produce works of a certain kind.

Again it is true that some arts and modes of manufacture reach a stage which we may call practical perfection, relatively soon after the initial discoveries are made which give them their first impetus. After this point is reached the improvements are few or none (and if any occur they come from an outside source, as the application of power to the loom). Examples are abundant, the hoe and other simple farming implements; the safety bicycle; the sewing machine; the aeroplane. It must, of course, be remem-

* An address delivered before the Minneapolis meeting of the American Chemical Society

possible that suitable materials for manufacture have been previously discovered and are at hand or can be quickly adapted In such cases as these the opportunities of later generations to develop and improve are meager, but the limitation is not of the inventors, but of the things themselves

For many years the great pyramid of Egypt was held up to the youth in all lands as an example of what had been accomplished by ancient peoples and which could not be duplicated to-day It was held in fact that the ancient Egyptians were possessed of mechanical knowledge and appliances unknown to us We must all concede that the great pyramid is a remarkable if useless piece of architecture laid out with extreme precision and carried to its completion in a masterly way But it turns out that the Egyptians of the Old Kingdom possessed rather limited knowledge of mechanics, not having even developed the movable pulley The great pyramid was built by man power multiplied many thousand times Finally can it be considered a greater work than a great railway system or battleship?

That arts have been temporarily lost at least for practical purposes is true The history of industry has not yet been written—possibly it is too great a task—and adequate data have not been collected and hence are not available but it seems true from the information available that there has been a remarkable continuity in industrial processes in spite of many adverse circumstances

War is probably the greatest cause of breaks in the continuity of manufacturing processes and the arts of peace and if we are to believe past records the domination of theological systems or religious dogmatism has been and is the most effective influence in restraining the development of scientific methods of inquiry and consequently progress in the arts On the other hand commerce and the migrations of peoples have been effective in spreading industries War destroys commerce but often causes migrations and hence has been an active influence in the spreading of industry as well as in checking it War has also imposed new civilizations on old and thus caused an unnatural intercourse between two civilizations which would naturally result in the extension of knowledge of the industries peculiar to each

Let us examine for a few moments some of the arts claimed to be now lost The knowledge of a process for hardening copper is commonly ascribed to many ancient and prehistoric peoples and is devoutly believed in by many persons Now in the first place if this knowledge was formerly possessed we have no direct evidence of it for the copper implements which have come down to us are no harder than those we might make ourselves to-day A metal may be hardened in two ways By physical treatment or by alloying it with other metals or substances Copper may be hardened to some extent by hammering in the same way that many other metals may be hardened The common alloys bronze and brass are harder than the pure metal It is probable that ancient peoples used the process of hammering to harden copper and it is certain that they made use of the alloys of copper first with tin and later with zinc for many purposes including tools and implements But because copper and copper alloys were used for implements subjected to rough usage this does not justify us in concluding that the makers had knowledge of a method for making the metal hard durable and serviceable The simple and direct explanation is that they had no better material for the purpose at their command just as in the bone and stone periods bone and stone were the best materials of construction available for tools and implements There is no justification for the idea that ancient peoples knew how to harden copper by means unknown to metallurgists of the present day

The ceramic arts are among the oldest known to mankind and the earliest development of them will probably remain unknown to us. They had their beginnings in the bone and stone age and were probably first practised by women not by men The first clay vessels may have been clay-covered baskets dried in the sun—we do not know certainly From those early beginnings to the highest types of the art required the labor of many potters numberless experiments and numberless failures We class ceramics among the chemical industries and properly so and yet the ceramic art originated, developed and flourished in many ages and in many parts of the earth without any thought of or aid from the science of chemistry It has always been and still is to a very large extent an empirical industry The essential difference between the pottery practice of ancient times and the most scientific practice of modern times lies in the reproducibility of bodies and glazes by modern methods. And yet few chemists in the industry have the temerity to predict how a new clay or glaze will come out of the kiln. The potters of long ago, by countless [illegible] of [illegible] materials and countless failures, were able to produce certain effects, and they were able to continue the manufacture of similar wares and produce similar effects so long as they were able to obtain materials from the same sources A change of material would almost certainly mean a change in product. It must not be forgotten that this same limitation affects the ceramic industry to-day to a very large extent The varieties and properties of clays are almost numberless It is true that potters of all times have been able to devise certain simple tests whereby they have been able to recognize differences and similarities in their raw materials but these tests were usually of too crude a character to make refined distinctions Now from the very fact that ancient potters were dependent on certain sources of supply for materials to produce certain wares it was very natural that wares made by a certain people at a certain time were not made by that people at an other period or by different peoples And such a case would probably be classified as a lost art But this cannot properly be called a lost art Rather it is a case of lost materials! Given the materials the wares could be made as at first This in fact has been the work of more recent times—to ascertain by careful analysis the nature of various bodies and glazes and reproduce them Of course the composition is not the whole secret the heat treatment is almost equally important and this is a matter for careful physical testing But as the result of modern research and practical experiment it can scarcely be maintained that any body or glaze exists which has not been and can not be reproduced

Glass manufacture is allied to the ceramic industry and is probably the outgrowth of it In spite of Pliny's fable to account for the origin of glass making it is altogether likely that glazes and enamels were the immediate forerunners of glass Glass manufacture had its origin in Egypt not far from 2500 B C Who shall say that the natural mineral resources of the country (among them limestone sand and alkalis) were not responsible for its origin there? It spread to the countries east and north of Egypt to Greece and Rome to Spain France and more recently to Saxony Bohemia and Austria—finally over the civilized world At the present time the data for a history of glass manufacture are probably as complete and available as that for any other of the chemical industries—and possibly more so The ancient glasses were usually not perfectly transparent but were translucent in some cases nearly opaque Transparent glass and particularly transparent glass in large sheets is a modern production Many of the ancient glasses and those of early modern times possessed great beauty considered from the standpoint of the fine arts although their utility as light transmitters is low In Greece and Rome glass was used for plates and saucers and other table ware for pitchers and ornamental objects as tile in pavements and walls but scarcely at all in windows With the advent of transparent glass the production of the translucent varieties did not expand until finally the art languished in many countries and has but recently been revived for many decorative purposes It should be noted that the art was never really lost but the interest in and demand for translucent tinted and rough surfaced glass was low

The dyeing industry is another which dates from the remotest antiquity and which was developed without the aid of scientific chemistry on an empirical groundwork However ancient colors largely derived from vegetable sources were reproducible The use of mordants was practised by many ancient peoples particularly by the ancient Egyptians who used them not only for fixing colors but for producing different shades from the same dye bath With increasing commerce between nations new sources of dyes became available and the vegetable-dying practice had reached a high degree of perfection when the coal tar dyes were brought forth in the chemical laboratory to the wonderment of mankind and the revolutionizing of the industry It has never been claimed I believe that the art of dyeing with vegetable colors has been lost or not practised But there is a strong tendency at the present time to disparage the aniline colors It is very commonly said and accepted as true that vegetable dyes are superior to coal tar dyes That vegetable dyes are fast and coal tar dyes are not Persia has recently prohibited the exportation of rugs and fabrics dyed with anything but vegetable dyes ostensibly to maintain her reputation in the rug industry Who shall come forward and refute these charges, which are of course all but groundless? There are good and bad dyes both coal-tar and vegetable and the best dyes must be skilfully used to produce good results Let us hope that the coal tar dyes will be increasingly appreciated and that the time will not come when people will lament the lost art of vegetable dying!

But what about the cement and plaster of the ancients which outlasted the ages and even the stones which it held together? In the first place any cement or plaster which was not remarkably durable could not possibly have been preserved to this day The ancients in various countries and at various times have been well acquainted with lime burned clay limestone (hydraulic lime) hydraulic cement various natural cements puzzolan and plaster Would it not be strange if among the materials used some would not be found to yield a cement of unusual strength? And if the setting process continued through the ages and conditions were such that weathering did not seriously attack it the final product yielded would certainly be extremely hard But in any case it is certain that the weaker cements have not come down to us but have been disintegrated long ago The cement which is being made in enormous quantity to day under scientific control will probably outlast any similar material which the world has seen

But we may go a step farther in our inquiry after relegating the lost arts to the same mythological museum which holds the lost Atlantis Not only is it unlikely that there are any lost chemical arts but it is highly probable that ancient peoples were ignorant of many arts attributed to them and which are well known at the present day Such a misunderstanding could probably best be dispelled by a carefully compiled history of arts and manufactures particularly ancient arts and manufactures The production of such a book is a consummation devoutly to be wished

I have an idea that it is not a difficult matter to gain a mental picture of conditions in ancient work shops I believe that the mental attitude of artisans has not changed much during the lapse of hundreds or even thousands of years Go into any small shop at the present day where a specialized art or craft is practised and I fancy that you will find the workers there in all essential respects so far as their craft is concerned like the craftsmen of distant ages You will find there the same lack of organized knowledge the same sort of unnecessarily detail d and elaborated empirical knowledge the same narrow conservatism and adherence to formula and rule of thumb methods If you talk to the men you may learn how they learned their craft of the most skilful members of the craft they have known If you gain their confidence they may tell you of their past experiments (most of them foredoomed to failure) and of future experiments planned when time permits or when they obtain material possessed of certain hypothetical properties And you will be impressed by the way results are sometimes accomplished in spite of the use of the clumsiest mental and physical methods of experiment imaginable A typical craftsman will experiment with all the materials he can lay hands on without the slightest scientific consideration of the case in an effort to produce a certain result These things are interesting and we must hope they will never be altogether lost But our ideal for the present and the future must be a large and adequately organized industry resting firmly on engineering skill and chemical investigation operating with a full understanding of all its processes and with assurances of consistent and logical future development and expansion — Science

The Atmosphere of Cities

THE German scientists are studying the atmospheric conditions of their cities The fact that sunshine lessens as population becomes more dense and especially when the activity of industrial centers expands superficially and increases in intensity has long been noted An increasing tendency to fog has also been observed and both are effects of the imperfect and incomplete combustion of coal

Modern industry pays toll for this in the injury of delicate fabrics the general depreciation in the value of many articles of trade and household use and the increased cost of cleansing Since the battle is waged with growing energy against tuberculosis physicians and students of social science feel that the problem of purer air for the dwellers in cities has become one of the first importance

Statistics have been collected for some time past They demonstrate that little sunshine falls to the lot of the residents of industrial cities even when the sun is obscured by smoke particles In no German city has the loss of sunshine due to fogs equaled that of London where the foggy days during the three months of December January and February increased from 18 to 31 during the last half of the last century

To Wash and Clean Embroideries—Dissolve 30 parts of borax in 1,000 parts of river water at moderate heat In washing embroideries do not rub but press them rinse with cold water to which a handful of salt has been added rinse for a few minutes in sharp wine vinegar and press between two other cloths

Automatically Drawn Curves

Instruments that Represent Varying Conditions

By Albert A Somerville

A PIECE of apparatus frequently called for in scientific work is one that will automatically record varying conditions and draw a curve representing the relation between the variables Some such instruments are used for example in the weather service work One of the variables there is nearly always *time* so an accurate time-keeping piece is part of the apparatus being used to move a sheet of cross-section paper at uniform speed while at right angles to the motion of the paper a lever arm moves in accordance with the change in length of a metal rod which expands or contracts with changes in temperature At the same time by means of a stencil arrangement pressing on the paper the lever draws a time-temperature curve from which may be read the temperature corresponding to any instant of time during the period over which the record extends

A very similar method may be used to record barometric pressures from day to day The instrument employed for this purpose is known as a barograph and may be used also to record altitudes reached by a balloon or aeroplane the barometric pressure decreasing with increase in altitude

In electrical work there is a big field for recording instruments and in a well-equipped station there are kept automatically made records of voltage current and power consumed and for certain times in the day the cost of electrical energy is less to the consumer than at other hours during which there is a big demand made on the power station

In all of these cases named one of the factors is the time variable

Just as interesting are other cases involving dynamical data e g forces and their directions and the motions due to those forces In such cases curves may be drawn representing the direction of motion only without respect to time change

One of the most interesting simple cases is that of circular motion as affected by friction and the curves shown in the accompanying illustration are representative of such a case The problem presented is of a type which is considered in probably every book on general physics now being used in schools or colleges

On the principles underlying circular motion depend the following phenomena The tendency of a spinning top to remain upright, the bursting of a rapidly rotating wheel the performance of a loop-the loop the action of cream separators and centrifugal drying machines the force of a sling-shot the necessity for the elevation of the outer rail on a curve in a railroad the lag and lead of trade winds and lastly an amusement device now being extensively used in popular parks whose action resembles in some features the phenomena presented by the trade winds It consists of a smooth horizontal wheel rotated about a vertical axis at such a speed as to throw off any particle resting upon it The wheel is ordinarily 20 or 30 feet in diameter and the amusement takes the form of allowing youngsters to pile onto it while it is at rest and then rotating it gradually increasing the speed until everyone has slid off into the surrounding gutter

The curves shown in Figs 1 and 2 are from a model of such a device In one of the recently published text books there appears the problem Given a certain value for the friction force at what speed is it necessary for the wheel to turn in order that a body may just slide off? To this may be naturally added the question In what direction would the body slide?

In order to clearly understand the problem it is necessary to review briefly certain principles known as Newton's laws relating to bodies in motion or at rest All we need to know is that if a body is in motion it has a tendency to move in a straight line and if it is kept moving uniformly in a circle there must be a constant force pulling in toward the center of the circle or else the body will fly off at a tangent to the circle as is the case with mud or water flying off a revolving wheel or as exemplified by the direction in which a stone travels when revolved in a circle by means of a string and suddenly released by the snapping of the string

It is also useful for us to know that the amount of this force toward the center necessary to keep a body moving in a circle with a uniform velocity is equal to the algebraic expressions $\frac{MV^2}{R}$, in which M is the mass or amount of material in the body V its linear velocity and R the radius of the circle in which it is moving From this we see that as the speed V increases the force necessary to hold the body in the circle increases, and also the smaller R the radius of this circle the smaller is this force

In the case of the boy sitting on the rotating horizontal wheel the only force that holds him at the center or that keeps him from sliding out is friction between him and the surface of the wheel Now friction is something which depends on the nature of the two surfaces in contact. The force necessary to overcome friction is equal to a certain constant K, characteristic of the surfaces in contact, multiplied by the pressure between those surfaces or in this case by the weight of the body which is equal to its mass M multiplied by the acceleration of gravity g

The friction Mgk is constant. If the speed of the

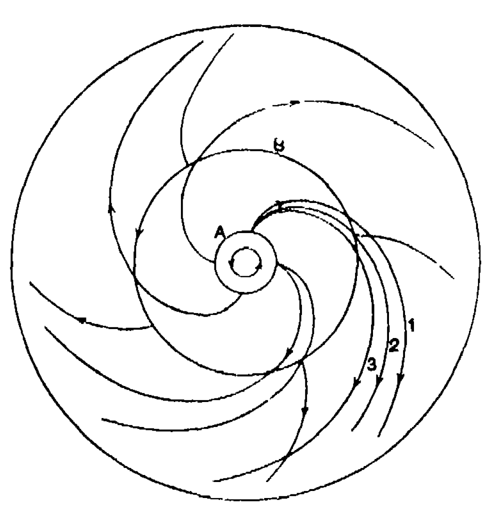

FIG 1

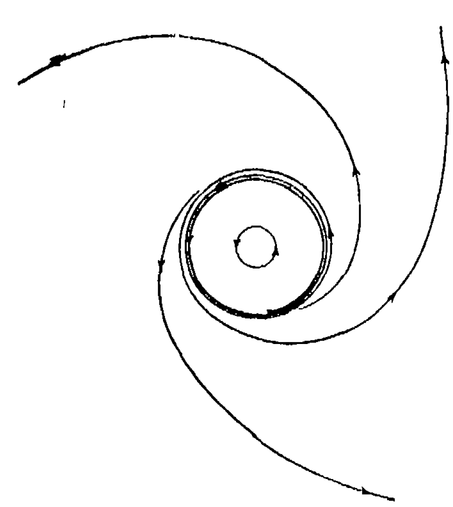

FIG 2

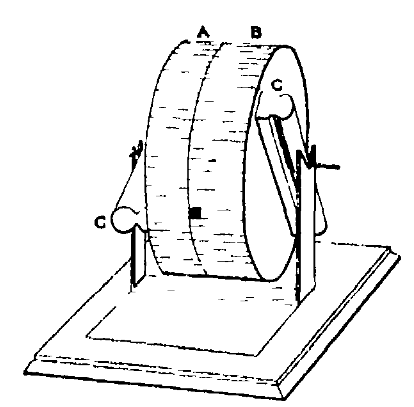
CURVES TRACED BY POINT SLIDING OFF ROTATING HORIZONTAL DISK

wheel is increased the body will begin to slide when $\frac{MV^2}{R}$ becomes equal to or just greater than Mgk i. e., as soon as the equation $\frac{MV^2}{R} = Mgk$ is satisfied

Since M occurs on both sides of the equation we see that the motion is independent of the size or mass of the body and since the force varies as $\frac{V^2}{R}$ and V the linear speed varies directly as R it is evident that a body near the edge will start to slide sooner than one near the center of the wheel To draw the curves a model wheel 2 feet in diameter was used, mounted on a variable speed motor The wheel was covered with a sheet of paper and a block holding a pencil placed on it The wheel was then speeded up until the block carrying the pencil would slide off and trace its own path on the paper The wheel was run in a counter clockwise direction as indicated by the arrows on the central circle. The block starts to slide off along the radius of the wheel, but soon falls behind as shown in the curves of Fig 1 Traces of the paths are shown starting near the center, and also starting about half way out from the center Curves 1, 2 and 3 represent different accelerations or rates of bringing the wheel up to speed. Curve 1 is the path of the moving block when the wheel is very slowly brought up to speed and curve 3 shows it is quickly brought to the speed at which sliding starts In all these curves the motion is represented with respect to the wheel, which is itself in motion, and taking any radius of the wheel we see that with respect to this line a body sliding on the wheel continually slides backward If now, as in Fig 2, the curves are drawn with respect to a fixed system, say the earth, instead of the wheel, which is moving we get an entirely different set of curves showing that when the body begins to slide it starts on a spiral but while the motion of the body with respect to the wheel was backward, with respect to the earth it is forward The curves in Fig 2 were drawn by placing the block bearing the pencil on the wheel, but pointing the pencil upward and having it attached to a spring to make it press against the lower side of a sheet of paper fastened to a fixed plane above the pencil Inasmuch as the curves of Fig 2 are, as it were inversions of those of Fig 1 it is only necessary to reverse the motion of the wheel in order to obtain with the second arrangement tracings similar in character to those prepared by the first method.

Multi-Cipher Device

JAMES TREVOR in the *Aust Min Stand* describes a multi-cipher device devised by him and shown in an accompanying illustration This device consists of two cylinders mounted loosely on an axle but so arranged that they can be securely clamped together in any position The axle rests in standards on a base



MULTI CIPHER DEVICE

board In the illustration A is the cylinder on which are the code words B the one on which is the key to the code C is a handle for aiding in turning the cylinders In case one pair of cylinders is not enough other pairs of cylinders can be mounted on the same axle A certain phrase in the key is always selected as the one opposite which the keyword of the code is to be clamped Each message is prefaced by a key word so that for each message the code is changed. This prevents easy deciphering of the code used and the message can be read more easily than if a book has to be used.

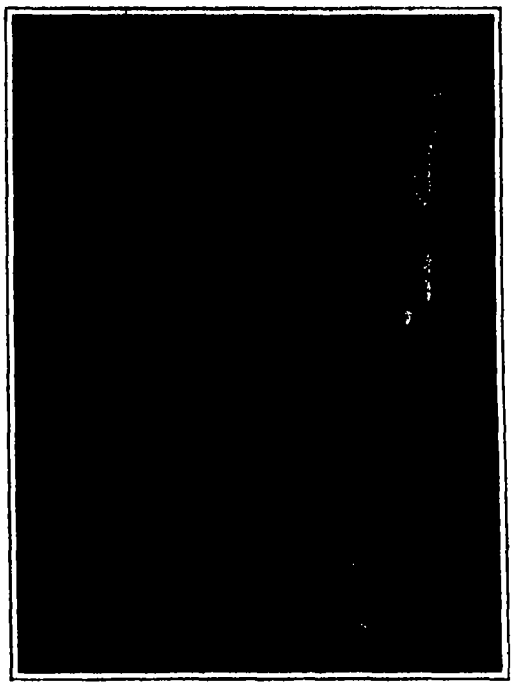
Excavations at Susa

By Our Paris Correspondent

The remains at Susa interest us in more ways than one for this city was not only one of the leading capitals of the Persian Empire and for a long period the residence of royalty but also figured as the scene of the biblical story of Esther and Ahasuerus. The site is now covered by immense mounds which rise above the surrounding desert plain We should no doubt know a great deal more about it but for its isolation in the far interior which renders it difficult of access and makes the transportation of finds extremely difficult M Dieulafoy an eminent Paris archæologist was the first to discover any important remains at Susa and some of the results of his work have been selected as the subject of this article

According to M Dieulafoy s description the city must have presented an imposing appearance as viewed on approaching it from the surrounding country with its royal acropolis a great fortified place situated on a height above the rest of the city Here the walls and towers built of sun dried brick rose to thirty times a man s height. After passing through the city and the commercial quarters we follow a wide avenue which leads up to the acropolis The fortifications were surrounded by a moat which took its water from the neighboring Choaspes stream No less than sixty feet thickness was given to the brick walls so as to furnish the strength to withstand the shocks of battering rams Spaced around the walls were watch towers and postern gates and a main gate at the front gave access to the interior This gate was flanked by two projecting towers as we see them in fortifications of the Middle Ages and there were also covered porticos here which served as the center of life outside the palace We may imagine Mordecai sitting under the portico according to the Bible story waiting to communicate with Esther who occupied the women s apartments in the King s palace within the walls

After passing the great gate we come to a high tower resembling the donjon of our early fortresses This formed one corner of the outer work being however separated from the main walls by a space so as to be better protected This part however remains to be excavated No doubt it served as a last refuge for the soldiers and inhabitants of the royal city where they could flee for protection in time of danger Farther on is a large central space which was originally the great central square or parade ground Around the square were various structures On one side is the Citadel occupying another point on the fortification walls and dominating with its great towers the rest of the work It was shaped somewhat like the Assyrian forts with which we are familiar On the other side of the square is the King s private palace containing the women s apartments where Esther lived We do not know as yet whether any parts of the ancient buildings remain as there have been no excavations made here up to the present time Opposite is the great throne room



CAPITAL OF COLUMN IN THE THRONE ROOM AT SUSA

A FRIEZE FORMED OF FIGURES REPRESENTING ARCHERS SUSA

FRIEZE OF LIONS AT SUSA

MODEL OF THE THRONE ROOM

EXCAVATIONS AT SUSA

which is shown in our illustration and which deserves special mention as it was on this spot that M Dieulafoy carried out most of his work The structure lies on an elevated space and covers much ground A great double staircase led up to it from the square with balustrades of enameled brick in handsome designs and colors and the steps were wide enough to accommodate thirty men abreast and even horsemen could mount them At the bottom and also at the upper level were high gates or pylons adorned with a handsome decorative border of lions in enameled brick Beyond the gate were gardens very tastefully laid out with trees and flowering plants and we may suppose that a gay array of brilliantly colored tents set up with cedarwood poles and fastened with silver rings were scattered over the landscape

Especially striking owing to its vast proportion is the *apadana* or throne room which was used by the Persian kings for special occasions Here the King held his court and received tributaries or ambassadors from surrounding nations Enough of the remains of this large building were found to give a very good idea of what it looked like in ancient times and the model shown in our illustration has been prepared in accordance The building was almost an open structure and had a central hall surrounded on three sides by porticos upheld by columns The entire building covered about half an acre Six ranges of great columns made from the gray stone of a neighboring quarry upheld the roof of the principal part The columns were no less than sixty feet in height One of the capitals of the columns was found almost entire and is shown in our engraving It was brought to Paris after much labor as this great mass of stone was very difficult to transport

The roof beams are supported on a double figure of gray stone representing kneeling bulls In the original state the horns and ears were no doubt of gold but they are now restored in copper The general treatment of the capital is a combination of Egyptian, Greek and Chaldean styles. Near the roof, all around the building, ran a wide frieze representing a long file of lions inclosed in a decorative border A part of this frieze was found sufficient to piece together a few entire panels in an excellent state of preservation This exceedingly handsome frieze is shown in one of our illustrations. The lions are represented between borders having a lotus decoration and are remarkably executed in molded brick colored alternately with different enamels The colors in the frieze are white yellow blue and green and the background is a soft turquoise blue so that the whole design gives a very rich effect. As enamel colors hardly change at all with time we have the frieze in almost the same state as in the ancient period The front of the throne room has no doors and it is likely that curtains were hung down in the spaces between the columns so as to shield the inside from the sun and these could be raised or lowered to give shade when it was needed

Oriental magnificence was not spared on the inside of the throne room to judge by the remains which were found on the spot. It was lined with a red stucco but no doubt the walls were nearly or quite covered with tapestries of the most gorgeous colors In the niches of the walls were gold and silver vases and like ornaments Some of these were gifts made to the King by tributary nations such as the gold plane tree presented to Darius by the satrap of Phrygia

Cedar of Lebanon formed the roof beams, and this was incrusted with gold and mother of pearl leaving the wood also visible as at that time cedar was counted as a precious wood and was no doubt treated by [illegible] were brightly colored, carpets [illegible] with men and animals, hunting scenes [illegible] The King sat under a dais upon a carved [illegible] and held a scepter in his hand. Amid all [illegible] nificence sat the descendant of Darius and [illegible] ruled at that time over all the neighboring [illegible] including Persia Chaldea, Asia Minor [illegible] The King was recognized as the elect of the [illegible] Ormazd and the remains of an inscription [illegible] a dedication to this divinity were found on the [illegible]

The present building was erected by [illegible] Memnon and lies on the site of a more ancient building of the time of Darius I A part of the decoration of the older structure was also found, among [illegible] a very handsome frieze of enameled brick representing the soldiers of the King's bodyguard These figures of the Persian soldiers or archers are remarkably well executed and the colors are most pleasing. The archers hold a short javelin before them and on their shoulder carry bow and quiver According to the ancient writers the Persian kings had in addition to their foot guard a special bodyguard of 10 000 men called the "Immortals Of these 9 000 had iron headed javelins with silver pomegranates at the end, a description which corresponds strikingly with the figures shown on the frieze The remaining 1 000 men were a special select corps and carried spears with gold pomegranates

As regards the story of Esther and Ahasuerus (Darius I) it is to be remembered that the events in question took place before the present *apadana* was built However the archers frieze belongs to that period as it was part of the earlier building Perhaps the remains of other buildings of the period mentioned in the Bible still exist in the parts which remain to be explored

Radiant Energy and Matter—II*

Sir J J Thomson's Royal Institution Lectures

Continued from Supplement No. 1849, page 364

IN opening his second lecture Sir J J Thomson said that he has on the last occasion discussed some views which had been put forward to explain whence the sun derived the enormous energy it radiated which according to various estimates ranged from 10 000 to 15 000 horse power per square foot of its surface

The radiation from the sun Prof Thomson proceeded traveled away through space, a small portion of it falling on the planets Of the energy they were thus continuously acquiring the planets saved but a small amount The earth for instance did not retain any appreciable quantity giving it back to space again also in the form of radiant energy

It was possible to form an estimate of the temperature a body would acquire under the influence of the suns radiation if it lost just as much energy as it received Prof Poynting had thus calculated the temperature of the different planets on this hypothesis In this calculation there were some uncertain factors particularly as to the quantity of radiation reflected In the case of the earth this was an appreciable amount Making however the most probable allowances and estimates it appeared that Mercury would have a temperature of 467 deg absolute or 194 deg C Venus one of 368 deg absolute or 95 deg C while the corresponding figure for the earth was 290 deg absolute or 17 deg C In this case the calculation could be checked and the figure given represented very well the average temperature of the earth Calculated in the same way the temperature of Mars came out as − 38 deg C or far below the freezing point of water This appeared unfortunate for the canals but he believed that Mr Lowell had ways of meeting the difficulty The temperature of Neptune calculated in the same manner was [illegible] deg C so that this planet presented exceptionally favorable conditions for the conduct of low temperature research In this connection the question also arose as to what would be the temperature of a body exposed to starlight only Astronomers estimated starlight as equivalent to [illegible] of bright sunlight and taking this as the basis of the calculation it appeared that a body exposed solely to the radiation of the stars would acquire a temperature of 10 degrees absolute

The main portion of his last lecture he proceeded had been devoted to showing the connection between the total amount of radiation given out by a black body and the absolute temperature of that body All the most recent experiments showed that the amount of energy radiated per square centimeter of surface could be represented by the $5 \cdot ? \times 10^{-5}\theta^4$ ergs per second The erg was a convenient unit for purposes of calculation but was too small for engineering purposes one erg being about the amount of energy exerted by a common house fly when it crawled up a window pane a height equal to the breadth of ones finger nail

The expression above given for the radiation from a black body had been applied in a most ingenious way to the measurement of the temperature of furnace fires and the like by means of the Féry pyrometer In this instrument the light from a furnace was focused by means of a mirror onto a thermopile which thus received a fraction of the total radiation emitted by the body to which it was directed It was thus necessary merely as it were to look at a furnace with the instrument in order to determine its temperature As he had stated last time the fourth power law had originated in some calculations made by Stefan on some experiments made long ago by Tyndall It had since been shown that this law was the only possible one in accord with thermodynamics

This conclusion resulted from a consideration of the pressure due to light In fact all radiant energy exerted a pressure on a body which absorbed it This was almost self-evident when light was thought to be a stream of small particles moving with great velocity If such particles were absorbed by a body the latter would be pushed forward the effect being equivalent to a pressure exerted on the body When the undulatory theory was introduced however it was not clear that there would be any similar pressure if light were a wave motion In fact, this very point had been taken as a crucial distinction between the old and the undulatory theory The experiment had been tried by Bennett who allowed light to fall on a delicately suspended disk and fortunately perhaps for theory, had failed to detect any motion We now knew that had more delicate methods been adopted the result would have been different but had this been the case the experiment would have been almost a death blow to the undulatory theory It was not till long afterward that it was shown that on the electro-magnetic theory also radiation must exert a pressure on bodies which absorb it.

It was somewhat remarkable that many of the more recently discovered properties of light were in many respects more easily explained on the old corpuscular theory than by means of its successor and this question as to the momentum of radiation was an instance in point Maxwell however, showed that if light were an electro-magnetic disturbance a beam of it must possess a certain amount of momentum in the direction of its motion, and was accordingly in this regard mechanically equivalent to a stream of particles Hence when light was absorbed all its momentum was communicated to the absorbing body as a pressure This was not likely however to lead to any practical inconvenience On an average-sized man standing in full sunlight the total resultant pressure only amounted to about ½ milligramme It was indeed a great triumph that these excessively small effects should have been demonstrated and measured within a few per cent, with laboratory apparatus in which the total force acting was but $\frac{1}{5000}$ part of a milligramme

The effect in question Prof Thomson proceeded, must be distinguished from that which caused rotation in Crookes radiometer When this was first invented the effect was believed to be due to light pressure, and the instrument was sometimes referred to as a mill driven by light Further work showed that the forces in operation had a different origin the motion observed being due to the communication of momentum between the hot plates of the rotating part and the colder walls of the containing vessel It was the lecturer proceeded easy to distinguish between a purely domestic affair of this kind and an effect due to an external cause such as was the pressure due to light In fact any effect due to the action of the glass in pushing particles of air against the vanes could not produce rotation of the apparatus as a whole a self-contained system being incapable of acquiring momentum It would be as impossible for the radiometer effect to produce rotation of the instrument as a whole as for the passengers facing the engine in a train to assist in propelling the latter by hitting those on the opposite seats Action was balanced by reaction and if the vanes moved round in one direction, then the casing if freely suspended, would turn in the other To show that this was indeed the case, the lecturer suspended a radiometer complete from a fine wire When exposed to a strong light the vanes rotated in one direction while the bulb of the instrument moved round slowly in the other

This radiometer effect, Sir Joseph continued was one of the difficulties which had to be got rid of in experiments on the pressure of light. Its effect was very large as compared with the latter Another difficulty arose from convection currents. If the air in the vessel used got warmed, currents were set up, which acted with forces almost infinite in comparison with the light pressure to be measured, These could be got rid of by placing the apparatus in a vacuum, but this made the radiometer effects worse. The problem was thus a difficult one. The radiometer effects could, however, be avoided by taking advantage of the fact that they were purely a domestic affair and that if the vane were [illegible]

* Report of Sir J J Thomson's lecture reproduced from *Engineering*

[illegible] containing vessel they would cancel out [illegible], the lecturer continued, in the apparatus [illegible] Prof. Poynting In this the vanes [illegible] the pressure of light were rigidly [illegible] their mica case, the whole being suspended in a vacuous vessel from a quartz fiber The mica [illegible] very little of the radiation and its temperature therefore remained much the same as that of the outer vessel On exposure to light the pressure on the vanes caused the whole of the mica vessel to deflect, the amount being measured by a spot of light reflected from a mirror

The pressure due to light was the speaker continued, first detected by the Russian physicist Lebedeff, and a little later Nicolls and Hull succeeded in getting a very satisfactory agreement with the predictions of theory On the theory that light consisted of a stream of particles there was also a pressure produced but different in amount, so that the experiments made served to discriminate between this theory and the electro-magnetic theory With the former the pressure produced would be just twice as much as with the latter Hence if we could trust our experimental results within a margin of 50 per cent, it was possible to determine which theory best satisfied the experiments Messrs Hull and Nicolls found their results in close agreement with the requirements of the electro-magnetic theory the difference not amounting to 10 per cent

Since light exerted a pressure it was possible to conceive of an engine operated by this pressure The amount of power produced might not be at all formidable and would make no show in the industrial world, but all such engines whether large or small were subject to the same laws since there was not in thermodynamics one law for the rich and another for the poor Suppose then a cylinder fitted with a piston and filled with light instead of with gas This light would exert a pressure on the piston Calling the energy of the light per unit volume E then the pressure per square centimeter on the piston was numerically equal to 1/3 E by the electro-magnetic theory while in the case of a gas filling the cylinder it would be 2/3 E

Suppose now the piston was allowed to rise so as to alter the volume below it by the amount v^1 Then the work done would be $p v^1$ At the same time however, in order to fill up the space left behind and thus keep the temperature constant energy equal to E v_1 must also be supplied

Hence the total supply of energy must be

$$p v^1 + E v^1 \text{ or since } p = 1/3 \text{ E}$$

we had

$$p v^1 + E v = 4 p v^1$$

But it was shown in thermodynamics that in that case we must have*

$$4 p v^1 = \theta \frac{dp}{d\theta} v^1$$

$$\text{or } 4 p = \theta \frac{dp}{d\theta}$$

where θ denoted the absolute temperature

Integrating this gives $p = 1/3 \text{ E} = c T^4$ which was the fourth power law

The existence of this pressure due to radiation had Sir Joseph continued been put to a great many uses as an explanation of phenomena Thus it had been supposed sufficient to account for the existence of comets tails and Arrhenius had suggested that it served to regenerate the available energy of the universe now being continually dissipated in various ways For his own part he thought a little too much had been made of the fact that light produced a pressure and that the application of a little cold arithmetic would show that the hypotheses framed were hardly warranted by the facts

As for comets s tails it was of course true that light from the sun would exert a pressure on small opaque bodies which, if sufficiently minute might be repelled in spite of gravitation Gravitational attraction was proportional to the volume of a body while the light pressure was proportional to the surface Hence if the bodies were made smaller and smaller we must at last come to a size when the repulsion due to light would exceed gravitational attraction For this repulsion to come into play however the light must be absorbed If the particles were transparent, there would be no repulsion If a comet s tail consisted of dust then no doubt, the light pressure would sweep out this dust from the doorsteps of the sun If however the tail were gaseous, then to get the gravitation balanced by the light pressure this light must be absorbed It could be shown that the light pressure due to the sun was one ten thousandth of a milligramme per square centimeter and hence if 1 square centimeter had a mass of one-tenth of a milligramme behind it, the light pressure would just balance the attraction Hence 1/10 milligramme must suffice to absorb all the light incident on 1 square centimeter No gas was however known which was capable of doing this Hence if the comet s tail were gaseous one could hardly conceive that its repulsion was due to the pressure of the sunlight

This pressure of light formed an excellent illustration of Le Sage s theory of gravitation which assumed that all masses in the universe were being bombarded by particles coming from all directions Each mass would therefore shield its neighbor from some part of the bombardment it would otherwise receive and hence the two would be impelled toward each other The same kind of thing happened in the case of radiation pressure Two cold bodies placed within a warm inclosure would each shield the other from a certain pressure it would otherwise receive from the radiation from the walls and the two would tend to move as if attracted to each other If on the other hand the bodies were hotter than the inclosure they would repel each other Prof Poynting had thus shown that two globes each of 20 centimeters radius and at the temperature of boiling water would if radiating freely into cold space repel each other with a force exactly equal to their gravitational attraction It might be asked he continued whether this effect was not a serious thing for experiments on gravitational attraction and undoubtedly it would be so if the walls of the inclosure in which such experiments were made were much cooler than the apparatus experimented with In the actual conditions of the experiment however the radiation pressure canceled out

(To be continued)

* Engineers will recognize the equation better in the form

$$v\,dp = L \frac{d\theta}{\theta}$$

the well known relation between the specific volume of steam and its latent heat This gives $L = \theta \frac{dp}{d\theta} v$ and L being the total energy added at the temperature T is the equivalent of $4 p v^1$ above

Fixing the Day of the Week of Previous Dates

Some Curious Rules and Their Application

By Robert Grimshaw

In combating the erroneous idea that Friday is an unlucky day, and in advancing the fact that for America it has been a particularly lucky one—if there be any such thing as luck—any one who will look up American history from the date of Columbus s sailing to the important battles in Mexico and elsewhere will be convinced that Friday and thirteen are for us lucky I incidentally stumbled upon the method of determining the day of the week on which a given date fell—a system of calculation which is employed by the lightning calculator Leo Erichsen on the German variety stage and which as it is probably new to most of the readers of this periodical, I present in detail

In the ordinary year of 365 days there are 52 weeks and one day over which latter extra day renders more difficult the determining of the day of the week in times gone by—a difficulty which is increased by the presence of the extra day of the leap year and still further by the absence of this extra day on certain even hundreds of years From this arrangement that the year ends on the same day of the week as that on which it begins springs the catch which is usually successfully employed as a bet—that this year Christmas and New Year s Day do not fall on the same day of the week.' Naturally for the New Year's Day" of which the victim thinks is not in the same year as the Christmas in question but in the next

Now if the year 1 of our Lord began on a Saturday the year A. D 2 began on a Sunday, and A. D 3 on a Monday After seven years of 365 days each, the same order occurs again So we start with the fact that the year 1 began with a Saturday The same is true of the year B C. 10001, which astronomers call minus 10000

In dividing by seven the number of the years of 365 days each since the year 1 of that period we have as remainders for Saturday 0 Sunday 1 Monday 2 etc. But the occurrence of leap year complicates the matter The number of days which have been "inserted" by the extra day of February is ascertained by dividing the number of the year by 4. This is good all the way through for the so-called Julian calendar, which is still in use and force in Russia, Bulgaria and Servia. But according to the Gregorian calendar by which we now reckon and which was introduced by the papal bull of 1582 October 6th *Inter gravissimas* there were cut out from the date mentioned until 1700 ten days for the eighteenth century 11 days for the nineteenth 12 and for the twentieth (our own) 13 from the Julian calendar This is to be considered after dividing the number of the year by four Therefore when we calculate the day of the week of the year A D 1 must be thrown back one day a year more from Saturday of the year 1 further by one day for each leap year and if the date according to the Gregorian calender is desired the number of the missing days is to be subtracted from the date according to the Julian calendar The result of the calculation determines the number of weeks which have elapsed from January 1st up to the date in question This is the only part of the calculation which requires any act of memory on the part of the lightning or other calculator He must keep in mind that on the 0 day of each month [illegible] January 1st there have elapsed in January 1 day, in February 30, March 58 April 89 May 119 June 150 July 180 August 211 September 242 November 303 December 333 days (With the aid of the ordinary mnemotechnic rules these numbers will not be very difficult to retain in the mind) It is easy to see that on the 16th day of January 15 days have elapsed since January 1st on November 7th 310 etc.

The practical application of the rule is much more easy than it would at first seem in view of this theoretical discussion First 1 is to be subtracted from the number of the year and the remainder divided by 7 The remainder if any of this division is called the first remainder Then the undiminished whole number of the year is to be divided by 4 From the quotient (which for dates before February 29th is to be lessened by 1) the number of missing days according to the reformed or Julian calendar is to be subtracted This difference is to be divided by 7 and the remainder if any called the "second remainder" Finally the number of days since January 1st is to be divided by 7 and what is over, if any, then called the "third remainder The three remainders are to be added together and the sum divided by 7 so that at last there is a final remainder which will be one of the numbers 0 to 6 inclusive If this final remainder be 0 the day of the week was Friday if 1 it was Saturday and so on

As an example we take the date 1628 January 28th (this order being chosen for convenience) 1611 1 = 1610 1610 − 7 = 230 first remainder 0 1611 − 4 = 402 The number of missing days for the seventeenth century is 10 then 392 − 7 = 56 with no remainder so second remainder is 0 On January 28th there were 27 days elapsed since January 1st the third remainder after dividing 27 by 7 is therefore 6 The sum of the three remainders is 6 which shows that the date in question fell on a Friday

Suppose we choose as an example 1423 May 30th 1423 − 1 = 1422 which after dividing by 7 gives as first remainder 1 1423 − 4 = 155 155 − 10 = 145 145 7 = 20 leaving as second remainder 5 May 30th (149 days elapsed) 149 − 7 = 21 third remainder 2 Sum of the remainders 8 then final remainder 1 calling for a Sunday

This method has been known for some time although not to a very large circle A novelty is its application to dates before the birth of Christ as explained by Kretzinger of Berlin To work this out it is necessary to call the year by its astronomical year number that is one less than the number which we give it This number is subtracted from 10 000 and the difference divided by 7 to get the first remainder The same difference is then divided by 4 and the quotient increased by 1 because minus 10 000 was a leap year Only in such years it remains up to February 28th unchanged otherwise the old rule applies As an example

—2865 B C February 17th

− 2864 + 10 000 = 7136 first remainder 3 7136 − 4 = 1784 (no addition because the date lies before February 29th and the year is not divisible by 4) 1784 ÷ 7 = 254 with 6 as second remainder On February 27th there were 47 days elapsed since January 1st remainder 47 ÷ 7 = 5 Sums of the remainders, 3 + 6 + 5 = 14 final remainder (after dividing 14 by 7) 0 Therefore the day of the week would have been Friday

The Alteration of Checks*

How Alterations are Made in Spite of Safety Tint Paper and Check Punches

By William J Kinsley

If all forgers were as skilful as painstaking and astute as was Charles Becker of Brooklyn when in 1896 he raised a draft of the Bank of Woodland California on the Crocker Woolworth Bank of San Francisco from twelve dollars to twenty two thousand dollars the protection of banks against alterations would be almost impossible—particularly so when drafts and checks are cashed in the rather hurried manner almost unavoidable in the rush hours

So artistic was Becker's alteration of this twelve dollar draft that a careful examination under the microscope was necessary for its detection The draft had been duly protected with a check punch but paper was chewed into a plastic pulp-like mass the old perforations were filled and these fillings were hardened and ironed The draft was on a safety tint paper but this did not prevent the erasure of the amount by means of acid the surface and tint being restored thereafter by means of water color The raised amount was then inserted in letters and figures new perforations to "protect" the twenty-two-thousand dollar draft were made with a hand punch and the raised draft was complete

The altered draft was cashed without exciting suspicion and without unusual difficulty and before its fraudulent nature was discovered Becker had disappeared It was only after a two years chase all over the United States that he was finally located and arrested in Newark New Jersey On his first trial the jury disagreed but at the opening of the second trial Becker pleaded guilty and was sentenced to two years imprisonment in the California State Prison

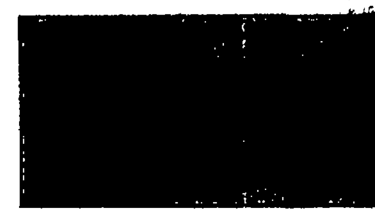
Upon the completion of Becker's sentence he returned to his former home in Brooklyn. I have been informed by one of the officers of a safety paper company that since then Becker applied [illegible] a position as salesman and demonst[illegible] the *advantages* of using safety paper for [illegible] drafts It is needless to say that he wa[illegible].

The Work of an Artist

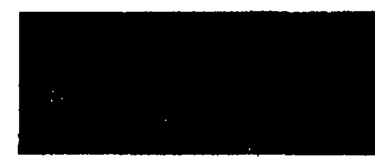
Probably the best educated and most [illegible] in the United States is Alonzo J Whit[illegible] now completing an eight year term in the Auburn New York State Prison for raising a draft drawn by the National Hudson River Bank of Hudson, New York on the Mechanics National Bank of New York city The draft was drawn for nine dollars It was raised to nine thousand dollars.

Preparatory to this transformation Whiteman purchased several small drafts from the National Hudson River Bank Experiments were then made with different acids to ascertain their effect when erasures were made. On two of the drafts the acids evidently failed to work properly, discoloring the paper. These damaged drafts were first burned sufficiently to efface the incriminating discolorations and were then returned to the bank by Whiteman or his confederates for redemption, with an explanatory [illegible]

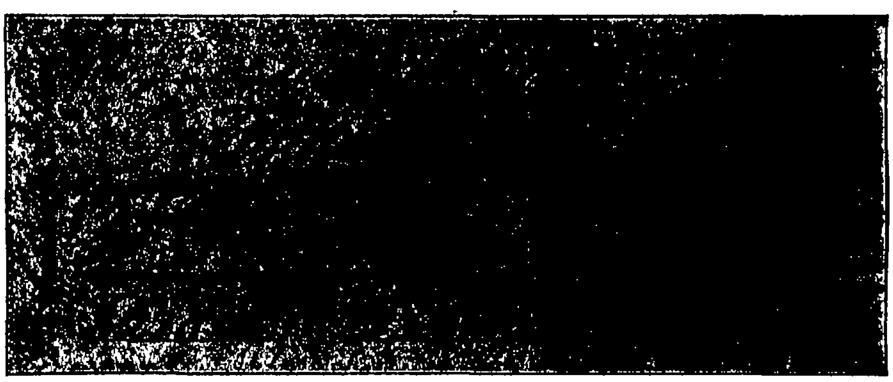
A DRAFT ORIGINALLY FOR TWELVE DOLLARS RAISED TO TWENTY TWO THOUSAND DOLLARS



RAISED FROM ELEVEN TO SEVENTEEN*

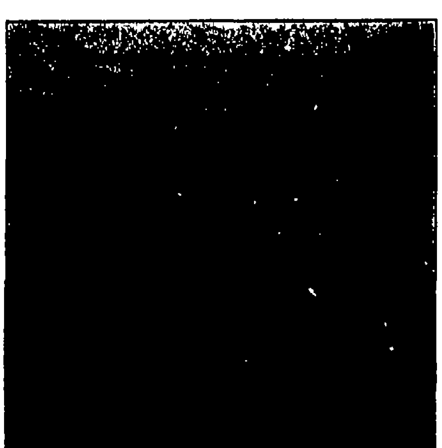


ARTISTIC CHECK PERFORATING ORIGINAL HOLES FILLED AND NEW AMOUNT PUNCHED*



RAISED FROM TEN DOLLARS TO TWO HUNDRED AND TEN DOLLARS

RAISED FROM FIFTEEN TO TWENTY THREE*



BOND WITH ORIGINAL SIGNATURE ERASED AND NEW SIGNATURE INSERTED

THE UPPER DRAFT HAS BEEN RAISED FROM NINE TO NINE THOUSAND DOLLARS THE LOWER DRAFT WAS DAMAGED IN AN EXPERIMENTAL RAISING AND WAS REDEEMED BY THE ISSUING BANK*

* *The Business World.*

* The illustrations marked (*) are from photographs made by Albert S Osborn Examiner and Photographer of Documents, New York.

[illegible] that the papers had been accidently burned by [illegible] ashes. The drafts had undoubtedly been burned and the bank very obligingly redeemed them both. The illustration on the preceding page shows one of the damaged drafts.

Whiteman's next attempt was evidently successful. Once one of the drafts originally for nine dollars but now raised to nine thousand dollars was shortly thereafter deposited in the Fidelity Trust Company of Buffalo, New York—where an account was opened—and a large part checked out before the fraudulent nature of the draft was discovered.

Whiteman fled but was arrested some six months later in St. Louis. While on his way home for trial he jumped from the window of a Pullman car within a few miles of Buffalo and made his escape. He fled to Mexico but later returned to his home in Dansville, New York, where he was again arrested. He was convicted in October, 1905, by Assistant District Attorneys Frank A. Abbott and John W. Ryan of Buffalo, and was sent to prison for a term of years.

I testified at Whiteman's trial. While securing autographs of the attorneys in the court room at the close of the trial Whiteman came over and said: "I know that you want my name," and put his autograph in my book as though proud to have it there. He seemed to feel no animosity for my part in his conviction.

After Whiteman had been in prison about a year I met his attorney and as a matter of curiosity asked him what work Whiteman was doing in jail.

The attorney replied "Teaching." I asked "Teaching what?" and the attorney replied "Business."

Common Methods of Raising Checks

There are various methods of raising checks. One of the commonest is to take advantage of spaces either before or after the original writing. If space is left to the right of the amount terminal letters or figures changing the amount are easily added. Thus a check drawn for seven dollars is, if moderate space has been left to the right, readily raised to seventy. Likewise if there is space at the left of the amount it may easily be raised by the insertion of the proper words and figures. Thus a check for five hundred dollars is by the insertion of forty, fifty, etc., in space at the left readily raised to forty-five hundred, fifty-five hundred, etc.

A Forgery or an Alteration

This method has been followed on occasions with much success. In the Bickart check shown in the accompanying engraving the depositor claims the signature is a forgery, while the bank claims that the signature is genuine, but that the amount has been "raised" from ten to two hundred and ten dollars—in the same handwriting. The writer of the body of the checks (who also cashed them) is serving a sentence in Sing Sing Prison for his part in the work.

Wholesale Alterations

In a recent case dozens of checks were put in evidence which the depositor claimed had been variously raised from six, seven, eight and nine dollars to larger amounts by adding 'teen' to them. The checks, both as to the original amounts and the raised amounts, were all in one handwriting, and it was charged that the bookkeeper made the changes after the depositor's signature had been affixed. This was, of course, a comparatively easy thing to do, but a fraud very difficult of detection.

Other Methods of Altering Checks

Another method of altering checks much in vogue is the actual change of the amounts themselves. Badly bungled examples of this method are shown in the accompanying half-tones, the change of amount from eleven to seventeen in the one and from fifteen to twenty-three in the other being easily apparent.

Another method of alteration, or a combination of methods already mentioned—is shown in the accompanying illustration. This is part of a promissory note which originally read two hundred dollars. A close inspection will show that a capital "T" was placed before the small "h" in "hundred" and the "hundred" altered so that with its prefixer "T" it reads "Thousand." An additional cipher added to the figures completes it.

Alteration of Check by Maker

Frequently checks are altered by bodily adding something to them after they have been returned to the depositor from the bank. It is of course but seldom that the amount of the check is changed in such a case. Usually the additions are explanatory of the supposed purpose of the check, as, for instance, "In full of account," "In full of all demands," "For interest on note," etc. In one such case I discovered that the pen in adding the words "In full of account" had slipped into one of the punch holes in the cancelling "Paid" perforated by the bank. As this cancelling perforation was of course made after the check had been paid, the ink marks inside the edges of the punch hole were proof positive that the writing was added after the check had returned to the depositor's hands, and not before as the depositor would have had the court believe.

ALTERED CHECKS. ORIGINAL NAMES AND AMOUNTS REMOVED BY MEANS OF CHEMICALS.

Another case hinged on whether the sentence "In payment one gray horse to be right in every way" was written in its entirety at the time the deal was made, or whether "to be right in every way" was inserted at a later date. The entire sentence is concededly in the same handwriting, is written with the same ink and probably with the same pen, but it was claimed by the defendant in the case that the phrase "to be right in every way" was added the day after the preceding words were written. A reproduction of the disputed sentence is shown in the engraving. Notice the difference in quality of line and slant between two portions of the sentence.

A Daring but Successful Method of Alteration

One of the most successful methods of altering checks is to erase the entire amount—both letters and figures—and then to replace it with any sum that suits the artist. This method is extremely difficult of detection if skilfully done and is applicable to any kind of instrument. Even on safety papers a portion of the face of the check can be washed off by

ORIGINAL SIGNATURES ERASED AND OTHER SIGNATURES SUBSTITUTED.

A NOTE ORIGINALLY FOR TWO HUNDRED DOLLARS RAISED TO TWO THOUSAND DOLLARS.*

acid the check be re-tinted as necessary and then the desired amount be written in This was the method pursued so successfully in the case of the Becker draft already mentioned

The Value of Check Punches

Check punches while useful as a general protective measure do not have any strong restraining influence on a professional check raiser If you wish to know why ask the agents of a check punching mechanism to show you how they can raise checks punched by a rival machine

The illustration showing the perforated $2 400 is a good example of a raised perforation It was made from a photograph taken by transmitted light in order to show the original holes—now filled in—and the new perforations made thereafter A casual or even careful examination under any ordinary conditions would not disclose the existence of the filled perforation

The eleven hundred and fifty dollar check shown in another illustration is another example of a raised perforation The original check it is claimed read One hundred fifty dollars this amount having been altered to read Eleven hundred fifty Notice the bad alignment of the punched figures

Bad Writing as an Obscuring Element

Indistinct writing sometimes plays as troublesome a part in obscuring the essential details of checks and others instruments as do actual alterations confusing amounts intention and even ownership

Some years ago I was consulted in a case of this kind The question to be determined was whether or not the name in a deed as recorded was Erving or Ewing Jones The original deed had long since been lost The recording clerk was dead There had been both an Irving and Ewing in the family The descendants of both claimed the property The difficulty lay entirely in deciding whether the writer had made the first part of his w like an r or had made an r like the first part of a w As the writer did not make the broad top r or a distinctive r with the shoulder it was very difficult to determine whether the property had really been deeded to Erving or Ewing An exhaustive comparison of the recorder's handwriting was necessary before the real ownership of the property could be finally established

Alterations for Purposes of Concealment

Occasionally the endorsements of checks drafts and vouchers are altered either to cover up some thing or to comply with some condition on the face of the paper

Thus in an investigation conducted in the office of the Borough President of New York some years ago several vouchers for carpenter work were found which had gone through the Controller's office with very palpable erasures of signatures and over writing of signatures In one instance shown in the illustration the camera brought out the signature as Boyce This was the real name of the party who signed but his signature was affixed inadvertently It was intended that he should sign a fictitious name To leave the signature would have clearly shown that the contractor and an official in one of the city departments were one and the same This was not desired hence the original signature was erased and the name Thomas A Tydings was written in its place The original endorsed signature had also been erased and the name rewritten in a different hand for somewhat similar reasons

The Detection of Alterations

In determining whether or not checks drafts or other papers have been raised or otherwise altered microscopical examination and comparison of the ink used in the written portions of the instrument will frequently determine whether or not more than one ink has been used The fact that different inks were used in different parts of the check or other paper is not of course proof positive of fraud but in the case of a suspected instrument is very strong presumptive evidence

A microscopical examination of a doubtful instrument will often determine whether or not the calendering of the paper has been removed also whether or not anything has been applied to the surface of the paper Photographs both by direct and transmitted light will frequently disclose things not observable even under the microscope

Where chemical erasures have been made and some of the original ink remains in the fibers of the paper this ink—if it contains iron—may be partially restored by exposure to the fumes of acid in a tightly closed box This restoration of the original writing is only temporary fading in an hour or so but it may be repeated as often as desired While in the restored state the original writing may be photographed and thus be permanently preserved

Time as a Detective Agent

When erasures on papers have been made by means of chemicals, these erasures can be, and frequently are so well done as to defy detection at the time But if the paper is examined again in six months it will usually show a decided yellow stain. And if photographed the photo-print will disclose the stain emphasized as the ordinary photographic plate is sensitive to yellow

The Freedman checks shown herewith are good examples of chemically erased checks, photographed three years after the erasures were made There were some thirty of these checks, amounting to about $25 000 The bookkeeper altered them by erasing the payee's name and substituting his own and occasionally by raising the amount In filling out these checks originally the bookkeeper (who confessed to altering the checks and who has served a term in prison for the crime) wrote the payee's name or the amount whichever was to be changed well above the base line This when erased left the usual place for the name or amount clean and unaffected so that the new matter could be written in with a free hand without danger of blots or roughnesses

In the writing on one of these checks shown herewith it is very difficult to discover any alteration while in the other shown in the same illustration it is plainly observable

Where erasures by mechanical means—abrasion for example—are made on papers that have been much handled or when a considerable time has elapsed since the erasures were made they are much more easily detected than is otherwise the case

The case of the State of New Jersey vs James Connolly hinged—not on an altered check but on substantially the same kind of erasure as is used in the alteration of checks The alteration here consisted of the chemical erasure of a signature on a bail bond The defendant was indicted for giving real estate which he did not own as security for a bond He denied that the signature on the bond was his And upon another inspection it was found that the name James Connelly —as it now appeared—was not in the handwriting of the defendant As was discovered later it was a new signature which had been written over a chemical erasure. In addition to this a blot partly obscured the writing and made the work of discovering the true conditions much more difficult

The defendant on his part engaged a handwriting expert who upon comparison reported that the signature as it now appeared was not in his client's handwriting The handwriting expert employed by the plaintiff then made photographs of the page and signature natural size and enlarged and at the trial these were introduced into evidence They showed unmistakably that the original signature was James Connelly but written in a different handwriting from the second James Connelly This original signature as shown in the plate was brought out faintly but distinctly On examination this original signature proved to be the signature of the defendant The expert for the defendants thereupon left the courtroom without taking the witness stand The illustration shown herewith is reproduced from the photograph used in court to prove that the questioned signature was in the defendant's handwriting

The Prevention of Alterations

A good ink a good check punch good safety paper and care in leaving no blank spaces will as a rule prevent raising of checks It may not absolutely prevent alterations but it will discourage the ordinary crooked operator—so much so that before exercising his art he will look around for a more careless writer who does not protect his bank account so well

Lowering a Check

I never knew of but one case where a check was lowered Here the forger stood near the window of a busy New York bank and saw a messenger from another bank present a check for certification The messenger said that he would return in a short time Before his return the forger stepped to the window, called out the name of the other bank and was handed the certified check for some thousands of dollars He had to act promptly and cash the check at once Knowing the difficult of securing so large a sum without identification he altered the check to read Nine hundred dollars, cashed it and escaped He was never caught.

YOUR SIGNATURE AND HOW TO WRITE IT

Identification by Handwriting

Millions of dollars frequently and human lives occasionally are balanced on a pen point

No other record left by man is so peculiarly personal characteristic, and identifying as his hand writing It is better than photographs or body measurements for establishing identity because it bears the stamp of the writer's individuality, his own personal touch It can be recorded in compact form and can be easily filed and kept for reference.

No other nation produces so many good or fast writers as the United States, yet judging by the illegible writing, especially of signatures, we find many business and professional men who, with [illegible] "Hold it a business to write fair, and labor [illegible] how to forget that learning."

A little more care and thought, especially in writing important papers, would save a vast amount of annoyance and even loss.

The three essentials of a good handwriting are legibility, ease of execution and speed. The greater part of the handwriting of this country is produced by the free, forearm movement. This is conducive to grace, speed freedom and ease of execution, but not necessarily to accuracy of form.

Variations of Handwriting.

School children, following the same stereotyped models and practicing and using them under the same conditions write very much alike, and their writing is crude, conventional characterless. A few years out in the world works a wondrous change Conditions and individual temperaments assert themselves making alterations in the handwritings that leave them scarcely recognizable A change of slant or size a lopping off here, an addition there an emphasis on a certain part of a stroke, the adoption of a new type of capitals or small letters—these are some of the things that produce the variations found in handwritings that were originally almost identical.

'There is certainly a peculiar handwriting, a peculiar countenance not widely different in many, yet always enough to be distinctive. —Boswell's 'Life of Dr Johnson"

These variations admit of almost an infinite number of combinations and when these peculiarly personal variations from the normal or conventional styles become a fixed part of the handwriting of the individual, they are known as characteristics" and serve as identifying hall marks or trade marks, as it were

It is by these characteristics or hall marks peculiar to each handwriting that the particular hand writing is separated from all others and unmistakably recognized and identified.

These identifying characteristics are a combination of many conscious and more unconscious repetitions Habits in handwriting may be formed as in other things and by giving thought to it during the formative period we can control our writing and make it good or bad characteristic or characterless

A little study of our handwriting is not only interesting but profitable as well

To-day a thing is hardly considered on the road to doing until it has been put into writing and it behooves us to select what is for us the best style of handwriting and a type of signature that will best protect the bank account and the other valuables safeguarded by signature

The Signature

A legal signature' or sign manual may be an assumed name a title a mark a sign or a pen flourish anything that may stand for or represent the name of the signer Ordinary modern interpretation and usage have construed the word signature to mean the writer's name written by himself Hence the modern signature at a glance discloses (1) the name of the writer (2) his peculiar spelling of the name, (3) the various lines forming a pen picture of the same (4) the writer's own personal technique or touch This in its entirety gives an identifying mark that reveals at a glance suffcent of the writer's character to satisfy a hurried demand, and yields much more on longer and closer inspection Then too 'Age cannot wither nor custom stale' its mark of identity It will be the same to-day to-morrow next year, and until time affects the materials with which and on which it was written

Style of Signature

The object of every penman should be to select a style of signature which while embodying his identifying characteristics is also legible and easily and rapidly written. Such a signature is one which can not as a rule be successfully imitated

Details of Signature

The first thing to consider is the spelling and any abbreviations of the name. If the name be John Henry Jones, it may be written J Henry Jones, Jno. Hy Jones, J H Jones, John H Jones, etc Select some one of these, and having once selected it do not change. It may be noted in passing that distinguished men rarely use abbreviations.

A married woman should sign her own name, Susan R. Brown,' not "Mrs Henry G Brown"

Next select the style of capitals and small letters you expect to use, and do not change because of desire for variety, or because of mere whim or caprice The constant repetition of the same signature will give you skill, and a peculiar touch and technique that will be most difficult for a forger to imitate.

Select the kind of pen suited for your hand and for your writing. There is a wide latitude here; pens are made fine, coarse, stub, stiff or elastic. [illegible]

only caution necessary is to select a pen that will not blur on the angles and short turns and thus hide the points of identity Very broad stub pens are not good and stylographic (one nib) pens should be let severely alone Never write with a lead pencil when any values are involved

Writing the Signature

While banks, as a rule, do not pay paper on the signature alone still it is of prime importance to aid them all you can by giving them a signature that protects them and you at the same time

A legible rapidly written free off hand signature is much harder to simulate than an illegible slowly written or shaky signature To successfully imitate any signature, the imitation must not only possess the correct form but be written at the same speed as the original, otherwise the quality of line will betray the forgery A poor penman cannot forge the name of a more skillful writer because the copy is beyond his skill Forgers usually copy the signature of a poor or slow writer as this requires less skill and gives more time while the pen is *moving* over the paper

This has been found to be true in the majority of cases of forged signatures submitted by banks and attorneys to the writer for professional investigation

So far as you can (and you can at your office) write with but one kind of ink

Do not patch mend or over write a signature This habit may deceive the paying teller when a forged check is presented for payment bearing similar alterations Do not depend alone on some little oddity, dot dash or flourish to redeem an otherwise bad signature and make it a safe one A forger will readily see and imitate such things

Even when the handwriting as a whole is neglected the signature and figures should always be legible since nothing can be judged by context to aid the reader Each figure and each letter in a name should therefore stand out with perfect legibility

A rubric or flourish is a good thing to add to a signature as it is difficult to imitate It should not however be allowed to obscure a legible signature Have a rubric that does not extend too far below or beyond the letters as space on checks is limited The flourishes used to connect the letters in the name may be employed as a rubric

If the initials of a name may be readily gracefully and *legibly* connected it is a good plan to do so Some initials look better not so connected Occasionally making one capital larger than another adds a distinctive touch to a signature

Picket Fence Style

Americans write illegibly not through ignorance or lack of skill but because of a mistaken idea that an odd or illegible handwriting is difficult to imitate or because of lack of time or through carelessness As an example take the picket fence style of signature used by some bankers and business men It is by the general appearance of the picture as a whole that this style of handwriting must be recognized and this fact makes it an easy style to imitate One or two strokes more or less makes but little difference in the pictorial effect

A story is told of the great lawyer Rufus Choate who was as famous for his bad handwriting as for his good law that at a town meeting he threatened to challenge a voter because the man couldn t read but desisted on a bystander s threat to challenge the jurist because he couldn t write

And Horace Greeley s letter of discharge of a composing room foreman for incompetence which because of its bad handwriting was used as a recommendation to secure another job is also famous

Noted men may perhaps be allowed an illegible signature as a characteristic of their renown and a tribute to it but for the ordinary man of business it is not a safe indulgence

The Ultimate Limitation of Mineral Resources

Its Significance to the Human Race

Prof J A Kemp s Analysis

Prof J A Kemp in his presidential address before the New York Academy of Sciences concludes his detailed consideration of the available sources of coal and the principal metals with some very apt reflections of a general character Incidentally he considers the nature of the change which we may expect to come over the present social conditions in the event that at some future time a scarcity should arrive in the supply of certain materials now appearing almost indispensable for the transaction of the great mass of daily business

Of iron ore there is no lack nor need any one be apprehensive regarding the supply of this metal but before very many years have passed the yield of the ore will have decidedly declined While the falling off will be gradual it will undoubtedly tend in the long run toward 40 per cent This change is in itself important because unless otherwise neutralized it will raise the cost of production It makes necessary the melting of more barren materials in the furnace so that the consumption of fuel rises with respect to the amount of iron produced It means also the mining and freighting of an additional burden which yields no return from whatever point of view we regard it other things being equal the cost of production rises

The greatest cause of apprehension as regards present processes of iron manufacture lies in the supply of coking coal We have built lofty furnaces and in their use we place upon the fuel as it progresses downward in the furnace a heavy load of overlying ore and limestone We need a very strong coke to stand up under the burden The coals which yield these high grade cokes are found in a small portion of the total coal bearing area and the life of the supply is one of the very serious phases of the present situation

While these physical and chemical factors operate to increase costs there is always the possibility of improved processes of greater efficiency to keep them down The improvement oftenest in people s minds to-day is the utilization of water powers to generate electricity which in turn may supply heat Now in a blast furnace smelting iron ores one-third the fuel is employed in reducing the iron oxide and two-thirds in developing the necessary heat for the reaction Were we able with water powers to economically furnish electricity and from it derive the necessary heat we might save the two thirds of the present amount of required fuel We might reduce costs The remaining one-third of the fuel we should always need but it is possible that poorer grades than high quality coke might answer The saving would lie of course in the difference between the cost of the fuel and the cost of the electric current, provided the latter could be furnished more cheaply than the former

The water powers in our own country or at least in the more thickly settled portions of it have not failed to attract attention nor have they gone altogether unutilized The more conveniently situated ones are already harnessed to the dynamos But in countries like Norway and Sweden where there are large water powers still available where there are rich deposits of ore and where coal fails the applications of electricity to iron smelting are likely to be first worked out successfully Data may be furnished in the life time of many of us which will cast light upon these improvements in their world wide relations

The only other apparent possibility of reducing costs lies in the labor charges Wages at present are not unduly high and unless the increasing population of the country brings to pass an inevitable struggle for existence which will cause the greater subdivision of tasks at lower proportional returns or unless the general reduction of expenses for subsistence makes lower wages possible there would seem to be slight prospect of change in this item In any event the reductions from this cause cannot compensate the falling off in the yield of iron

Suppose iron goes up in cost other conditions of our daily life remaining the same—transportation and all manufacturing based on machinery would become more expensive and less freely carried on Undoubtedly an appreciable pressure would be developed to turn our people back to the rural districts and to tilling the soil for a livelihood The tendency under the stimulus of manufacturing development has been the other way The migration of late years has been toward not from the cities Shall we perhaps find in the long run in the increasing cost of iron and steel a partial solution of a much vexed problem? Will the cry Back to the soil receive support in a way not generally anticipated? The question is an interesting one for speculation

The general inference regarding copper is that the pinch of higher cost of production will be felt sooner than in the case of iron We have no knowledge of such enduring reserves of copper ores as we have of iron On the other hand copper despite its vast importance is not the fundamental necessity that is iron It is used in less quantity in machinery and its increase in cost would less vitally affect manufacturing industries based on machinery Advancing cost would cut it out of much ornamental work of inferior esthetic merit The most serious effect would be found in raising the expenses of service in the applications of electricity Electrical transportation telegraphy and telephony would be more expensive than to-day Unless wireless methods of transmission eliminate copper or unless some discovery in the domain of physics which we do not now foresee furnishes a substitute for the omnipresent copper wire of to-day we may find ourselves face to face with some curtailment in these modern aids to the easy conduct of life s affairs If in the course of several centuries the falling off in supply and the growth in population should raise copper to relatively high figures we may wonder if a return in a way to the conditions of the Middle Ages will not result Will copper then become to a greater degree than now the basis of skilled *handiwork*? Will the bygone craftsmanship be revived and with a lessening total output shall we see an advance in artistic skill? In fact if the vast development of machinery and the huge output of metallic objects at low cost a condition so characteristic of to-day should be checked or curtailed would not hand work on more valuable mediums of expression be restored? It is not altogether unreasonable to anticipate fewer objects and higher crafts in their production

The cases of lead and zinc are even more emphatic than that of copper We have still fewer assured reserves and the pinch of increasing cost may manifest itself at an earlier date The two metals are not however quite such vital factors in modern life as is copper and the larger effects would be less apparent Zinc is a necessary component in the manufacture of brass which industry absorbs the greater part of the copper output A curtailment of either lead or zinc would cause inconvenience but would scarcely occasion fundamental changes

Silver will be very seriously affected by a decrease in the output of either copper or lead Gold will feel these changes in an appreciable but far less degree There will always be sufficient however of each of the precious metals for coinage and beyond this use their applications except perhaps in photography concern luxuries rather than fundamental necessities We can not attribute to them any profound possibilities in their influence upon civilization should the contributions of the mines decline In the recent past we have been more apprehensive regarding a too great supply of the precious metals than regarding one too small

We can perhaps justifiably forecast a future in which agriculture will figure more and more prominently and in which the moral intellectual and spiritual life of the nation will readjust itself accordingly Great and concentrated wealth is likely to be less in evidence materialistic influences less pronounced and from the vantage ground afforded by the greater comforts and opportunities of modern life as compared with that of a century or a half century past we may in the distant future look forward to an evolution upon somewhat different lines Broadly viewed the national life will probably be increasingly sympathetic with art and with ideals

Increasing Use of Bamboo

There appears to be an ever-increasing use of the bamboo in the public parks and gardens of this country, where it bids fair to become a favorite ornamental plant.

The bamboo, generally speaking, comes from the Far East, notably China, where the bamboo reed is cultivated for exportation as well as for domestic use. On its native soil it is used in different ways. Its young shoots are eaten as a vegetable its juice gives a sweet liquor like thin honey that ferments easily so that it may be used as a beverage

France carried the plant to Algeria, but the experiment was of no particular value California s great plantations are fine examples of what can be done with bamboo under favorable conditions As the great daily journals consume the forest timber the builders turn to the woods used in home building in the tropics In parks and in gardens for seaside tents and for bungalows the bamboo wood is especially adapted being light durable easy of transportation and comparatively inexpensive

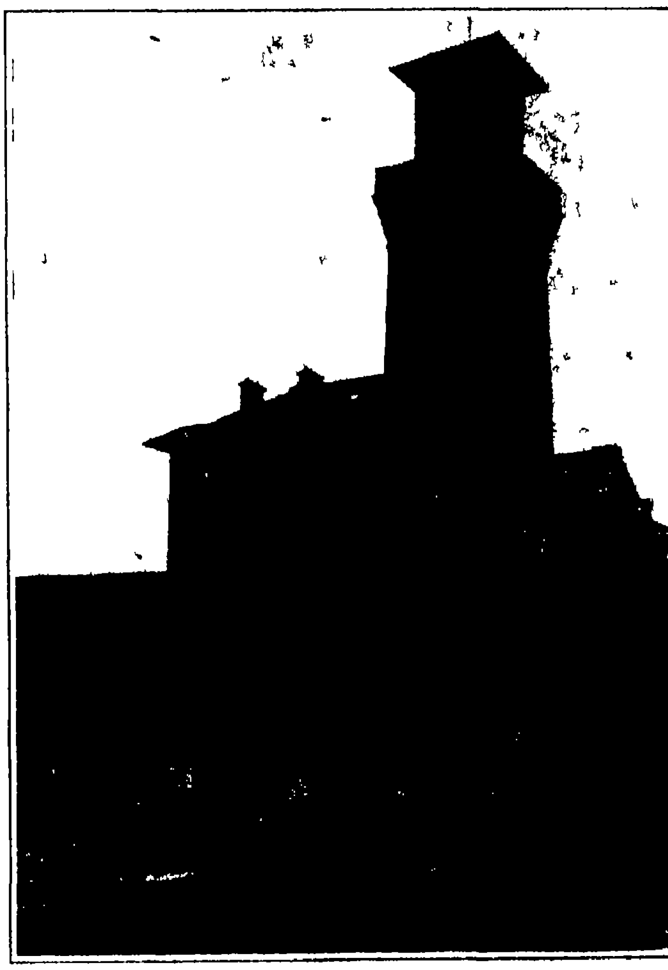
France led the way in western utilization of the bamboo but California will deserve all the praise if the bamboo supplants the high priced timber hitherto used for building houses In a climate like that of southern California bamboo reeds are ideal material

Paris Oceanographic Institute

The Prince of Monaco's Splendid Foundation

By the Paris Correspondent of the Scientific American

Oceanographic work is among the most fascinating of modern science and it may also be said to be among the most recent that is so far as it relates to exploring the deep ocean bottom. By means of new instruments which are frequently being invented we are able to bring to light many strange-shaped animals some of these having a phosphorescent glow whose very existence was unsuspected a few years ago. The Prince of Monaco gave a great impulse to deep sea sounding by building a special yacht the Princesse Alice, especially for ocean exploration and has been carrying on this work for twenty years in the Mediterranean and other waters. The very valuable results which were obtained in the first expeditions of this kind led him to found a special oceanographic building at Monaco overlooking the sea, and it contains many laboratories for use in examining all the finds which come in from the expeditions of the Princesse Alice. After this institution which we already have illustrated had been in very successful working order for some time under the active direction of Prof Berget, the Prince of Monaco conceived an idea which all scientists will consider as a most valuable and timely one that is to found an oceanographic institution which should be specially equipped for this work and which should serve as a center for European research. For many reasons he was led to found the new institute at Paris and it lies under the control of the French government. However its scope is European and even world wide as in connection with the institution there was founded a scientific committee and this includes members eminent in the scientific world and selected from all countries not forgetting America by any means.



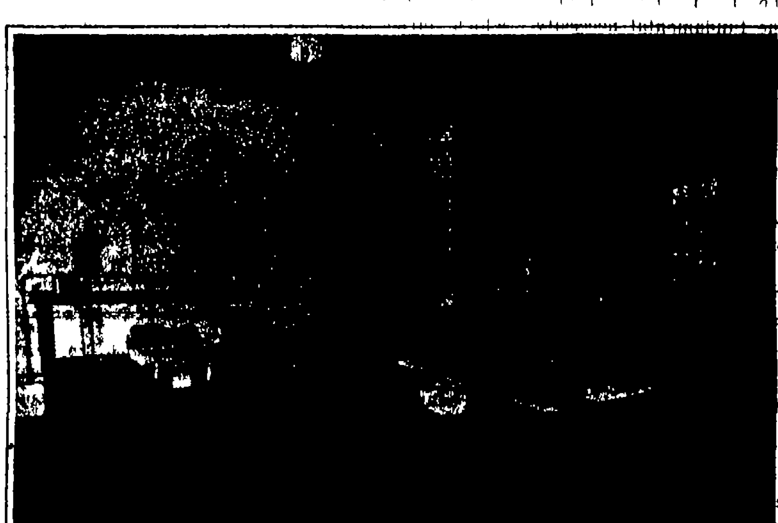
PARIS OCEANOGRAPH MUSEUM FOUNDED BY THE PRINCE OF MONACO

The Prince of Monaco endowed the institution with a fund of $800 000 in order to erect a suitable building at Paris and to carry out the needed arrangements. The object of the institution is to form a headquarters for oceanographic work which replaces the Monaco establishment although the latter is also retained for aquarium purposes and to carry on such laboratory work and examination of new specimens which must naturally be done at a point lying near the sea. The Paris institution is reserved for research and educational work in oceanographic science in the different fields of geography geology marine animal life, etc. In order to interest the public in this science there will be collections on view both at Paris and Monaco, and at Paris especially are to be organized lecture courses on the same plan as university courses or others of a more popular character, often accompanied by lantern projections. The results of oceanographic work will be embodied in different publications which will contain papers written by scientists of all parts of the world.

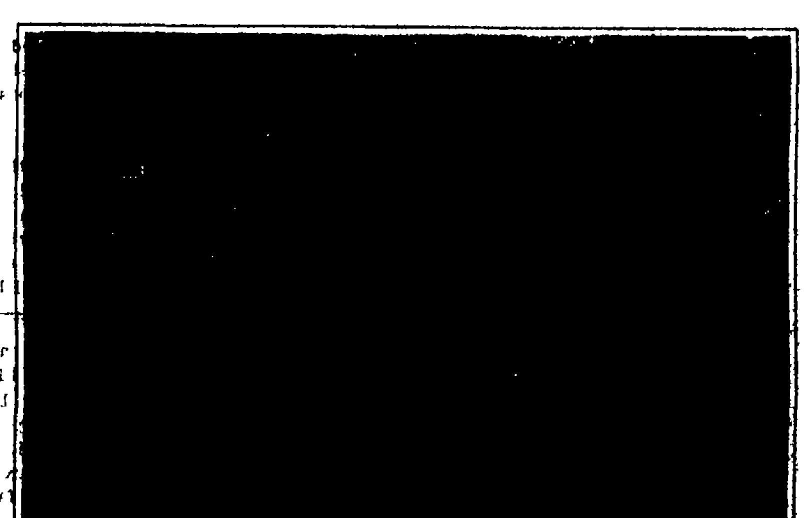
The building which our engravings represent is a handsome one and will provide roomy quarters for the laboratories and lecture halls. It lies in the University quarter of the town on the old Rue St Jacques which was one of the great Roman roads crossing the city in ancient times when Paris was scarcely more than a small island in the Seine. At present the new building is completed and the laboratories are installed so that it is soon to be in full working order. Lecture courses which are open to the public commenced in February. The building was designed by Architect Neriot and is handsomely decorated with wall paintings by prominent artists. The Prince of Monaco's address at the inauguration which took place amid a brilliant gathering representing the official and scientific world was a warm appeal in favor of oceanographic research as being especially one in which the public as well as scientists would be interested. Moving pictures were then shown on the screen and the audience followed the maneuvers of the Princesse Alice while nets or other deep sea sounding instruments were brought on board or large fish captured by lines. Other views showed some of the strange-shaped animals in their movements and the colored views of specimens taken upon autochrome photographic plates were a striking example of this new process as applied to science.

One of our views shows the main lecture hall and especially to be remarked are the very handsome wall paintings one of which represents the Prince of Monaco in the act of harpooning a porpoise. Others show the deck of the yacht when the specimens are coming in. Next to the main hall is a smaller lecture hall especially adapted for scientific courses and each hall has a well equipped projection lantern apparatus with a large screen. The building contains four stories and on the ground floor is the council room very tastefully decorated with deep sea paintings followed by the assembly room which contains a marble relief of the Prince of Monaco. The remaining floors are devoted to the laboratories. In the one which we represent herewith Prof Portier has charge of physiology of marine animals. Another laboratory is used for biology under Prof Joubin and a third for physical oceanography under Prof Berget who is at the head of the institution and is also one of the chiefs of the Monaco establishment. Collections of specimens and also of various apparatus are to be one of the features.

We should say that in connection with each of the main laboratories each professor has his own small private laboratory in which he may carry on special work while the main laboratories are open to persons who wish to enter by paying a small fee so as to follow the educational courses. However these are intended only for scientists and lie apart from the public lecture courses. In the basement a large aquarium is installed for holding live specimens and later on it will be one of the main features to be



ONE OF THE LABORATORIES OF THE PARIS OCEANOGRAPHIC INSTITUTE



MAIN HALL OF THE PARIS OCEANOGRAPHIC INSTITUTE

Here is also an electric plant and a machine where special ocean work or laboratory apparatus made.

English members are Prof Bruce of Edinburgh Prof Buchanan of Cambridge University also Sir John Murray of the 'Challenger' expeditions We note also the name of M Nansen the well known Arctic explorer Among the French members besides those already mentioned are Prince Roland Bonaparte Dr Richard the head of the Monaco establishment and M Yves Delage Germany is represented by Drs. von Drygalski of Berlin M Hergesell of Strasburg Drs Chun and Hensen and others, and in all there are thirty members and many countries thus aid in the success of the enterprise

Steel Cars for Passenger Trains

Designed and Built by the Pennsylvania Railroad Company

The Pennsylvania Railroad has in service 764 all steel cars of various types and 358 cars now under construction The company has gone further in the direction of the use of steel cars than most other roads The Pennsylvania's policy in this respect was the result of a long period of inquiry and experiment in which the late President Cassatt took an active part After several cars had been built the president appointed a committee of motive power officials to make a thorough report on the designs to be adopted and the cars are now being built in accordance with the recommendations of that committee

WOODEN CARS DO NOT MEET MODERN REQUIREMENTS

The demand for passenger cars which would be stronger and better able to meet the severe conditions of service led to the consideration of other materials than wood for their construction Growing scarcity of suitable timber and its rapidly increasing price played an important part in the development since wood cars would soon cost as much as those of non combustible materials

TYPES OF CARS

After carefully considering the problem from all sides the Pennsylvania Railroad Company decided to adopt two types of steel passenger equipment

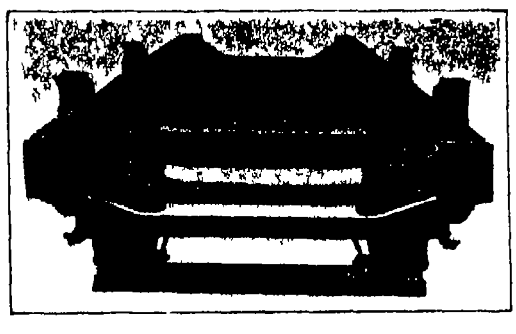
(A) For through trains drawn by steam or electric locomotives and composed of mail baggage sleeping dining or day coaches A long car of heavy construction suited to withstand the strain incident to pulling coupling or buffing in long trains

(B) For suburban trains drawn by a locomotive or propelled by motors upon the truck axles a short car of lighter construction well suited to operation in frequent short trains to accommodate the traffic

REQUIRED STRENGTH OF FRAMES

In preparing the designs for heavy type equipment great care has been exercised to provide ample strength to resist end shock of buffing or collision Standard steel freight cars are designed to resist an end shock equivalent to 400 000 pounds compression Experience with freight cars during the last five years indicated that this is not excessively high An experimental determination of this figure was made by allowing a dynamometer car weighing 51 000 pounds to bump a number of loaded freight cars standing upon the track The dynamometer registered 607 000 pounds Another experiment was made by allowing a loaded steel freight car and the dynamometer car weighing together 181 400 pounds to bump a loaded freight car standing on the track

normal loads due to the weight of the car and lading Under these conditions the combined fiber stress is limited to 12 500 pounds per square inch for cars in through train service and 20 000 pounds per square inch for cars in suburban service In determining these stresses none of the material above the belt rail is included excepting in the case of the horse-express car and the car designed for the Newark Rapid Transit Service which have sufficient reinforcement above



THE NEW TYPE OF SIX WHEELED TRUCK

the doors to take care of the various strains In the rest of the cars the sides beneath the window sills form girders about three feet deep for which the belt rail acts as the top flange and the outside sill as the bottom flange Owing to their great length the thinness of the web and the comparative shallowness of the flanges these girders would probably collapse if subjected to end thrust In calculations therefore the web and upper flange are not considered as resisting any of the 400 000 pounds load assumed to represent the effect of buffing

The superstructure of cars is made strong enough so that they can roll completely over without danger of collapse Posts car lines and other parts are proportioned under this assumption

The ends of cars are framed in such a manner as to resist end shock Deck or I beams forming the frame about the end door and securely fastened to both end frame and roof are proportioned with this idea in view These features are shown in one of the accompanying illustrations

TYPES OF FRAME CONSTRUCTION

In the design of framing for steel cars two general types have been developed One in which the center type is usually rather light being designed to resist the end loads developed by ordinary pulling and light buffing This type of framing follows the general form used in wooden cars where the transverse loads are carried by wooden trusses within the sides of the car reinforced by truss rods beneath the side sills

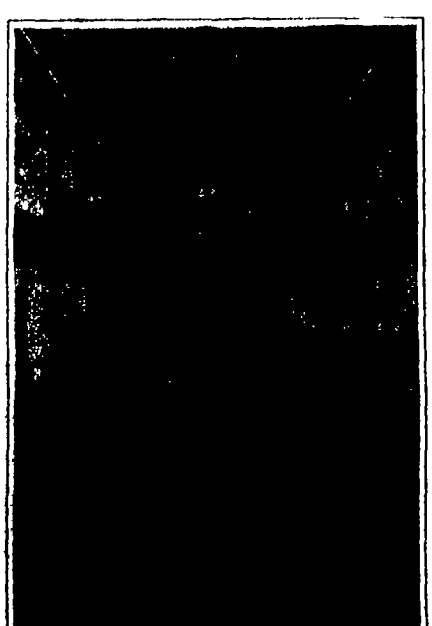
For through train service subjected to heavy buffing and pulling the center sill type of frame has been selected It has also been used in designs for suburban type equipment as it has been found that with a modified form of center sill sufficient room for motors was provided between the underframe and track

DESIGN OF CENTER SILL

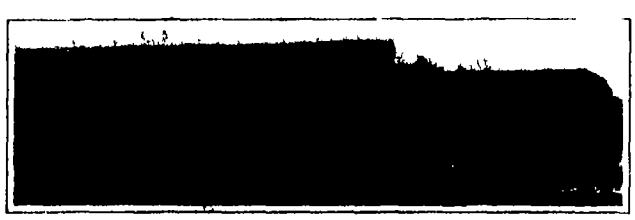
The height from the track to the center of coupler is determined by law and the height to the top of the floor is practically regulated by custom The center of the draw bar is therefore fixed at about 17 inches below the floor

In wooden car construction the center sills are usually rather shallow and the coupler is supported below them Loads upon the underframe brought about by buffing tend to bend down the ends of the car due to the fact that the center sills are not symmetrically loaded In the steel car of the through train type the center sill is made deep enough to bring the line of coupler within its section

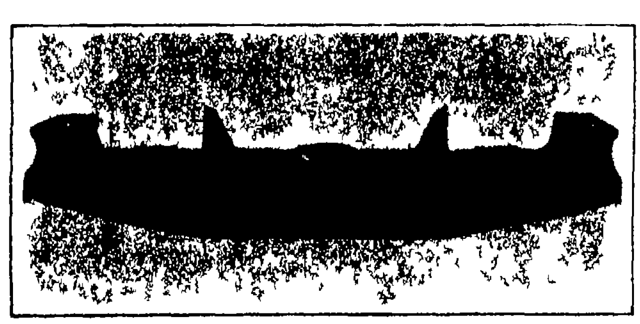
With the heavy center sill frame body bolsters as used in wooden car construction are unnecessary for the major part of the transverse load is delivered directly to the center sill which transmits it to the trucks through center plates carried on its under surface The transverse loads which come upon the sides of the car and which must be transferred to the center girder are delivered at four points to equalize the loading The center sill is a continuous girder supported at two points by truck center plates and loaded with a practically uniform longitudinal load which it carries directly together with four transverse loads delivered to it from the sides of the car through cross bearers and body ends The points of application of the concentrated loads are so selected that the two loads at each end are about equidistant from the center plate Under this condition it has been possible to obtain in the center sill practically equal fiber stress at the middle and over the center plates thereby securing great economy in the metal and avoiding the use of a center sill of deeper cross section at the middle than over the trucks With the comparatively thin sheet steel metal used in sheathing the sides and roof it is of great importance to avoid unnecessary



INTERIOR OF THE STEEL MAIL CAR



GENERAL VIEW OF THE STEEL CAR SUPPORTED ON TWO SIX WHEEL TRUCKS



STEEL BOLSTER OF THE TRUCK

INTERIOR OF THE PASSENGER CAR

The dynamometer recorded 400 000 pounds In a collision between passenger and freight cars it is desirable that the passenger car should be the stronger in order to escape with as little injury as possible.

In computing loads upon the various members of the frame it has been decided that a compression load of 350 000 pounds between buffers, also 150 000 pounds between draft gear is to be added to the sill is made strong enough to resist the end loads developed by pulling and buffing in addition to the transverse loads due to the weight of under frame superstructure and lading The other type in which the plate girders formed by the sides of the car beneath the windows are relied upon to carry the transverse load due to the weight of the under frame, superstructure and lading The center sill in the latter loading as it is likely to cause loosening of the joints and working of the rivets in their holes With this form of construction the side girders are made comparatively light as they sustain little transverse load and are supported at four points Side doors required by mail express, or baggage cars can be located where most convenient without requiring any material strengthening in the side truss

The following table gives the comparative strength and weight of steel and wooden cars

	Standard Wooden Passenger Coach 58 Feet Long	Heavy Type Steel Passenger Coach 70 Feet Long	Suburban Steel Passenger Coach 54 Feet Long
Number of passengers	68	88	72
Car weight pounds	91,000	116,000	86,000
Car weight per passenger pound	1340	1307	1071
Area center sill at middle of car, square inches	152	50	24 22
Area center sill at center plate of car square inches	109	50	33 88
Stress in center sill due to 150,000 pounds buffing and 1,000,000 pounds draft gear and ... per square inch	10,850	11,000	18,500
Comparative strength of center sills	25	18	60

HEAVY TYPE 70-FOOT STEEL PASSENGER COACH

In general arrangement and appearance this car is almost an exact copy of the standard wooden passenger coach

Two 18 inch by 44 2 pound channels with ½ inch × 24 inch cover plates top and bottom form the center sill Cast steel center plates are riveted to the under side of the sill which is reinforced at these points by steel castings riveted inside Projecting beyond each end of the center sill are steel castings designed to transmit directly to the center sill the loads due to buffing and to support the spring rods carrying the vestibule buffer plates

These castings are provided for the introduction of the vertical channels forming vestibule posts Within the center sill near each end are riveted steel castings arranged to carry the couplers and draft gears

The side sills are of 5 inch × 3½ inch × 9/16 inch angles Each sill is supported at its end by end sills and at two intermediate points about 14 feet from each end by cross bearers

The end sills are of the cantilever form riveted to the center girder and built up of angles the outside sheathing plate acting as the web

The cross bearers also of the cantilever form and each composed of two triangular plates flanged about the edges are riveted at their base to the center sills Opposite cross bearers are joined by cover plates which pass over the top and under the bottom of the center sill

Each side sill is held in line by nine struts of 5 inch channels connected to the center sill These struts do not transmit any vertical load from the side sills to the center sill

Cast steel side bearings for engaging the trucks are secured to the side sill in line with the center plates

Pressed steel posts spaced 5 feet 11 inches centers support the superstructure They are of channel section and the edges are flanged out and riveted to the inside sheathing forming a box section Their lower ends are securely riveted to the outside sills and their upper ends are tapered down and bent inward forming lower deck carlines At their upper ends these posts are riveted to the plate carrying the deck sash The lower edge of this plate is bent out beneath the ends of the posts and forms a continuous beam of angle section running the entire length of the superstructure

Between the main posts are shorter intermediate posts which extend only from the window sill to the plate carrying the deck sash They are of light channel section with edges flanged for riveting to the outside sheathing forming thereby a box section

Upper deck carlines are of sheet steel pressed to channel section with edges flanged out for riveting to the 3/32 inch steel roof plate The ends of the car lines are riveted to the plate carrying the deck sash The upper edge of this plate is bent outward and down forming a continuous beam of channel section to which the edge of the roof plate is riveted Malleable iron braces unite the ends of each post and its corresponding carline

The outside sheathing is of ⅛ inch steel and the course below the belt rail is riveted to the outside sill and vertically to each post.

The steel shape forming the under sill for the windows laps over the side sheathing and rivets passing through the belt rail which runs the entire length of the car secure this joint The outside sheathing above the windows is riveted vertically to the posts and its upper edge is riveted to a channel shaped steel section forming the eaves for the lower deck and extending the entire length of the superstructure

The inside lining including ceilings and bulkheads is of 1/16 inch steel to the unexposed face of which 3/16 inch asbestos is cemented Molding closely resembling that used in wooden construction is pressed and drawn from steel and its use adds greatly to the artistic appearance of the interior

The window sashes are of wood and slide in a formed steel frame Malleable castings riveted to the posts support the window frames The window stops, which also form ways for the curtains, are of extruded bronze The deck sashes are of malleable iron

The floor is formed by corrugated or keystone steel plates which are supported by the center sill and upon longitudinal angles secured to the side posts. These plates are covered to a maximum depth of 1½ inches with a plastic surface filling, composed largely of cement.

A sub-floor of asbestos ⅜ inch thick supported by No 20 galvanized sheet steel is secured to the center and outside sills.

Along each side of the car just above the floor rectangular ventilating ducts are provided which inclose the heating pipes and discharge warm fresh air into the car

In the construction of the platform and vestibule an effort has been made to secure sufficient strength in the end of the car to prevent the superstructure from being swept off from the underframe by the next car in the event of a collision The center sill is the main support of the entire vestibule and to it are securely framed the 9 inch bulb angles forming the end door frame together with the 9 inch channels forming the vestibule posts These vertical members are relied upon to prevent damage to the superstructure during collision

The vestibule floor plate the end sills and sheathing and the vertical bulb angles are securely framed together to give an exceptionally strong foundation for the end construction

The end of the vestibule is supported by two outside posts of pressed sheet steel together with two channel posts forming a doorway The base is formed by a pressed steel platform end sill and the top support is given by the vestibule ceiling plate

SUBURBAN TYPE—54 FOOT STEEL PASSENGER COACH

The general arrangement and appearance of this car are similar to the heavy type equipment but the car is lower shorter and the space allowed each passenger is less than in the larger cars The arrangement of seats has been modified to suit the traffic

The underframe construction closely resembles the heavy type car but in order to provide sufficient space for motors the center sill is made more shallow It is formed by two 9 inch channels with a single ¼ inch cover plate on top and two ⅝ inch cover plates upon the bottom This form of section keeps the center of gravity low and decreases the bending movement brought about by the fact that the drawbar is below the center sill entirely The center plate is of special form adapted to reach the same trucks on heavy type equipment and the casting in closing the coupler and draft gear is attached to the under side of the center sill instead of being placed within it as in the case of the heavy type car

The framing of the body is similar to that used in the heavy type coach the main posts being identical except in the matter of length and shape at the top There are three windows between main posts instead of two as in the heavy type coach

STEEL SLEEPING CAR

In order to complete the equipment of steel cars for passenger trains the Pennsylvania Railroad Company has arranged with the Pullman Company to design and build some all-steel parlor and sleeping cars of which 638 are now in service

In both exterior and interior appearance they closely resemble the standard wooden Pullman car except in the interior finish where steel replaces the highly polished natural wood

Steel is used for inside finish and is backed by asbestos to act as a non-conductor of sound and heat except in cases such as the back wall of upper berth the berth partitions and possibly a few other cases where non inflammable composition material is used as the steel is too cold to the touch

The trucks are of standard Pullman type supplied with cast steel frames in place of the usual wooden members

The principal dimensions of the cars are

	Feet	Inches
Length over end sills	72	6
Length over platforms coupled	80	6
Width over side sills	9	9¼
Width over eaves	10	0
Height over all	14	7

THE SIX WHEEL TRUCK

An entirely new form of truck was required for the steel cars owing to the fact that the deep center sill of the underframe lowered the center plate until it just cleared the middle axle of a six wheel truck Advantage was taken of the opportunity offered for re-design and a truck based upon a new principle was evolved which is applicable either to four wheel trucks for motor cars or four and six wheel trucks for those drawn by locomotives The new truck utilizes to the best advantage the valuable properties of steel as a structural material, is designed to carry a load equivalent to the maximum capacity of the ... inch axle, weighs 21,000 pounds (which is the same as the weight of the old wooden trucks), but is considerably stronger Transoms, spring planks and equalizers, though important parts in former truck designs, are not required, as their functions are performed by other elements in the new principle of design

The accompanying illustration, page 377, shows the exterior appearance as well as the construction of the truck Two elementr are embodied, the rectangular frame carrying the vheels, and the bolster which transmits the load delivered at the center plate to the axle through the spring rigging

The axles run in boxes of the usual type which slide vertically in pedestals, secured to the wheel pieces and connected at their bottom ends by pairs of tie bars (sufficient space being allowed between the bars to permit the use of a jack in removing bearings) Each wheel piece is composed of two 10-inch channels (with their flanges turned toward each other) separated to permit certain of the working parts to go between them and secured to one another at intervals

Two wheel pieces are held together by four pressed steel cross members of channel section, one at each end of the wheel pieces and one at either side of the middle wheels. They are depressed below the bottom of the wheel pieces in order to clear the center sill of the underframe

The bolster is composed of four girders running crosswise of the truck to the top of which are secured two girders running lengthwise of the truck The center plate rests upon two short transverse girders of pressed steel The lower flange of these girders is turned up at the ends and the plate riveted to the lower flange is brought up and riveted to the longitudinal girders Between the transverse girders is riveted a reinforcing casting to transmit the load delivered by the center plate A horizontal rectangular plate forms the lower flange of both longitudinal girders and acts as a diaphragm to square the bolster Spring beams are riveted to the under side of the longitudinal girders and to the rectangular plate which forms their lower flanges They extend on both sides beneath the wheel pieces and are confined between guides which allow only vertical and transverse motion of the bolster with reference to the truck frame The spring beams are of sufficient width to admit between their downwardly projecting legs four elliptical springs

The entire load borne by the truck is delivered by its bolster to sixteen elliptical springs which rest upon equalizers having a ratio of 2 to 1

The equalizers are suspended from hangers which deliver to each box of the middle axle one-sixth and to each wheel piece one third of the entire load borne by the truck This load is delivered to the wheel piece at two points near the outside pedestals so that each box of the outside axle received one-sixth of the entire load borne by the truck Each box receives its load through a nest of three helical springs which in the case of the end axle bear upon castings secured to the wheel pieces and in the case of the middle axle bear upon short equalizers connected to the hangers The boxes of the middle axle therefore move up and down freely and without any connection or relation to the wheel pieces

Side motion of the bolster relative to the wheel pieces provided by the hangers and guides is limited by abutments secured to the spring beam Helical springs resting upon followers guided by the wheel pieces and engaging the abutments centralize the bolster and give easy riding qualities equal to those secured by the link suspension generally used on wooden trucks.

The outer abutments also act as side bearings for the car body and engage castings secured to the outside sills

COUPLER AND DRAW BAR.

It was found upon careful investigation that the standard form of draw-bar and coupler heretofore used on wooden cars did not allow sufficient side motion of the coupler head in rounding curves The resultant binding was particularly noticeable upon long cars, and to remedy the defect an entirely new arrangement was devised by means of which a lateral motion of about 8 inches each side of the center was secured

Owing to the large amount of side motion, coupler heads would interfere with steam and air pipe valves in their regular position. Projecting arms are provided on each side of the center sill at end of car for supporting these pipes, allowing them to move to clear the coupler on curves.

FOUR-WHEEL TRUCK FOR SUBURBAN TYPE COACHES.

Designs for a new type of truck for suburban service have been completed and trucks are now being built accordingly. This design is arranged in such a

manner that the same frame, bolster and detail construction may be used for either the motor or trailer truck.

The frame consists of two side frames which are composed of 8-inch Bethlehem H beams equipped with cast steel pedestals at each end. A transom is rigidly attached to the side frames by means of corner gussets and a bolster is placed inside of the transom supported on quintuple elliptic springs carried by spring carrier bars flexibly attached to the side frames. The transom corner gussets include the brake hanger fulcrums. The transom is made of pressed steel channel shaped so as to permit the placing of the bolster between the vertical legs of the transom.

Stalactites

How they are Formed in the Laboratory and in Nature

By George H. Martin, M.A., F.C.S.

It is a matter of common experience in everyday life, says *Knowledge*, that when an article appears to be hopelessly lost, it is often found again in the process of looking for something else. So also in the domain of science when experiment after experiment has failed in the search for the constitution of a compound for a method of preparing some substance on an advantageous commercial basis or what not, the clue to the problem is frequently found in the course of an entirely different investigation.

In the case in point, for example, attempts were being made in connection with a course of lessons in elementary geology to prepare stalactites in the laboratory. The process seemed simple enough; all that was necessary theoretically was to allow a solution of bicarbonate of calcium to drop slowly from a small aperture and patiently to await results. Nothing, however, happened although the experiment was tried in several ways. About the same time for a different purpose a burette full of lime-water was so arranged that the lime-water dropped from it with extreme slowness. This experiment also failed, but for some reason the apparatus was not dismantled and the burette was left for some weeks with the lime water still dropping slowly. When, however, the burette was again examined it was noticed that a slight deposit was forming around the aperture of the nozzle, and it seemed just possible that if the process were allowed to continue a stalactite growth might form at the end of the burette.

And so it proved—a strange result when one considers that of the two experiments, one of which was started in the hope of making a stalactite, this was the one that was not begun for that purpose.

The growth of the stalactite was watched with much interest and it proceeded with comparative rapidity. At the end of six months it had reached a length of one inch and a half, which means a growth at the rate of 1/150 inch per day. The stalactite grew in the form of a hollow tube, not quite straight but gently waved (see Fig. 1), and of approximately the same diameter throughout its length. The growing end of the tube was fringed with tiny fern-like projections which clasped the pendant drop as a jewel is grasped by its setting. Through a microscope it presented a beautiful appearance.

The projections were then seen to be fronds of crystalline growth—wonderfully fern-like in appearance and sharp in outline (see Fig. 2). The drops which at the beginning of the experiment soon became milky afterward remained perfectly clear the whole time they were forming; no separation of opaque calcium carbonate appeared to take place.

At the end of six months it was desired to show the stalactite at the annual meeting of the Public Schools Science Masters Association (January 1910), so the experiment was stopped and the burette was emptied and carefully laid on its side. Then with the point of a knife the stalactite was detached from the burette with the utmost care and successfully introduced into a glass tube on a cushion of cotton wool, where it still remains. In appearance it is a delicate cream-colored tube of interwoven silky crystals, its whole weight being only one-fifth of a gramme.

The drops of lime water had fallen from the burette at intervals of about three and a half hours, making a total of eight drops, that is about three-quarters of a cubic centimeter (0.046 cubic inch) per day. The drops fell upon a watch glass where they evaporated to dryness, leaving a slight and apparently amorphous deposit.

It is interesting to compare the weight of the stalactite given above with the maximum weight of calcium carbonate theoretically obtainable from the amount of lime water used. Three-quarters of a cubic centimeter a day mean about 137 cubic centimeters (8.36 cubic inches) in six months (the burette was replenished as required from time to time), and since the solubility of calcium hydroxide in water at the ordinary temperature of a room is 0.14, the above volume of water will dissolve 0.19 gramme of calcium hydroxide at that temperature if a saturated solution is formed; and 0.19 gramme of calcium hydroxide ... 0.144 gramme of calcium oxide, which is equivalent to 0.257 gramme of calcium carbonate. The stalactite itself weighs 0.2 gramme, the difference being due partly to the fact that some of the stalactite remained adhering to the burette and partly to the fact that some of the lime remained in the drop as it fell, and further the lime water in the burette, even

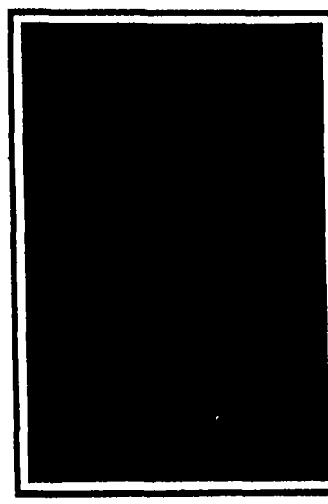


Fig. 1

A Stalactite Forming on a Burette From Which Lime Water is Slowly Dripping

if fully saturated at the start, did not remain so, but there was always a certain amount of amorphous calcium carbonate precipitated from the solution, as may be seen at the bottom of the burette in the first photograph. The volume of carbonic acid gas required to form the calcium carbonate of which the stalactite is composed would be contained in about one hundred and thirty-three liters (35.13 gallons) of ordinary air. It might be noted here that the stalactite grew in a room which was only occasionally used, and for only short periods, so that the percentage of carbonate acid gas in the air would correspond pretty closely with the normal value.

So much for the facts; how do they compare with the generally accepted theory of the formation of stalactites, viz., that they are invariably produced by *the deposition of calcium carbonate from a solution of* bicarbonate of calcium? Here we have an obviously stalactitic growth formed by the dropping of a solution not of bicarbonate of calcium but by one of lime, so that an alternative method of formation seems possible. Do the conditions necessary for this alternative method ever obtain naturally? Is lime water ever dropping through the air in conditions similar to those in which it drops from the burette in the above experiment?

Fig. 2

One of the Crystalline Projections Which Clasp the Drop Shown in Fig. 1 as Seen Under the Microscope

The answer to these questions is apparently yes. It has been tacitly assumed by geological writers that the stalactitic deposits formed under railways and other arches are produced in precisely the same manner as the stalactites and stalagmites of a limestone cavern. But is this so, at any rate in the earlier stages?

Is it possible for the whole of the lime—that is, for one-third or one-fourth of the whole bulk of the mortar contained in the two to three feet in thickness of brick or stone work which usually compose the masonry of a newly built railway arch—to be changed into carbonate of lime by the time that the first signs of stalactitic growth appear? Apparently not, for according to Mr. Dibdin in his Lime Mortar and Cement, the absorption of atmospheric carbonic acid gas by mortar, although at first rapid, gets gradually slower. Mortars even centuries old are said to still contain appreciable quantities of hydrate of lime. This being so, it seems incredible that there could be any free carbonic acid gas available for dissolving calcium carbonate, at any rate in mortar under ordinary conditions, although it may be possible for the mortar in damp railway arches through which rain water is constantly passing to become saturated with the gas more rapidly. However this may be, the fact remains that this complete transformation is not necessary; stalactites of carbonate of calcium can be formed from lime water in contact with the carbonic acid gas of the air, and the general similarity in appearance between the stalactites of such bridges, hollow fragile tubes of approximately even diameter, and the artificially formed stalactite described above points to the conclusion that these stalactites and those of limestone caverns are due, at any rate in their initial stages, to quite different causes. In the case of the railway and other arches the rain water *percolating through the mortar must dissolve some of* the lime, the carbonic acid gas in the rain water combining at the same time with another small portion of lime, thus rendering it insoluble in the water which has *already lost its carbonic acid gas*, so that the drops issuing from the under surface of the arch must consist practically of lime water. As shown above, lime water will form stalactites when allowed to drop slowly, so that stalactitic growth may start very shortly after the brick work has been put into position—as soon, that is, as the mortar in it becomes saturated with rain water.

That the explanation given above is the true one is supported by the marked difference in the method of growth of the two kinds of stalactites, viz., those formed from bicarbonate of lime and those formed from lime water. Sir Archibald Geikie, on page 475 of volume 1 of the new edition of his Text Book of Geology, says in connection with chemical deposits: "Of these by far the most abundant is calcium carbonate. The way in which this substance is removed and re-deposited by permeating water can be instinctively studied in the formation of the familiar *stalactites* and *stalagmites* beneath damp arches and in lime-stone caves. As each drop gathers on the roof and begins to evaporate and lose carbonic acid, the excess of carbonate which it can no longer retain is deposited round its edges as a ring. Drop succeeding drop, the original ring grows into a long pendant tube, which by subsequent deposit inside and outside becomes a solid stalk, and on reaching the floor may thicken into a massive pillar. At first the calcareous substance is soft and when dry pulverulent, but by prolonged saturation and the internal deposit of calcite it becomes by degrees crystalline."

It is here clearly stated that the original deposit which goes to form a stalactite (whether in a limestone cave or under a damp arch) is soft and that it only becomes crystalline by degrees, whereas the stalactite formed from lime water grows by a *method of crystallization*, as may easily be seen in Fig. 2, which is a microphotograph of the growing point of the tube, in which the magnification is about thirty-eight diameters. It somewhat resembles, except in rate of formation, a frond of crystalline salammoniac as seen growing on a glass slide under a microscope, and it is in striking contrast with the soft amorphous deposit of calcium carbonate one so often sees in lime water. Again, the deposition of the calcium carbonate which goes to form a stalactite, as stated in the above extract, is due to loss of carbonic acid gas, and takes place at the base of the drop,

but as may be seen on an examination of the drop in Fig 1 the claws of the crystalline growth nearly encircle the drop and it appears almost as if the extension of this crystalline growth was due to and coincident with the absorption of the carbonic acid gas of the air by the lime water a suggestion which is supported by the fact that the drop of lime water remains absolutely clear and bright through all the stages of its formation, none of the milkiness usually caused by prolonged exposure to the air being apparent

It would be strange indeed if the causes of formation of the two kinds of stalactites should be of such an opposite nature viz In one case the loss, and in the other the absorption of the carbonic acid gas of the atmosphere, but one seems forced to that conclusion unless, as is just possible, both processes take place in the case of the drop of lime water, the gas being absorbed in the earlier stages of its formation and lost in the later stages as the water in the drop evaporates but if this explanation were the true one, the drop would be milky in the earlier stages of the growth whereas, as already stated, this does not appear to be the case

The "Olympic" and the "Titanic"*

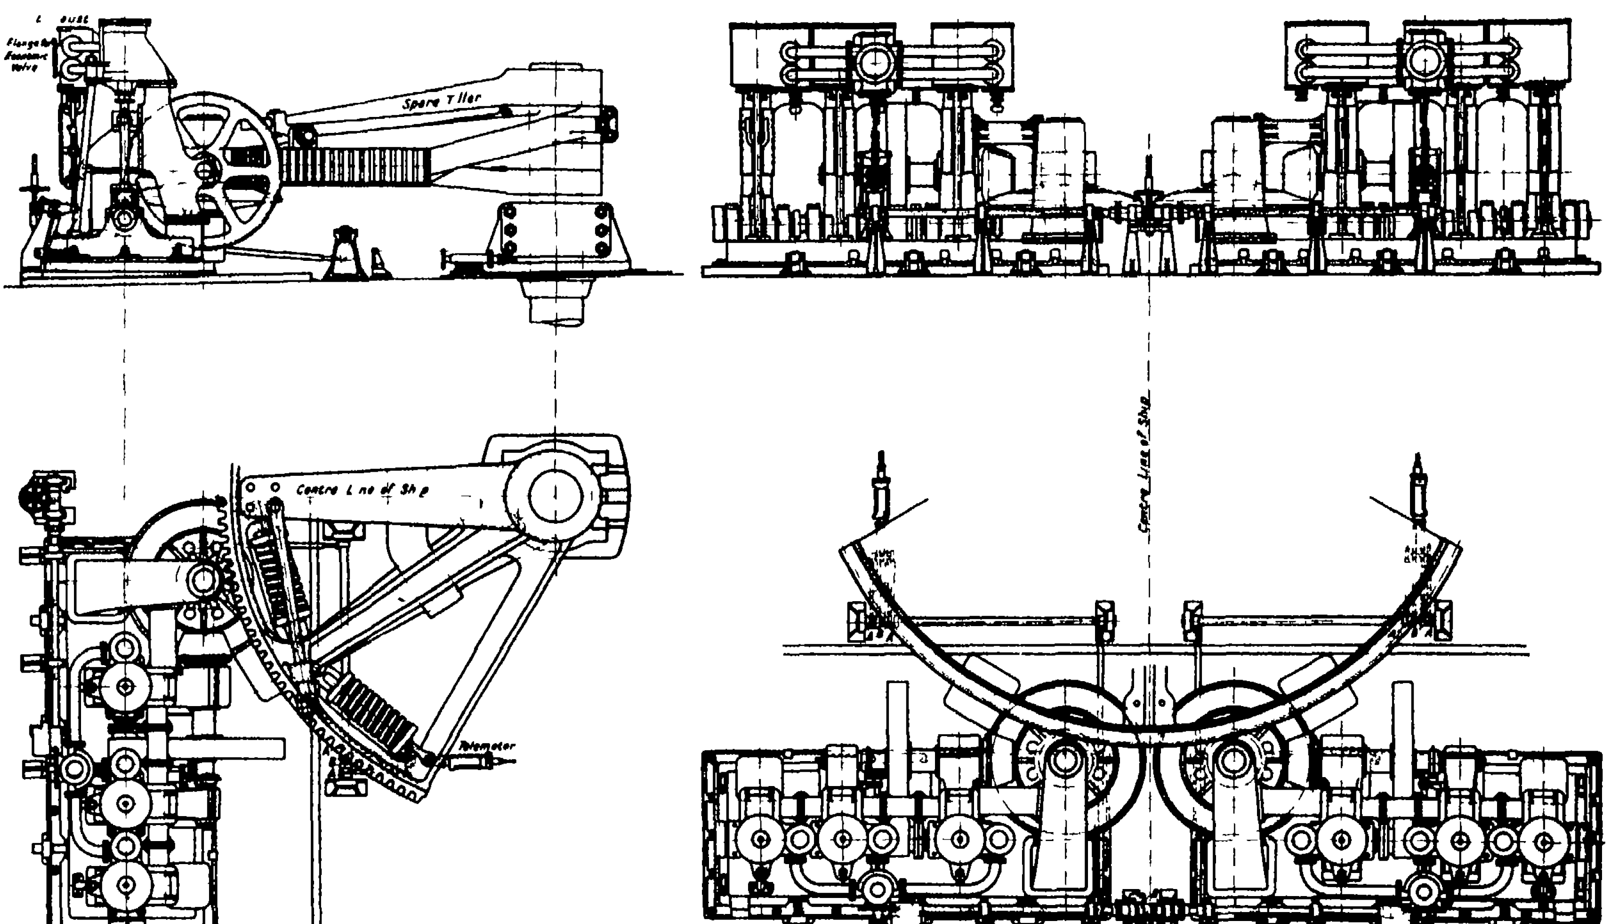
Two Giant Ocean Steamships

Thanks to the courtesy of the owners and of the builders Messrs Harland and Wolff we have been permitted to make a thorough inspection of the whole of the Olympic and her machinery as she now lies afloat off the fitting out quay situated some distance farther down Belfast Lough than the yard from which she was launched Here she lies with a huge 200 ton floating crane alongside and with her forward launching cradle still attached till she can be placed in the big graving dock 886 feet long by 96 feet wide at the entrance which is now under construction specially for her and her sister by the Belfast Harbor Commissioners Drawing as she does some 14 feet less than she will do when fully loaded and equipped her great height above the water does not permit her real size to be appreciated though there is no doubt that she is very well named Indeed on expressing worthiness only those who have had experience of the comparative behavior of the big and little ships in a heavy head sea can appreciate Another rather striking feature which is clearly brought out by the diagram is the comparatively insignificant increase in the amount of draught from the early boat amounting to only 30 per cent though the length is nearly doubled Draught is of course likely to have a restraining influence on any further great increases in size for some little time to come as its increase would entail very heavy expenditure in further dredging operations The actual dimensions of the two new boats are

Length over all	882 feet 6 inches
Beam	92 feet 9 inches
Depth	97 feet 4 inches*

* Bottom of keel to boat deck

accessible for marking off with the sheer strake A more fitting occasion on which to give details of the passenger accommodation will arise later on but it may be of interest to mention here that in addition to luxurious suites of rooms there will be a swimming bath 33 feet by 14 feet with a depth of water of about 9 feet a squash rackets court 16 feet 6 inches high electric passenger elevators etc The ventilation too will be carried out on a very elaborate scale with a view to insuring perfect comfort and health below even though the weather is so bad that ports cannot be opened or the passengers allowed on deck for fresh air and exercise The heating will be designed as far as possible to suit the comfort of chilly passengers or the reverse air is drawn by means of a number of electrically driven Sirocco fans through steam radiators and delivered at a temperature of



STEAM STEERING GEAR OF THE WHITE STAR LINER "OLYMPIC"

our wonder that two such typically White Star names as Olympic and Titanic had not been pressed into the service before we learned that they had been specially saved up for some really worthy representatives of this mammoth fleet which now amounts to 418 000 tons We are almost tempted to express further wonder why this should be considered the critical moment for the bringing forth of these hoarded treasures in the way of nomenclature and to ask what will happen when judging from past history the inevitable 1 000-footer comes along—and surely even then we shall not have the R M S Finalic ? It seems but yesterday that the names Britannic and Germanic were mentioned almost with awe as being the last word in steamship construction—certainly well within the memory of a generation and yet our diagrammatic sketch showing one of these boats together with the Teutonic launched some fifteen years later compared with the Olympic shows that these wonderful old ships have been left far behind in point of size One of the most striking of these elements of size is, we think, that of freeboard forward which in the case of the Olympic is considerably more than double that of the 'Germanic" and what this means in comfort and sea

* *The Engineer*

Added to the above the following statistics may be of interest Height of funnels above casings 62 feet keel to top of funnels 165 feet launching weight about 26 000 tons gross tonnage 45 000 displacement, 52 000 tons draught 34 feet 6 inches shell plates (largest) 36 feet long and 1¼ inches thick, number of decks 11, number of water tight bulkheads 15, capacity of double bottom 5 700 tons cargo capacity 5 600 tons, number of passengers provided for 2 500, crew 850 while over 2 000 sidelights are fitted in the ship and 16 boats are carried It may further be noted that the smallest steamship ever built by Messrs Harland and Wolff—71 feet in length—could easily be accommodated on the poop deck of the Olympic

Naturally the designing and building of such a ship has called for many special appliances such as the 200-ton floating crane mentioned above. This crane can lift a weight of 150 tons to a height of 149 feet at a radius of 100 feet with a list of only 4 degrees while the small hook can lift 50 tons at a radius of 140 feet. While in the drawing office we noticed that the ¼ inch to the foot half-breadth model used for measuring off the plating plant was carried on a special worm and wheel elevating gear to enable the garboard and bilge strakes to be equally

about 60 degrees through trunks to all the saloons state rooms etc those who desire greater heat will find electric heaters in their cabins, by which they can roast themselves to their hearts content. All the lavatories galleys, etc, are however ventilated by means of suction fans of slightly greater capacity than the pressure fans so that the air below is always kept sweet and fresh The water closets and lavatories are arranged toward the center line of the ship, which, though complicating the pipe arrangement, allows of a greater number of outside cabins than on the usual plan. Throughout the passenger accommodation the steel deck plates which are joggled, are covered with Lito-silo a composition accepted by the Board of Trade which is fireproof, pleasant to walk on and not slippery or noisy, while nails or screws can be equally well driven into it.

There are of course a great number of other matters of interest from a shipbuilding point of view, but we propose to confine ourselves henceforward to a description of the purely engineering features of the ship, these in themselves, as is to be expected, would demand a great deal more space than we can afford if we were to attempt to deal with them all in full detail, so that we shall endeavor to give a fairly complete and general description, and where possible dis-

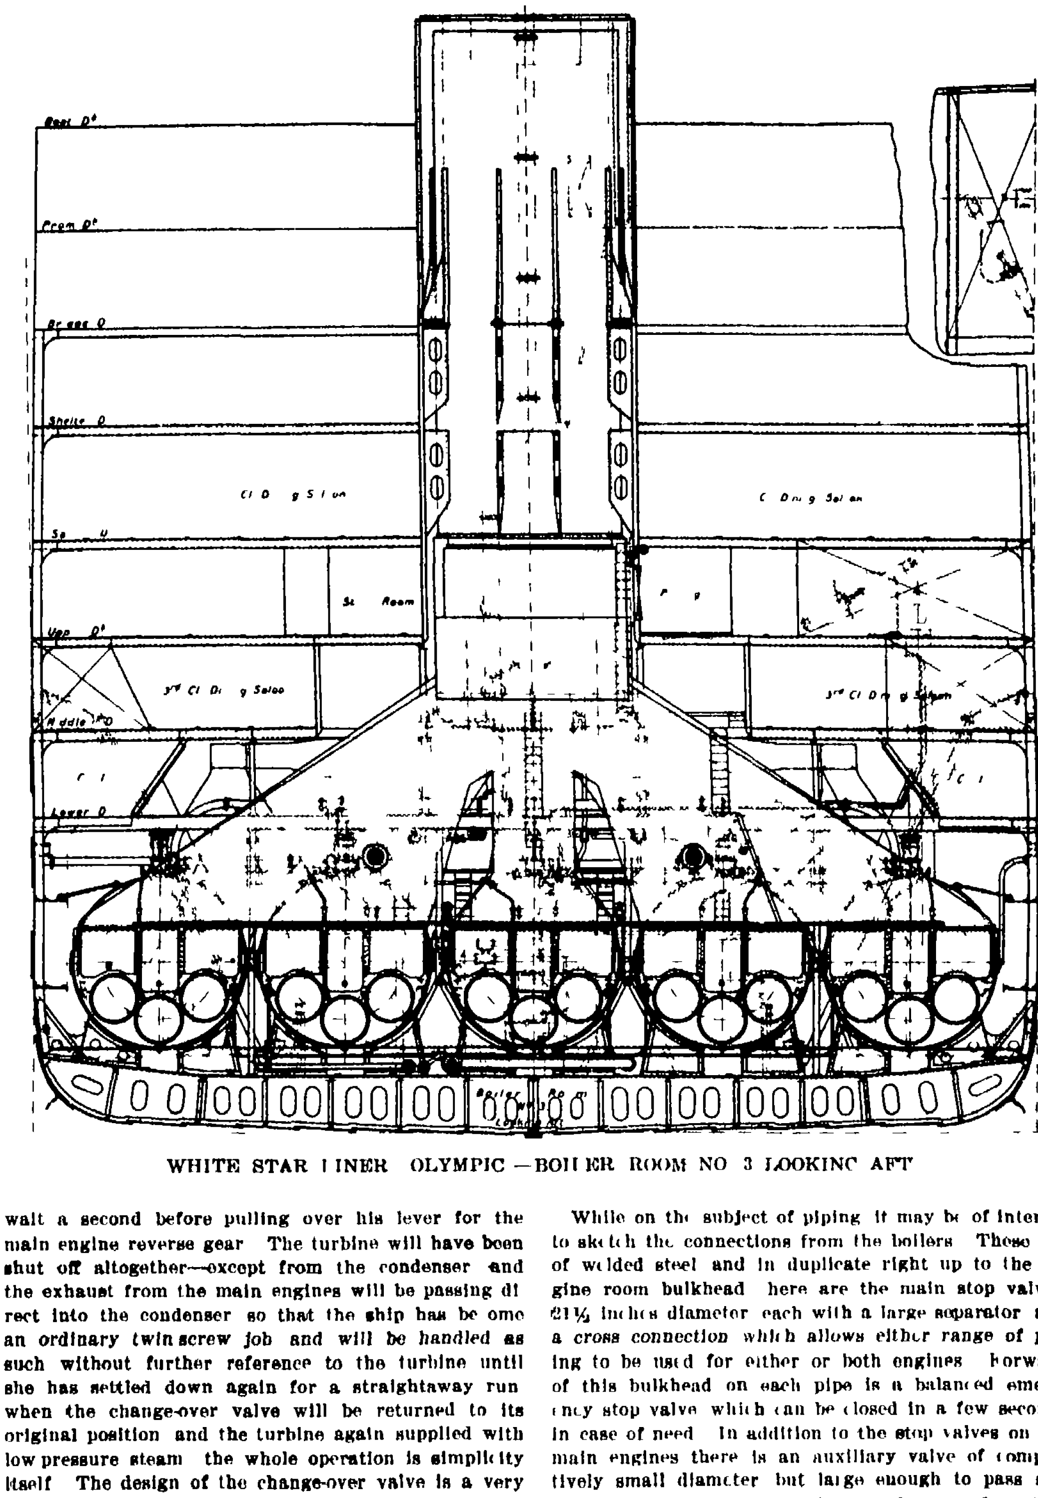
... the most interesting features and not go into figures to any very great extent. By so doing we shall hope to avoid any resemblance to a mere catalogue of particulars, and so present our facts that they shall be of such general interest as befits a record of what may almost be called a national possession—as it is indeed to Great Britain that the credit, at all events, for such a wonderful production certainly belongs.

In spite of the vast range of machines to be dealt with there is no difficulty in knowing where to begin, as the feature which is bound to create the greatest interest is undoubtedly the adoption of the combination of reciprocating engines with a turbine which has already been announced an arrangement designed, as is well known, to secure the maximum possible economy and which we understand has given remarkable results on the White Star liner Laurentic" The engines have been already briefly referred to and described in our issue of October 21st 1910 from particulars largely supplied by the builders but in describing them now from a personal inspection we shall recapitulate some of the facts for the sake of obviating the need for constant references to a back number and to make this article complete in itself

In designing the machinery for a transatlantic passenger steamer it will probably be safe to say that there are two main points to be considered after that of safety namely economy and the comfort of the passengers—that is absence of vibration—and it is rather remarkable how well both these points are met by one and the same arrangement The introduction of the low pressure turbine allows the steam to be expanded down very much further than could be done in any reciprocating engine and so economy is obtained while its addition to a twin set of reciprocating engines enormously reduces the size of such engines compared with what would be necessary if only twin screws were adopted As the vibration as it affects the passengers is largely a question of the total mass of the reciprocating parts in relation to the mass of the ship herself it will be obvious that the smaller each set of engines can be made the less will be the vibration felt by the passengers so that there will be a point when the relation between ship and engine will be such that the reciprocating engine will cause no more annoyance to the passengers than would a turbine Of course the better balanced an engine is in itself the larger it may be in relation to the ship so that in the case of the Olympic the engines, which are balanced on the well known Yarrow Schlick and Tweedy system are comparatively large It is perhaps hardly necessary to add that the combination while thus retaining all the advantages of a complete turbine installation obviates its great draw back and provides a ready and practically full powered means of reversing

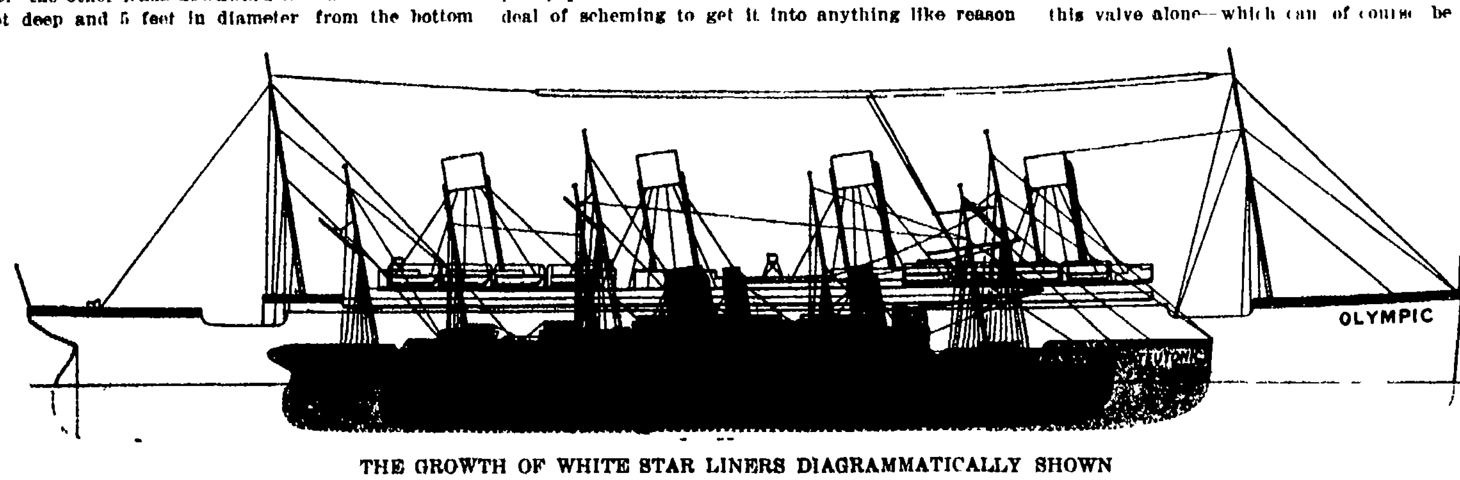
Making this our opportunity for leaving generalities and coming to particulars it will be well to begin by describing how this reversing is done as we must admit that, before going fully into it on board we anticipated that it would entail considerable complication and multiplication of duties for the engineer but this is not so The exhaust from each forward low pressure cylinder is led out along the front of the engine into a steel T piece on the after low pressure cylinder where it is joined by the exhaust from that cylinder and continues through the water tight bulkhead Here it enters an enormous change-over valve One branch from this valve leads to the condenser the other leads downward into a strainer some 9 feet deep and 5 feet in diameter from the bottom of which a pipe leads at right angles to the low pressure turbine, it is to be noted that the whole of this is in duplicate; and that there are two change-over valves, two condensers, and two steam admissions to the turbine. The change-over valve consists simply of what may be called a deflector piston in a casing, when the piston is up, the steam is deflected or guided downward to the turbine, when the piston is down, it is guided across the casing and out to the condenser

The pistons of both these change-over valves are inter connected through levers to a common Brown's hydraulic cylinder reversing gear on the bulkhead which is controlled by a lever on the starting platform close to the main reversing lever When the order to reverse is given the engineer has simply to pull over his lever for the change-over reversing gear and pay no further attention to it he need not even



WHITE STAR LINER OLYMPIC —BOILER ROOM NO 3 LOOKING AFT

wait a second before pulling over his lever for the main engine reverse gear The turbine will have been shut off altogether—except from the condenser and the exhaust from the main engines will be passing direct into the condenser so that the ship has become an ordinary *twin screw* job and will be *handled* as such without further reference to the turbine until she has settled down again for a straightaway run when the change-over valve will be returned to its original position and the turbine again supplied with low pressure steam the whole operation is simplicity itself The design of the change-over valve is a very pretty piece of work and must have required a great deal of scheming to get it into anything like reason



THE GROWTH OF WHITE STAR LINERS DIAGRAMMATICALLY SHOWN

able dimensions—especially when it is considered that the bore of each exhaust pipe—which by the way is of lap-welded steel with a strap riveted over the weld —is no less than 5 feet. Expansion in a case like this, when everything is so heavy and so many rigid connections have to be made is a matter requiring careful consideration, especially in view of the absolute necessity of excluding any trace of air from the pipes, which practically bars the ordinary stuffing-box form The difficulty has been overcome by the provision of a number of concertina joints one between each rigid connection consisting of two thin steel disks, riveted to and about 3 feet larger in diameter than the steam pipes and riveted together at their periphery through a steel ring the flexibility thus provided by the steel disks is found to give ample breathing capacity

While on the subject of piping it may be of interest to sketch the connections from the boilers These are of welded steel and in duplicate right up to the engine room bulkhead here are the main stop valves 21½ inches diameter each with a large separator and a cross connection which allows either range of piping to be used for either or both engines Forward of this bulkhead on each pipe is a balanced emergency stop valve which can be closed in a few seconds in case of need In addition to the stop valves on the main engines there is an auxiliary valve of comparatively small diameter but large enough to pass sufficient steam to run the engines at slow speed so that this valve alone—which can of course be opened and closed quickly compared with the big stop valve—is used when handling the engines Altogether in spite of the non reversing turbine and the huge size of the engines—cylinders 54 inches 84 inches 97 inches and 97 inches diameter by 75-inch stroke—the gentleman on the bridge ought to have no cause of complaint against the engine room when maneuvering this unwieldy charge. In the ordinary way a pipe arrangement would be considered a very dull subject, and

would certainly not furnish material for more than two of these lines but we venture to think that the installation under discussion presents sufficient points of interest to warrant our prolonging our description still further After passing through the turbine the steam leaves the top of the casing through a rectangular hole on each side and passes to the two pear shaped condensers the only auxiliary exhausting into the main condenser being the steering engine to accord with White Star practice Each of these rectangular holes is fitted with a big electrically-operated sluice valve which will enable the turbine to be completely shut off from the condenser in case of damage to the casing The eduction pipes are of welded steel and extend from the sluice valve casing out to the whole length of the condenser, so thoroughly distributing the steam over the tubes

With the steam from twenty nine big boilers to be dealt with it may well be imagined that a lot of circulating water will be required and this is provided by two circulating pumps with independent steam engines having cylinders 13 inches and 22½ inches in diameter—truly a decent little tug engine in itself The hole in the ship's side for the circulating injection was in the case of the Titanic which we saw on the stocks being used by the workmen as a means of ingress to and egress from the engine room After leaving the main engines the pipe arrangement naturally becomes inextricably mixed up with pumps etc but we will try and follow the combination a little further Copper pipes are used here and generally for the smaller steam pipes off the main range and we noticed in the shops that the edges of the copper used for big bends etc are chamfered off for brazing by means of a power hammer which should help to produce good work We were rather surprised to find that no higher vacuum than 28½ inches is expected from the four Weir dual pumps which are fitted though within ¾ inch of the barometric pressure could probably have been reached if desired The Weir arrangement has a single 22 inch diameter steam cylinder operating two 36 inch diameter pump cylinders connected together by a rocking lever the one cylinder pumps the water to the hot well in the ordinary way the other is connected to the upper part of one arm of a V in the air pump suction pipe into which the air and vapor rise and are drawn off leaving the water pump free to work at its maximum capacity From the hot wells two pairs of 14 inch duplex type pumps deliver to the oil filter and the surface and contact feed heaters placed in the reciprocating engine-room the latter on the level of the saloon deck and clearly shown in the elevation and cross section whence the hot feed passes down with a good head to the four 19 inch main Weir feed pumps and so to the distributing valves on the engine-room bulkhead It will be understood that the air hot well and centrifugal pumps and main condensers are in the turbine engine room while the main feed together with the auxiliary condenser and numerous ballast bilge and sanitary pumps and the two Hall's CO_2 refrigerators are in the reciprocating engine-room There are no pumps whatever on the engines and all are in duplicate so that when four are mentioned it will be understood that two will be sufficient in the ordinary way to do the work In addition to those auxiliaries already mentioned there are two turning engines one auxiliary condenser and circulating pump ash ejector pumps three lubricating oil pumps four Railton and Campbell ash hoists twelve See ash ejectors and three 60 ton evaporators about ninety in all together with others electrically driven which will be referred to later

We trust we may not be thought to have attempted to cook our hare before we have caught him in thus detailing the pipe arrangement before we have got our engine in place so to speak but we think our description has up to the present maintained a fairly logical sequence None the less we had perhaps better retrace our steps and get ahead with a general outline of the main engines

The low pressure cylinders are arranged one at each end as usual with the balancing system adopted and each has two flat valves worked off a common cross head by a single set of double-bar links and eccentrics and each having an ordinary balance cylinder No doubt the two valves and crosshead result in a slightly greater total weight than a single valve but this should be more than compensated for by the greater ease of handling and of maintaining steam-tightness A single piston valve is fitted on the high pressure cylinder and two on the intermediate pressure In studying the engines of this ship we could hardly help being struck by the wonderful way in which the old link gear still retains its place in the favor of marine engineers in spite of the many good radial gears that have been put upon the market from Hackworth Joy, Marshall Brock and Morton onward but at the same time we could not help feeling that even if we were directly interested in any of these gears, we should have to admit that their chief claim to recognition—that of saving space fore and aft by bringing the valves out to the front of the engine—would in this case have very little weight, even though the steam distribution might be a little better, the whole space devoted to the machinery is simply enormous– in fact, it may be said that it extends for practically the whole length of the ship

Certainly the impression gained in all three engine-rooms is one of vastness—vastness not so much of the machinery though that is big enough a cylinder column alone for instance weighing 21 tons as of the space available for and devoted to it over 90 feet across! The electric light engine room for instance to which we refer elsewhere is bigger than many a big ship's main engine-room However to return In spite of the big weights apparent weight does not appear to have been wasted and we noticed that the weigh shaft is tapered down in diameter outside the intermediate and high pressure valve gears where it has only a single set of links to carry Each set of links by the way has its own separate adjustment, so that the Brown reversing gear may always be set at full stroke whatever the cut-off required in each cylinder Running at 77 revolutions per minute with a boiler pressure of 215 pounds per square inch about 30 000 indicated horse-power are expected to be obtained which with another 15 000 from the turbine at 165 revolutions per minute should give the ship a speed of about 21 knots though it is a curious thing that all the crack White Star boats have made their best passages at least ten years after their launch—the old Britannic if our memory serves us right making her record after some twenty six years service

An interesting problem arises in connection with the overhaul and examination of such an engine as this where the built up crank shafts weigh somewhere in the neighborhood of 120 tons each and where a single nut off the bottom end is more than a man can conveniently deal with single handed the engine room floors have had to be specially strengthened to receive such trifles as a main bearing cap and altogether the engine seatings built up on the tank top are a study in themselves Further electrically operated lifting gear is provided on the tops for handling covers pistons etc while below are electrically driven winches with tackles etc for dealing with bearing caps bottom ends and eccentric straps The turbine casing also has its own electric motor and lifting gear while four machined vertical steel columns are fitted in guides on faces on the casting to insure its seating properly and without damage to the blades In this connection we would draw attention to one point which struck us rather forcibly in the course of our inspection of this turbine—which is of course of the ordinary Parsons low pressure type—though it is a point which is quite well known by now among marine engineers We should incline to the opinion that the sea-going engineer would desire to make the same sort of inspection of the interior of his turbine—the rotor etc—as he does of the piston valves etc of his reciprocating engine after a round trip This however would be no easy matter in spite of the splendid lifting arrangements which are provided nor could it be accomplished in the length of time usually available at the end of an Atlantic trip The number of joints to be broken the size of the joints and the need for absolute air not steam tightness and the weight of the various parts eduction pipes casing top etc which would have to be moved would obviously involve several days work though we have no exact information on the subject and it seems that the ordinary sea going axioms may be permissibly and in fact are safely ignored in the case of turbines

An electric motor is provided for turning the turbine though the reciprocating engines have steam turning engines The turbines were not built by Harland & Wolff but there is now under construction at their yard an enormous new shop the framework of which is of beautiful design as combining lightness with strength and the whole of this is to be given up to the construction of turbines in the future In fact the patterns for a set have already been constructed No less than fourteen collars are fitted on the thrust shafts of the Olympic" which with the line shafting are hollow a 9-inch hole being bored from end to end Loose couplings are fitted on the tail shafts of the reciprocating engines to enable them to be withdrawn outboard for examination—a very necessary arrangement for a 28-inch shaft There are eleven plummer blocks on the turbine shaft all of which are provided with forced lubrication at a pressure of about 28 pounds per square inch obtained by gravity from a tank high up in the turbine engine-room holding a ten minutes supply in case of failure of the pump The oil escaping from the bearings is collected in special drain tanks and pumped through strainers and coolers back to the gravity tanks; the tubes of which these coolers are composed are fastened into an oval just beyond the point where they fit into the tube plates, and it is found that the oil does not tend to harden on the surface as was the case with circular tubes, a very cheap and simple method of getting over the difficulty

The days when the engineer had to stand by the throttle and do his best to close the valve at the correct moment to prevent racing and open it again in good time to allow the engine to get away when the propeller again became immersed are, of course, long since gone by and the well-known Aspinall governor is fitted to make a thoroughly good job of what a man at the best could only make a poor job of, fitted on a special rocking arm in the absence of the usual air pump lever this is connected to the throttle of each engine and forms a very perfect mechanical governor while the turbine is similarly cared for by means of a ball governor acting on the Brown's gear which operates the two change-over valves so that in the event of a fracture of the turbine shaft, or loss of the propeller the turbine would be shut off and the reciprocating engines would go on their way with unruffled serenity

As is probably well known the White Star Company only permits the use of forced ventilation and not of any system of forced draught on its ships and though this tends to increase the grate area necessary yet with a height of funnel of 150 feet above the bars there cannot be much difference between the two with the advantage of induced in stead of forced draught It is rather curious to consider what a great advantage from a steam producing point of view is this great height which is after all rendered necessary strictly speaking solely by æsthetic demands and by the desire to obtain a smart looking ship of which the proportions shall be well balanced the top weight, however of four oval funnels 24 feet 6 inches by 19 feet and over 70 feet above the boat deck, with their inner casings must be enormous The boilers themselves are twenty nine in number—twenty four double-ended and five single-ended each 15 feet 9 inches in diameter the former being 20 feet long and the latter 11 feet 9 inches with plates 1 11/16 inches thick the shells having only one joint The comparative insignificance of the battery of boilers in relation to the ship is illustrated by the fact that the boilers are placed in the ship no less than five abreast although actually a walk from end to end of the boiler rooms is a big undertaking Thwartship bunkers are placed between each pair of boiler fronts with a bunker door opposite each boiler so that trimming on the plates is reduced to a minimum The wing bunkers are above the level of the boiler tops each wing boiler being secured by rolling chocks direct to the skin of the ship Even the uptakes on a job like this are a source of wonder they are even in fact provided with expansion joints

Naturally in such a ship many interesting little gadgets are to be found in the course of a tour of inspection of the stokeholds and elsewhere for instance each stokehold is provided with Kilroy's stoking indicators one for each boiler—neat little electrically operated signal disks with loud gongs which give visible and audible intimation to the fireman as to the exact moment when each furnace is to be fired The instruments are so arranged that there shall be the minimum number of doors open at the same time, and no two opposite doors in the same double end boiler shall be open together The interval between the times of firing any one furnace are under the control of the engineer and can be varied if found necessary but when once set insure perfect regularity of firing and so promote economy and smokelessness The current is provided by the ship's circuit so that when set and the switch opened the gear is automatic and requires no further attention

Even the whistle arrangements, embodying as they do a device designed by Mr W J Willett Bruce, of the White Star Company to insure a supply of perfectly dry steam immediately the whistle is required, are out of the ordinary though they are what are now used on all the White Star boats An automatic non return valve having a drain leading into the exhaust system is fitted in the whistle valve casing so that there can be no accumulation of water to sputter and muffle the sound when the lanyard is pulled, and a clear blast immediately follows. In addition to this, an electrically controlled timing apparatus operated by current from the lighting circuit is provided by which the whistle can be blown at perfectly regular pre-determined intervals in order to comply with the Board of Trade regulations for signaling in a fog, so relieving the tension on the nerves of the passengers, and reducing the duties of the officers of the watch. Another provision toward safety is the rather obvious arrangement for controlling the closing of the watertight doors in the bulkheads. These are kept open by means of a clutch kept in engagement by a [illegible]

[illegible] can be lifted by an electric arrangement [illegible] by a float in the bilges, so that any water [illegible] below the floors to more than a pre-[illegible] depth will raise the float, release the clutch [illegible] the door—this taking place comparatively [illegible] owing to the pneumatic cushion cylinder on [illegible] having its piston connected to the door There is also a hand control by which a man who might be trapped below could delay the closing of the door till he had made good his escape These points are detailed to show the care and thought which have been expended in even the smallest items of the equipment of the ship

There are also Silley wedge action smoke-box door fasteners which do away with the usual many handles and tend to keep the doors from warping a complete outfit of telegraphs to indicate the requirements of the engine-room in regard to steam etc while each stokehold has its own pumps in their own little engine-room completely screened off from the coal dust Some 176 firemen will be carried with 72 trimmers and these have their own special passage and spiral staircases leading to their bathrooms and quarters so that they never need be seen by the passengers while on their way to or from duty We should not omit to mention, too, that there is a series of escape trunks leading from the engine-rooms and stokeholds to the upper deck to enable the men to escape in case of the ordinary means of egress being rendered useless by accident.

THE ELECTRICAL OUTFIT

Those who remember the early days of the introduction of electricity on board ship when any old other wise useless corner was good enough to stow the dynamo in would appreciate the great importance to which this department has now attained on board ship by an inspection of the palatial room devoted to the generating plant on this ship The whole width of the ship—except for the space taken up by the three shafts and their plummer blocks—for a length of some 64 feet and 24 feet high is entirely given up to it Here are situated the four sets of 400-kilowatt multipolar dynamos, each driven by a three-cylinder compound vertical inclosed Allen engine having cylinders 17 inch, 20-inch and 20 inch diameter by 13 inch stroke running at 320 revolutions per minute with a steam pressure of 180 pounds per square inch Forced lubrication is, of course used with special arrangements to prevent the oil getting into the cylinders and so to the boilers, and we were interested to note that Renold silent chains instead of belts were used for driving the tachometers and that watt meters are fitted to each set It may be mentioned here that in addition to these four sets there are two 30-kilowatt sets having cylinders 9 inch and 12-inch by 5 inch running at 380 revolutions per minute, fitted on the level of the saloon deck above the water line, so that if the main generating room were flooded it would nevertheless be possible to have sufficient light to avoid panic among the passengers and for signaling purposes etc It will naturally be asked why reciprocating engines have been adopted for the dynamos instead of turbines and this question received very careful consideration on the part of the builders and is largely a commercial rather than a mechanical one The whole of the exhaust from these engines was required for the feed water heater so that the economy of turbines would have been seriously interfered with and this favored the adoption of the reciprocating engines

The whole of the installation has been most carefully thought out complete wiring plans having been prepared giving the position of every switch light and motor throughout the ship and what this involves may be guessed from the following list of machines for which electricity is used in addition to the arc and incandescent lights Deck cranes cargo, boat and engine-room winches, Waygood s elevators for first and second-class passengers and lifts for stores mails, and pantries eight 55 inch two 50-inch and two 40-inch stokehold fans delivery fans for cold hot and warm air cylinder lifting gear, turbine turning, and turbine lifting pneumatic conveyor Marconi apparatus gymnastic apparatus, ice rockers domestic machinery such as dough mixers, potato peelers, roasters knife cleaners, slicers, whisks, etc., sluice valve operating gear steam whistle, sounding machines illuminated signs clocks, water-tight doors, helm indicators, submarine signaling wireless telegraphy telephones (loud speaking and ordinary) bells, cabin fans heaters hot plates and similar appliances, electric irons and electric baths. The total number of motors is between 140 and 150 from ½ to 40 brake horse-power while there are 450 heaters from 750 to 2 500 watts each

The dynamos are compound wound the equalizer cables being led to interconnecter switches situated below the deck at a position approximately equidistant from the four machines with a view to minimizing and equalizing the resistance when running in parallel The positive cables run to the main switch pillars and thence to the feeder panels or switchboard proper which is placed athwartships on a raised platform or organ loft which runs right across the ship arranged as it is to distribute some 20 000 amperes at 100 volts—equal to the central station of a good large town the heating lighting ventilating and power each account for about 25 per cent of this The adoption of tantalum lamps which are fitted throughout (with the exception of some ordinary incandescent lamps in the engine-room) permitted the voltage to be reduced to 100 which it is estimated will result in a great economy in spite of the higher cost of the metal filament lamps The latter have been found to be quite suitable for use on shipboard except where there is any pronounced vibration On this same platform are arranged the four main switches and contact breakers above mentioned one for each dynamo the levers of each of which there are five being interlocked so that only the correct sequence of operations can be carried out The operator faces the generating plant and has under his control an illuminated sign actuated by a round handle by which he can signal to the engineer in charge of the generating plant for more or less speed or for a given machine to be started or stopped The whole switch when completed is of course completely cased in by planished steel sheets All switches etc are connected to illuminated and numbered signs so that the effect of the movement of any lever is clearly and unmistakably indicated From the feeder panel 46 leads of 91/13 cable are carried together with their returns in two steel water tight trunks through the various decks distributor boxes are fitted on each deck from which the leads are sub-divided to the various circuits so that all the wiring is kept as compact as possible all wires leading through a water tight bulkhead are collected together in a steel tube filled with bitumen for the sake of neatness while maintaining water tightness We noticed a neat method of leading the cables to the stokehold fan controllers The cables are fitted permanently into screw plugs the holes for which are bored and tapped in the joint of the cover so that they can be placed in position and the cover screwed down making a simple and yet water tight joint These controllers by the way have rods supported on ball thrusts leading down into each stokehold so that they can be operated either from above or below the ball thrusts enable the gear to work with so little friction that the different positions on the controller can be easily felt even at the bottom end While on the subject of electricity we would like to draw attention to the method adopted for lighting the ship while being fitted out The whole of Queen s Island is covered by cables lead ing from the main generating station in the works but the Olympic is lying beyond the reach of these so the firm have installed four dynamos on the main deck of their tug the Jackal which is lying along side and have made her into a portable central station supplying the whole ship a fire engine has also been installed with hydrants all over the ship and fire drill is carried out once a week This with the big floating crane and the special steel gangways already referred to is suggestive of the huge capital outlay to be considered in the construction of such a ship which alone puts the work beyond the reach of all but a few firms

OTHER AUXILIARIES

There is, of course much other auxiliary machinery in all parts of the ship but we will only refer to some of the more important items

In order to keep the weight of the anchors down as much as possible and yet to comply with the Board of Trade regulations an unusual arrangement has been adopted in having a hole in the stem to allow for a third anchor which is housed on the forecastle the two side anchors housing in the hawse pipes as usual Two large vertical steam windlasses by Napier Brothers are provided for the side anchors the starboard one of which has additional clutch gear operating through bevels to a worm and wheel on a large central drum grooved to take the huge steel wire which is fitted to the center anchor instead of the usual cable the thrust block on this worm shaft is quite a striking piece of machinery and gives some indication of the power required for dealing with this important part of the ship s equipment The big anchor weighs some 15½ tons Two warping engines are also fitted under the forecastle which in itself forms a small engine room

Right aft we were faced with a feature of which we are afraid we could hardly appreciate the precise value or at any rate the value commensurate with the cost involved Here we found a pair of enormous three-cylinder steam steering engines of the firm s well known make Only one set is in gear at a time the other set being a stand-by which can be quickly engaged by means of screw jacks embodied in the framing which slide the base plate along for the distance necessary to engage the teeth of the pinion in the rudder quadrant the bends in the steam pipe being sufficiently flexible to allow of this without the need for making any joints We should have thought that the rudder head would have been more likely to prove the weak spot failure of which would of course render both engines useless while the ship could be safely navigated into port by her propellers only However perhaps it is not for us to criticise a feature which a firm of such enormous experience as the White Star Company has apparently found to be desirable The gearing of the engines is of the double helical or herringbone type cut from the solid Citron gear It is designed for silence and strength and we were informed that it is perfectly noiseless and entirely does away with back lash The pinion on the gear shaft meshes with the teeth on the quadrant which is loose on the rudder head but the quadrant is connected by springs to a double tiller below which is keyed to the rudder head so that the engine and gearing should be relieved of all shocks which in view of the fact that the rudder weighs 100 tons and is 15 feet broad will not be inconsiderable An emergency tiller is also fitted which can be connected up to the two warping engines in the wings in case of damage to the quadrant the teeth of which are in interchangeable sections bolted to the casting The control is by means of a Brown s telemotor from the bridge actuating the steam valves There is also fitted a Brown s Economic valve—or get out of the way valve if we may be allowed to coin a word to prevent leakage of steam while the engine is standing due to the absence of lap on the piston valves This valve consists of a conical seated valve in the steam admission port with a coned projection extending into the engine valve chest and when closed shuts steam completely off the engine When the engine valve is moved by the telemotor it acts on the coned projection and pushes the valve back off its seat and admits steam a strong spring returning the valve to its seat when the engine valve has resumed its central position We understand that the engines are capable of putting the helm from hard a port to hard a starboard in twenty seconds

Though it is practically impossible and not always desirable to describe all the details of such a mammoth installation as this we think we have outlined the main features of interest without dwelling upon points which are matters of too common knowledge For instance we have given no description of the turbine as details of one set such as this are common to many others which have frequently been described in recent years and a Parsons turbine does not present so many possibilities of design as a reciprocating engine—at all events outwardly To go over such a ship while under construction is a liberal education in itself and affords a better idea than could the completed ship of the wonderful organization necessary to enable the swarms of men employed in the ship construction engineering electrical and other branches to work synchronously and harmoniously together in the rapid completion of the whole structure

Temperature and Humidity of Workrooms Etc

The effect of different temperatures and degrees of humidity in the air in different workrooms, mines, etc., has been tabulated by a German, who sums up his observations and recommendations as follows

At a temperature of 10 deg. C. (50 deg F) the worker is liable to catch cold if not protected specially by warm clothing. If the work is severe physically and the body thereby greatly heated, a temperature of at least 12 deg C (53 6 deg F) is necessary for comfort and health If a lower temperature is unavoidable, then thick clothing is necessary If the work is physically less exacting with ordinary clothing 18 to 20 deg C (64 4 to 68 deg F) and about 40 per cent of saturation is right Miners tunnel laborers bakers, etc, who are compelled to work where the temperature is 30 to 56 deg C (86 to 132 8 deg F), with humidity 60 per cent and even over, are in danger of heat-stroke unless special precautions be taken to prevent it For temperatures over 50 to 60 deg C (122 to 140 deg F) where the air is dry—say with humidity 20 per cent—as is the case with glass blowers and distillers the work is not so exacting by reason of the low degree of moisture

The two sets of workmen mentioned last should as far as is practical strip for their work and should enjoy good ventilation also should use heat veils and screens

Airship Anchorages

By Major O C von Verschuer

The airship cannot become a practical means of transit until its safety has been assured by an organ ization as thorough and comprehensive as those of railways and steamship lines Airship harbors and anchorages are especially necessary The loss of the stately passenger airship Deutschland was due to the lack of suitable anchorages

The peculiarities of airship traffic will probably develop stations of three classes

1 Terminal stations, analogous to railway termini

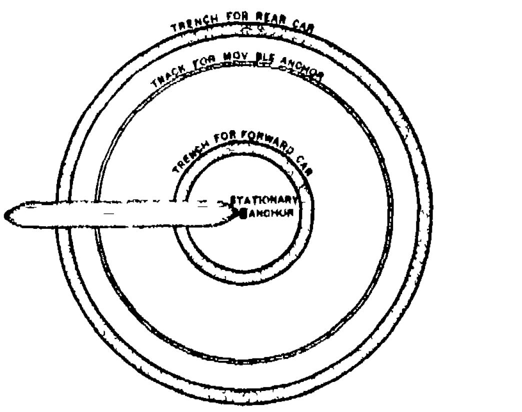


Fig 1 – Plan of Airship Anchorage

in large cities and provided with shelters or sheds and every requisite for the preservation maintenance equipment and repairing of airships

2 Way stations at suitable points in the vicinity of small towns and villages

3 Emergency stations in places well sheltered from the wind such as valleys surrounded by forests, and situated if possible near towns and villages

Costly shelters will not be required at way stations for the stops at these stations will usually be short and even a longer stop caused by adverse winds or a disabled motor or propeller will not necessitate the housing of the airship if the anchorage is pro vided with appliances which will assure the safety of the vessel even in a violent storm

An anchorage suitable for a Zeppelin airship can be constructed as follows The vessel is secured by a stationary anchor placed at the center of a sheltered level field about 1 000 feet in diameter and also by a movable anchor in the form of a wheel rolling in a hollow circular track about 250 feet in diameter The stationary anchor is attached to the bow and the movable anchor to the stern of the airship which therefore automatically keeps it head to the wind

In order to allow the bottom of the cylindrical hull to be brought very near the ground two circular trenches 6 or 7 feet deep and concentric with the anchor track are provided for the reception of the two cars which move along their respective trenches as the airship veers with the wind On account of the downward pressure of the wind the bottom of

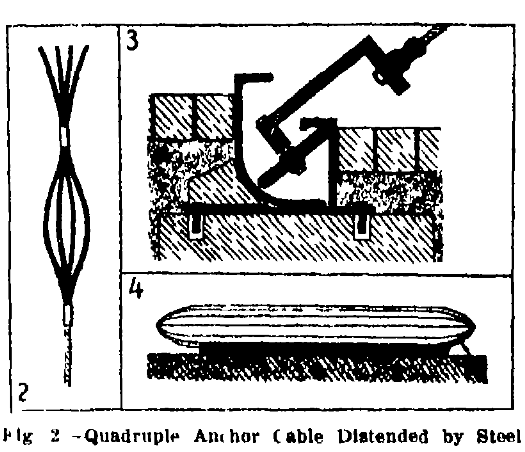

Fig 2 – Quadruple Anchor Cable Distended by Steel Springs Fig 3 — Movable Anchor and Its Track Fig 4 — Airship at Anchor Showing Protective Apron

the longitudinal gangway should be about 20 inches above the surface of the grass grown soil and should be protected at its after end by leather bags filled with wool or shavings

Thus anchored the airship is little liable to injury from head or side winds The injurious effect of puffs of wind which force themselves between the hull and the ground and which contributed largely to the disaster that befell the Zeppelin II" at Limburg may be prevented by surrounding the lower part of the hull with an apron of sailcloth with its lower edge stiffened by light metal rods and weighted with sand bags (Fig 4)

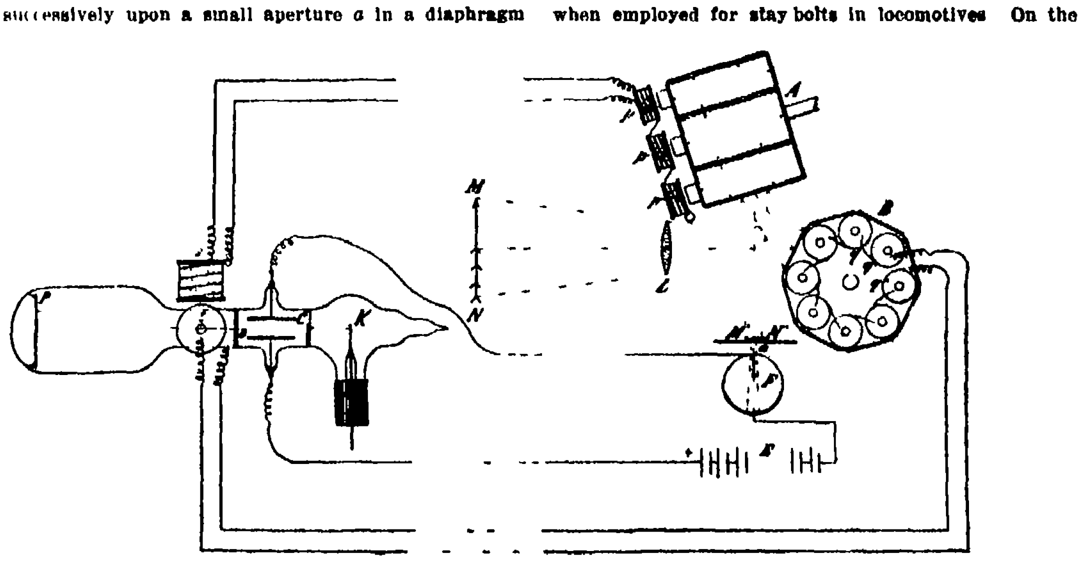
In order to prevent the rupture of anchor cables and other damages caused by sudden gusts of wind, it is advisable to employ a group of four cables, stretched over four curved steel springs wrapped with wire (Fig 2) The elasticity of this contrivance will equalize the tension, diminish the effect of gusts and protect the airship and its connection with the cable from violent shocks.

The cost of constructing an anchorage of this sort would not be out of proportion to the importance of the purpose for which it is designed —*Umschau*

Prof Rosing's Electric Eye —A New Apparatus for Television

Several methods of television, or seeing at a distance with the aid of wires and electric currents have been announced in the course of the past decade, but none of these methods has come into practical use The Russian journals now announce that Prof Rosing, of St. Petersburg has solved the problem of television The following description of Rosing's method and apparatus is taken from an article contributed to *Cosmos* by Jacques Boyer who derives his information from the *Bulletin* of the International Technical Society of St Petersburg

The electric eye as Prof Rosing calls his apparatus is illustrated in the accompanying diagram, of which the right hand part represents the transmitting station and the left-hand part the receiving station In the diagram the stations are shown connected by six line wires but the number of wires can be reduced to four At the transmitting station two drums *A* and *B*, covered with plane mirrors rotate on mutually perpendicular axes in such a manner that every point of the image *M N* which is formed of the object *MN* by the lens *L* and the mirrors falls successively upon a small aperture *a* in a diaphragm



PROF ROSING'S ELECTRIC EYE A NEW APPARATUS FOR TELEVISION

Receiving station at the left – *K* cathode *I* fluorescent screen *C* condenser *O* diaphragm *P* electromagnets. Transmitting station at the right – *A B* rotating drums carrying mirrors and magnets, *M N* object *L* lens *M N* image *A* diaphragm *F* photo-electric globe *B* battery *p p' p" g g' g"* coils

placed before a glass globe *F* The interior of the hemisphere opposite the aperture *a* is lined with an alloy of potassium sodium or rubidium which is con nected with the negative pole of the galvanic battery *E* The negative charge which the alloy thus acquires is carried away by the negative ions which the alloy emits under the influence of the illumination which it receives from the aperture *a* In this way a charge varying in magnitude with the intensity of illumination or the brightness of the point of the image *M N* opposite the aperture *a* is transmitted to the condenser *C* at the receiving station, through the wires connected respectively with the alloy and with a positive electrode which occupies the center of the globe *F*

The rotating drums *A* and *B* which carry the mirrors also carry magnets which as they pass the coils of wire *p p' p"* and *g g' g"* generate alternating currents which are transmitted to the receiving station where they energize the electromagnets *s* and *t*

A pencil of cathode rays emanating from the cathode of a Crookes tube *K*, traverses the common field of the two electromagnets the axes of which are mutually perpendicular and is thus subjected to deviations corresponding to the displacements of the image *M' N'* with respect to the aperture *a* at the transmitting station The result is that the luminous point produced by the impact of the pencil of cathode rays upon the phosphorescent screen *p* moves in exact correspondence with the relative movement of the aperture *a* over the image *M' N'*

Before the pencil of cathode rays enters the electromagnetic field it passes successively through a small orifice in a diaphragm (shown in the figure but not lettered), between the plates of the condenser *C*, and through a small orifice in a second diaphragm *o*. The relative positions of the two orifices and the cathode *K* are such that the rays do not traverse the second orifice *o* unless they are deflected by the electrostatic force exerted by the charged condenser, so that the fraction of the pencil that passes through the orifice *o* is proportional to the deviation, and therefore to the charge. Hence the intensity of the active pencil and the brightness of the fluorescent [illegible] are proportional to the charge of the condenser, and consequently to the brightness of the point of the image *M' N'* which momentarily illuminates the photo-electric alloy at the transmitting station.

In consequence of these electromagnetic and electrostatic actions exerted upon the cathode rays, every point of the image *M' N'* and the object *MN* is reproduced with its proper relative brightness, on the fluorescent screen *p* at the receiving station As the entire operation is repeated forty times per second the fluorescent screen presents to the eye, in consequence of the persistence of retinal impressions a motionless picture of the object *MN* The fluorescent screen the electromagnetic field, the diaphragms and the condenser are of course inclosed in the Crookes tube with the cathode *K*

Aluminium Copper Alloys

The British Association of Mechanical Engineers has a committee whose business is research concerning the properties of various alloys which are now coming so rapidly into use A recent report deals with alloys of aluminium and copper Various experiments have shown that such alloys are erratic in behavior especially under tests for yield point and at high temperatures

Copper alloyed with 7 per cent of aluminium was shown in some experiments to give disastrous results when employed for stay bolts in locomotives On the contrary these alloys show good results in other ways It has been shown that copper alloyed with from 1 to 10 per cent of aluminium becomes practically in corrodible in sea water But this does not hold for tank water

Cement-Protected Iron

The use of cement to protect iron is not a new invention At Brest the demolition of subaqueous con structions has brought to light iron bars which were thus covered and which have remained in perfect condition for more than 100 years At Rochelle a bridge erected in the fifteenth century was found to contain cement protected iron and the metal had not suffered from the effects of moisture

The International Hygiene Exposition at Dresden

The International Hygiene Exposition which was opened in Dresden last month after four years of diligent but unostentatious preparation and which will continue open until November, is called an exposition in default of a better name. The real purpose of this great enterprise is the promotion of the health of humanity. A hygiene exposition was held in Berlin as far back as 1882, when the science of hygiene was in its infancy, and small local exhibitions of similar character have since been held in various countries, but none of these compared in extent and importance with this year's international exposition at Dresden, which forms a comprehensive review of everything which the mind of man has devised for the preservation and promotion of human health since history began.

The immense mass of material which has been collected in accordance with this far-reaching plan is divided into five departments, each of which constitutes an extensive exhibition in itself. These include a scientific, a historical and ethnographic, a popular, and a sport and exercise department, with each of which are associated appropriate parts of the fifth department, devoted to industries and manufactures. This fivefold division is a happy idea, and it possesses the great merit of giving proper recognition to the needs, tastes, points of view and powers of comprehension of each individual visitor.

The advantage of separating the scientific from the popular department will be recognized after a moment's consideration. The exhibits of the scientific department chiefly interest the specialist, while those of the popular department appeal to the popular mind. It is desirable that the attention of the ordinary visitor shall not be burdened and distracted by things which do not interest him and which he does not understand, and it is equally desirable that physicians, students of

THE INTERNATIONAL HYGIENE EXPOSITION AT DRESDEN

hygiene and public health officers shall be able to study the special exhibits which they alone can comprehend without being annoyed by the intrusion of material which is perfectly familiar to them and therefore superfluous.

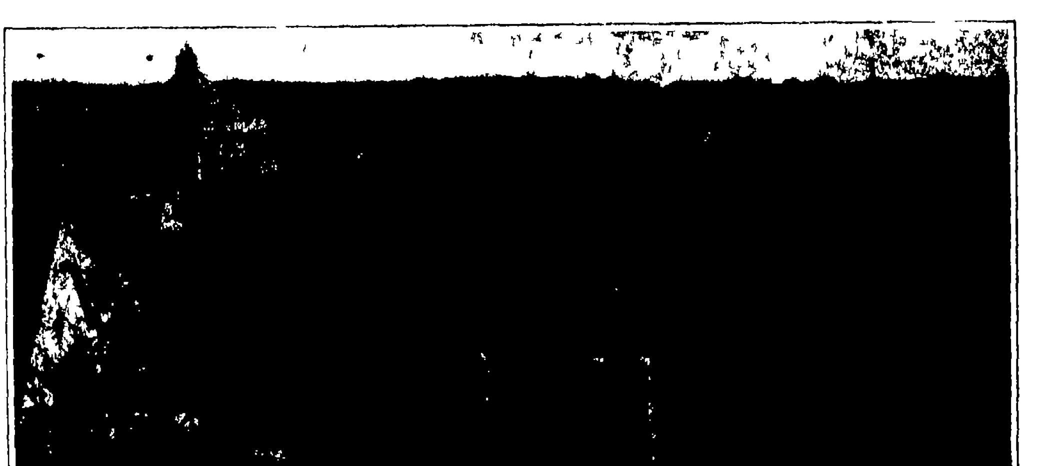
The historical department presents for the first time a complete and systematic history of hygiene. Here to the amazement of the average visitor is exhibited evidence of the attention which was devoted thousands of years ago to the health of the individual and the community. For example it is shown in a striking and original way that the basic idea which underlay all the laws and admonitions of Moses was the restoration of the physical health of his degenerated people as a necessary pre-requisite to their spiritual development. The religious precepts in which he embodied an advanced system of hygiene are the work of genius. It is probable that the Jewish race would have become extinct if it had not been preserved by this well-conceived plan of social hygiene.

This is only one of the examples which prove the incorrectness of the popular idea that hygiene is a very modern science.

The hygienic idea however is steadily progressing as is proved for example by the increasing popularity of athletic sports in which many brain workers find an indispensable source of physical recuperation. Hence sport will be represented at Dresden by a special group of exhibits and also by competitions for the championship of Europe in various events. Like other good things sport may be and often is carried to excess and has thus fallen into disrepute among large classes of the community. An endeavor will be made at Dresden to establish safe and sane limits which must be respected in order to secure the benefits and escape the evils of athletic sports. For this purpose a laboratory is provided in which the effect of various exercises upon the human organism will be studied in detail. No similar laboratory of sport is now in existence even in America or England, the two countries in which athletic exercises are most honored.

Associated with each of these departments is a group of industrial exhibits. The demand for space for these exhibits has made it necessary to enlarge some of the buildings several times. Certain industries which have had to contend against popular prejudices are represented far more extensively at Dresden than at any former exhibition. Single firms and societies have expended many thousands of dollars in order to convince consumers that the increased hygienic demands of the present day have been met by the newest industrial products.

The numerous buildings of the exposition distributed over some eighty acres of a municipal and a royal park present a harmonious and imposing appearance. The principal buildings are in the style of the classic Greek temple typifying the sacred character of health. Eminent judges have expressed the opinion that the Dresden exposition is architecturally one of the most beautiful expositions that the world has ever seen.



THE BRIDGE HUNGARIAN BUILDING AND POPULAR BUILDING

THE INTERNATIONAL HYGIENE EXPOSITION AT DRESDEN

China and Japan as well as America and all the nations of Europe are represented at this great exposition of hygiene. With few exceptions, each country has a special building. Individual cities with their smaller and consequently more intensively cultivated fields of public hygiene are also represented in large numbers.

The two great objects which the exposition is designed to promote are: First, the improvement of the hygienic conditions of the mass of the people which is the special function of municipal and national governments and second the instruction of the individual in the laws of health, as the influence of governments on the hygienic conditions of individual life is necessarily limited. The history of the International Hygienic Exposition may be said to have begun in 1903 in which year an Exhibition of German Cities was held in Dresden. Here and subsequently in Munich, Frankfort and Kiel was shown a special group of exhibits relating to epidemic diseases and their prevention, which proved so interesting to specialists and the general public alike that many persons expressed a wish that it might be enlarged to embrace the whole field of hygiene and continued in the form of a permanent museum or shown as a temporary exhibition, either of technical and compact or of general and if possible international character.

THE MAIN EXPOSITION BUILDING AND THE HALL OF CHEMISTRY AND SCIENTIFIC INSTRUMENTS

The field of hygiene has been extended enormously since the first attempt to illustrate it in a general exhibition was made in Berlin in 1883. Then there was only one professorship of hygiene in Germany, where now every university maintains a department of hygiene. Corresponding progress has been made in other countries. Hygiene has received much attention from lawgivers and administrative officers and has been popularized by the publication of many books and journals and by the efforts of hygienic societies whose members number many thousands. Industrial firms not always under compulsion have vied with each other in making their products unobjectionable on the score of hygiene.

It was evident, therefore that any State that should undertake to hold an international hygiene exhibition which should adequately represent present conditions must be prepared to perform thoroughly and conscientiously a great and difficult work, at considerable expense. In 1905 a committee met in Dresden to consider the possibility of holding such an exhibition in Germany. The obvious suggestion that the task should be assumed by the Imperial or by the Prussian Government was abandoned because the sentiment of Berlin was averse to the holding of great exhibitions. This narrowed the choice to the two great States of Bavaria and Saxony, that is, to their capital cities, Munich and Dresden. A favorable reply having been obtained from the Saxon Government, the most eminent hygienists of Germany, together with numerous representatives of the Imperial and State Governments, assembled in Dresden in 1906 to consider the project more fully. It was unanimously decided to hold the exposition if possible, in Dresden and to make its scope international and exceedingly broad. A board of directors was selected and a general plan was formed which required a subvention of two million marks, a guarantee fund of one million marks, the occupation of a large area of a city park and the adjoining royal park, and the gratuitous erection of the main exhibition building by the city of Dresden. After considerable difficulty and delay these modest demands were granted by the authorities, and the guarantee fund was raised by popular subscription.

All doubts respecting the reception which the project would meet in industrial circles were quickly dispelled. Prominent manufacturers pronounced the exposition peculiarly opportune and necessary because the industries which are most intimately connected with hygiene had not had opportunities at other great expositions, to show adequately and convincingly the progress they had made in satisfying the requirements of modern hygiene. Applications for space came in in embarrassing profusion as has already been mentioned.

In determining the general idea and plan of the International Hygiene Exposition little aid could be obtained from the study of previous expositions, the general character of which has scarcely varied in a hundred years. According to the orthodox program the special purpose and scope of the exhibition is first determined the public officials societies, firms and individuals interested are invited to take part, the exhibits contributed are grouped according to subject, and places of refreshment and amusement are added. In short the purposes and methods of the modern great expositions like those of the old-time annual fairs have been almost exclusively commercial.

Although exhibitors and visitors have derived much benefit from such expositions complaints have come from both sides. Many exhibitors have complained that the benefits derived did not compensate them for their outlay while visitors have objected that the accumulation of vast numbers of similar objects produced weariness made it difficult to find the exhibits of real importance and detracted from the educational value of the exposition. The question of reform in expositions has lately been much discussed and various methods of raising expositions to a higher plane have been proposed. All of these schemes, however retain the fundamental defect of previous expositions, dependence upon the will and caprice of exhibitors. The exhibits are determined largely by chance. Many interests decline to exhibit at all, others are represented by a few forms of little prominence, while still others demand an inordinate amount of space. Hence some groups are very defective, while others are overfilled.

The Dresden exposition, on the contrary, has been designed to present a clear, intelligible and complete picture of the present state of hygienic science and practice, so arranged that the ordinary visitor can obtain much information in a short time and that the specialist can quickly find the objects that interest him. This involves the division of the exhibits into sharply defined groups, shown in separate buildings. In ordinary expositions little attention is given to the visitors' capacity for understanding and appreciating the exhibits. The average visitor, for example, stares at a machine which is a marvelous piece of [illegible]

impressed by its size, complexity, bright polish and swift and silent movement, and goes away without the slightest idea of its real nature and value A little elementary information would make a visit to the machinery hall far more interesting and profitable At Dresden each limited group of objects is accompanied by instruction in the theory and history of that group

The whole field of hygiene is covered in the first place, by 12 principal groups (divided into 44 smaller groups) of exhibits of purely scientific interest, each of which has its own building or sharply defined part of a building With each of these groups is associated in the same building if possible the corresponding group of industrial exhibits

Separate from all of these is the historical and ethnographic section which serves as an introduction to the whole subject of hygiene and illustrates the hygiene usages of civilized and uncivilized races of all periods and countries Another building is devoted to the popular section, which is designed to impart elementary notions of human anatomy physiology and hygiene, to show the purpose and operation of sanitary regulations and to overcome popular prejudice against disinfection, quarantine vaccination and other necessary hygienic precautions

Finally there is a section of exercise and sport containing athletic and gymnastic apparatus of every sort together with a scientific demonstration of the effects of various exercises on the body

The buildings of the exposition are constructed and assigned in accordance with this general plan Separate buildings are provided for the sections *House and Home*, *Food* *Clothing and Care of the Body* ' *Traffic*, *Nursing and Life Saving* *Army and Navy* *Hygiene of Childhood and Youth* and *Baths and Water Cures* The eastern part of the main building is assigned to the historical and ethnographic section and the western part to infectious disease and allied subjects with which no industrial exhibits are associated A special building is provided for the sub-section of chemistry and scientific instruments The section Exercise and Sport includes a large stadium a scientific collection and a laboratory in which experimental researches on the effect of exercise will be made Olympian games football tennis wrestling military drills golf fencing pool rifle shooting horse racing rowing and motor boat automobile airship and aeroplane contests are some of the sports that will be represented this summer at Dresden in connection with the International Hygiene Exposition

The buildings of the exposition designed by twenty one leading architects of Dresden are singularly dignified appropriate and harmonious in style Most of them are built of wood but in order to minimize the danger of fire they are completely covered and lined with plaster stucco and fire-proofed fabrics The architects unanimously agreed that the buildings should appear to be exactly what they are—temporary structures designed for a special purpose and should not be fantastic monumental creations or pompous imitations in wood and plaster of historical stone palaces and temples.

The buildings are for the most part of one story with side walls about 13 feet high The wider halls have a higher central wave with a clerestory for the illumination of the central part Wide aisles unobstructed vistas and abundant side light are found in all of the buildings Simplicity and repose are the keynotes of the interior architecture the idea is to present the exhibits clearly and not to distract attention from them by impertinent ornamentation Outwardly the buildings are equally simple they produce their pleasing and harmonious effect by the distribution of masses and by a sound and simple color scheme The walls are covered chiefly with a coarse grained stucco painted white which is diversified by a few colored lines and simple ornaments in relief The roofs are brightly tinted with colors harmonizing with the green foliage of the fine old trees which surround them The buildings cover about 18 of the 80 acres occupied by the exposition

In connection with the exposition courses of lectures on various branches of hygiene will be given and a number of congresses will be held under the auspices of various scientific technical industrial charitable and athletic associations

The Oldest Steam Threshing Engine

Thirty Years of Service

By H A Steven

Of all the threshing engines in use to-day in the world the oldest is located within four miles north west of Wheaton Ill For over thirty years this iron horse has done its work outliving any traction engine and is in as good condition as the day it came from the shops of the Aultman Company of Ohio When it was purchased the owner Mr A G Ransom reasoned that a perpendicular engine would not wear out as soon as the horizontal type mostly in use and the result seems to have confirmed his view While the present boiler is the second one used and a new set of flues has been put in still the engine does not look the worse for wear

The first test of this well taken-care-of engine was in the threshing on my father s farm of oats which were dry and in the best condition On the morning in question in 1880 it started its work with a steady even motion and the grain was sent through a separator propelled by this old timer until evening when it was found that the outfit had threshed out 2 750 bushels for the day s run This is the world s record for oats threshed in one working day by a 10 horse-power mechanical contrivance To be sure there were no elevators or blowers or self feeders on threshing machines at that period but even with the aid of modern accessories operators in the business to-day would be glad to average 2 750 bushels of oats with their 25 horse-power engines and 60 inch separators

There are three facts that must be admitted First The average threshing outfit has not lasted fifteen years Second The perpendicular engine will outlast any of the horizontal type Third In spite of theorists and book learned engineers the owner of this engine is the most practical engineer a statement which I can substantiate by ample proofs

He levels the separator and the engine with his eye using the horizon and not a level It takes him five minutes to set the machine and if a pulley is squeaking on the running separator he can tell which one of the former it is before it makes six revolutions This almost instinctive knowledge may account in a great measure for the long life of the engine and its extraordinary capacity for work as shown in what is probably another record viz the greatest amount of grain threshed by any one apparatus during a continuous period of thirty years

The speed maintained during all these years for the cylinder on the threshing machine has been about 1,150 revolutions per minute, which partially explains why the wear and tear is so slight. At this speed the separator will stop before it is torn to pieces on wet grain, stones pieces of iron, etc. The perpendicular pulsations or vibrations give a perfectly steady motion on the large belt. This, of course tends to prevent the wearing out of the bearings and the working loose of the nuts.

In traveling up and down hill along highways, the water in the boiler has never left the part around the firebox, a condition which invites melting of the [illegible], and in some instances the explosion of the [illegible]. When a horizontal boiler is moved forward down hill the water rushes ahead and leaves the firebox bare save for the dry steam which latter will not prevent melting This partly accounts for the long life of the two boilers used in this case

THE OLDEST STEAM THRESHING ENGINE, STILL IN CONSTANT SERVICE

Carrying out the erroneous idea of housing engines when they are not in use causes many engineers to be particular in this direction but most negligent in others This one was never put under shelter but the essential parts were always coated with grease and when the owner got through at the end of the season he always lubricated the cylinder

The modern method of feeding a thresher is most unscientific. Thoughtless youths and men eager to get through throw in six or seven bundles at a time and expect the cylinder, fanning mill and elevators to do good work This cannot be done and as much time is lost as is gained by hurrying in this manner

The last large belt from the engine to the separator is made of canvas, and has lasted twenty years, and in reference to this phase of the work Mr Ransom claims that rubber belts will last still longer when not exposed to the wet.

On warm days he uses from 1,000 to 1,200 pounds of soft coal, while in cold weather he burns from 1,200 to 1,400 pounds. The steam carried ranges from 80 to 100 pounds.

The team of horses used to guide the engine partly removes the danger of runaways along the public highways.

This engineer has a gasoline engine for use in churning pumping etc which was purchased from the Fairbanks & Morse Company twelve years ago and it is just as good as new How does he manage it? is the question He claims that the average engineer does not think or does not care about machinery that the average man running an engine is not a natural mechanic nor does he school himself to take care of everything and that the machinery will break and then the engineer will blame the manufacturer when the absent minded or negligent operator is the cause We seldom find all of the following qualities in one person that Mr Ransom possesses namely a good carpenter having built house shop and barn for himself and for others a successful well digger having sunk over 150 wells an excellent blacksmith and wagon maker a good farmer having averaged over 40 bushels of oats per acre and over 60 bushels of corn per acre for the last twenty years and withal a broad minded and well read man on many subjects His theory on the use of galvanized pipe in the ground is worth considering the automatic float which he uses is highly interesting

This engine so ably run and so carefully preserved by its original and only handler is indeed an object of interest as viewed in the illustration and the record herewith of its performances and the lessons handed down by the practical owner should appeal to all young men who may aspire to become engineers and who may wish to take care of all kinds of machinery

The Gutta-percha Tree

On account of the extreme usefulness of gutta percha in constructing submarine cables every effort is being made to save the tree that yields the valuable gum from destruction No satisfactory substitute for gutta percha found in the forests of the Malay Peninsula and in Malacca has been discovered but the natives in order to get quick returns are destroying the trees so rapidly that a gutta percha famine is feared To prevent this the French Dutch and British governments are striving not only to prevent the waste of the trees already existing but to increase their number by transplantation and cultivation Experiments with transplanted trees are being made in Reunion and Madagascar

To Produce Nitrogen (According to Tichborne) — In a retort of sufficient capacity (about 1½ liters) place 10 parts (grammes) of sulphate of ammonia 10 parts (grammes) nitrite of sodium 40 parts (grammes) of glycerine and 60 parts (cubic centimeters) of water Incline the neck of the retort rather sharply upward, so that the condensed water will drain back into the retort and heat it. The generation of gas commences at about 90 deg C (194 deg. F) and continues, at moderate heat steadily, until the nitrite is completely reduced.

An Air Propeller Testing Apparatus

Professor Prandtl's System

THE following description and the accompanying il lustrations deal with an air propeller testing appar atus described by Paul de Jeuhr in the *Zeitschrift für Flugtechnik und Motorluftschiffahrt*

Most aeroplane propeller testing plants are wrongly conceived because the conditions are not similar to those of an aeroplane in flight Hence the results ob

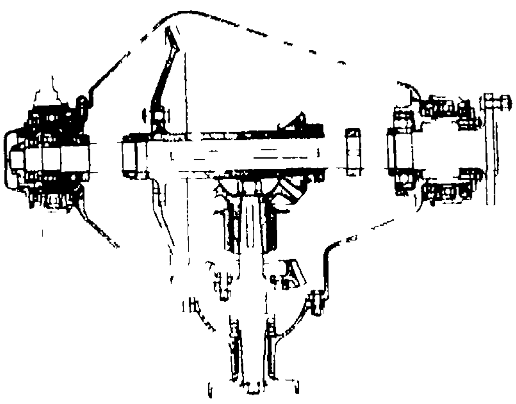


FIG 1—PROPELLER DRIVING GEAR UPPER PORTION

tained cannot be directly applied to the flying machine without due allowance for many factors of error Prof Prandtl of the University of Goettingen was in trusted with the task of devising an entirely new type of propeller testing apparatus which would be free from any of the objections to which the stationary testing plant is open This design was intended to furnish the following data

1 The altitude of the apparatus was to be suf ficiently large to measure propellors of great size and high speed

2 The propellers were to be tested under con ditions as similar as possible to those which ob tained in a flying machine

3 The apparatus was to be so constructed that it

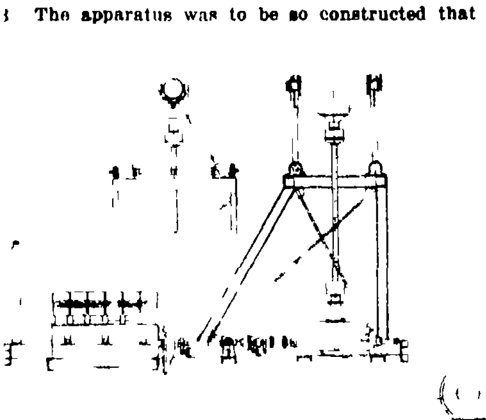

FIG 2—SIDE ELEVATION OF PROPELLER-TEST ING CAR AND VIEW OF UPPER PORTION (END ELEVATION)

could easily be transformed into a stationary testing plant if necessary

The first condition was satisfied largely by cor respondence with firms engaged in the construction of airships and flying machines From this cor respondence it followed that the largest possible pro peller to be tested would have a diameter of about 5 meters and that the propeller shaft in every direction would deliver about 60 horse-power when revolving at speeds of 200 to 1 200 revolutions per minute

At first it was thought that a small boat such as the Zeppelin company originally used for the testing of its propellers might be available It was finally de cided however that it would be better for all pur poses to have a machine which could be used on land Naturally some form of structure which traveled on rails suggested itself This in turn gave rise to the first difficulty the constantly changing direction of the wind and its influence upon the results obtained This difficulty was overcome without a single acci dent by laying the track in the general direction of the wind and by limiting tests to lateral winds which blew at an angle of not more than 20 degrees

The front end of the car should offer as little re sistance to the air as possible and especially avoid the creation of eddies To this end it is found best to employ a buoy shaped casing for the driving gear since a smooth passage of the air in the vicinity of the propeller is particularly desirable

The wide variation in the dimensions of the screws

FIG 3—DRIVER S SEAT AND INSTRUMENTS

At the right of the seat is a lever for throwing in the trans mission to the left is a lever controlling the motor a pedal controls a friction clutch In front of the driver s seat are the frequency meter tachometer and manometer On the table in the background are the contact clock special circuit breakers, and a chronograph

tested caused another factor—the smooth running of the car—to assume importance and this in its turn led to the endeavor to make the car as light as possible

To be prepared for all contingencies the rims of the wheels were made suitable for the rails either of standard gage railroads or tramways

The wire-spoked wheels of 500 millimeters diam eter with reinforced tire, are fixed on the axles, and turn with them in triple ball bearings which permit at the same time a certain play of the axles

The casing of the ball bearings is suspended in a cast steel hanger between two spiral springs and this hanger also serves as a support for the angle lever of the unusually powerful internal expanding brake

The brake worked by a hand lever from the driver s seat has two shoes inside the rim of each wheel The driver s lever transmits the power through a shaft to a rod fixed beneath the two longitudinal girders and this in turn acts on the two wheels of one side Since the wheels of each axle are firmly at tached to it, this gives a double security

The frame of the car consists of four pressed-steel girders 100 × 40 × 4 millimeters in size, strengthened by two diagonal struts.

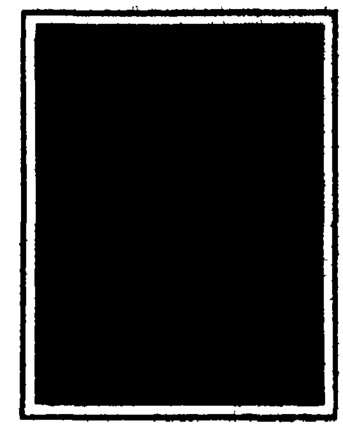

FIG 4—THE PROPELLER CASING

The octagonal sand packed walls of the propeller space are visible as well as the open straw packed doors.

On this light frame the essential part of the driving machinery is mounted This has proven advisable on account of the very considerable vibration. The parts consist of a 100 horse-power motor with normal speed of 1 800 revolutions per minute propellers from the smallest up to 5 meters diameter and cap able of making 200 to 1 200 revolutions per minute. The direction of rotation of the propellers may be

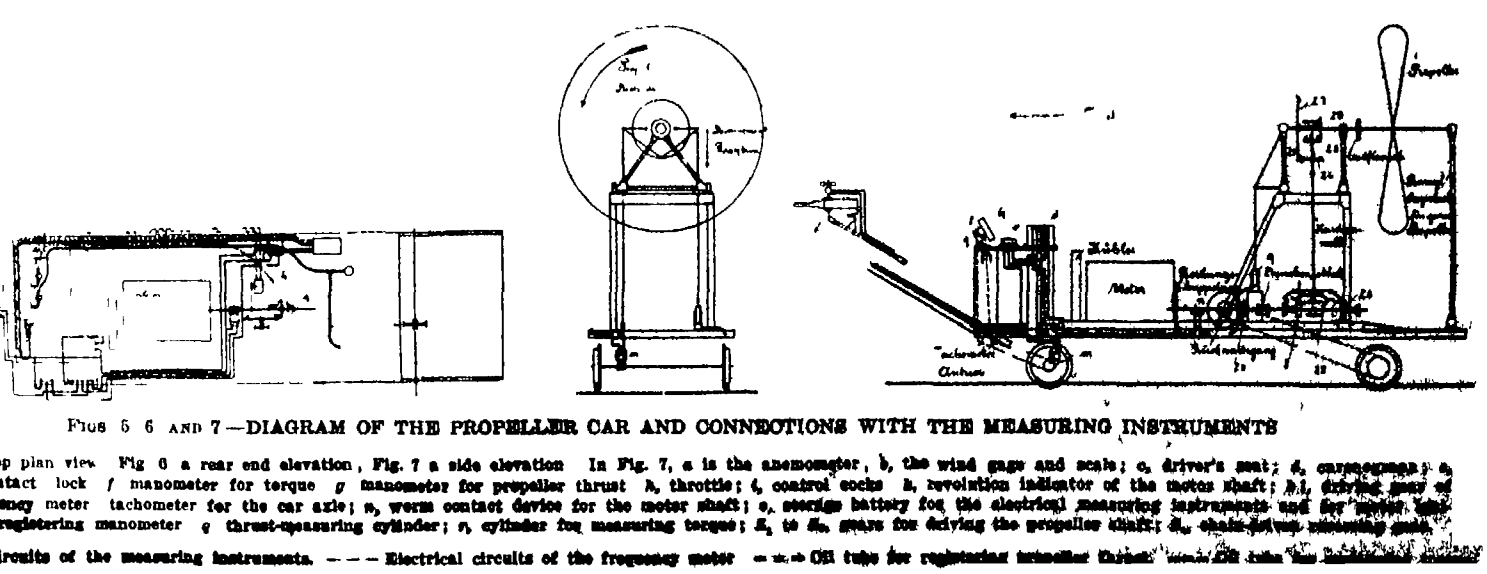
either right or left.

The original idea of a planetary reversible drive was dropped because on account of the enormous power too much noise would have been made and the wear would have been too rapid Furthermore



FIGS 5 6 AND 7—DIAGRAM OF THE PROPELLER CAR AND CONNECTIONS WITH THE MEASURING INSTRUMENTS

Even in the testing of many different propellers as is customarily the case in prize competitions, a certain grouping is possible so that a change of gear is necessary only after the testing of the group

As the greatest propeller thrust was taken as 300 kilogrammes the greatest turning moment demanded was 300 kilogramme meters on the propeller shaft if the construction was carried out on the basis of this valuation

The motor and propeller shafts located at different levels were connected through two sets of bevel gears and a vertical shaft.

The four changes of speed desired made necessary double sets of bevel gears while still another pair of bevel gears on the engine shaft made possible the rotation of the vertical and hence of the propeller shaft in either direction so that either right or left hand propellers can be tested In the upper casing a large and a small set of bevel gears were arranged while a second set mounted on the engine shaft on the opposite side of the vertical shaft served to give the reverse

The reversal above is effected by sliding bevel gears on the vertical shaft upon which they are mounted on a feather The four bevel gears on the horizontal engine shaft extension are secured to the shaft The lowermost bevel of the vertical shaft and the hub of the upper wheel (which extends into a socket) are fixed upon the shaft in their positions

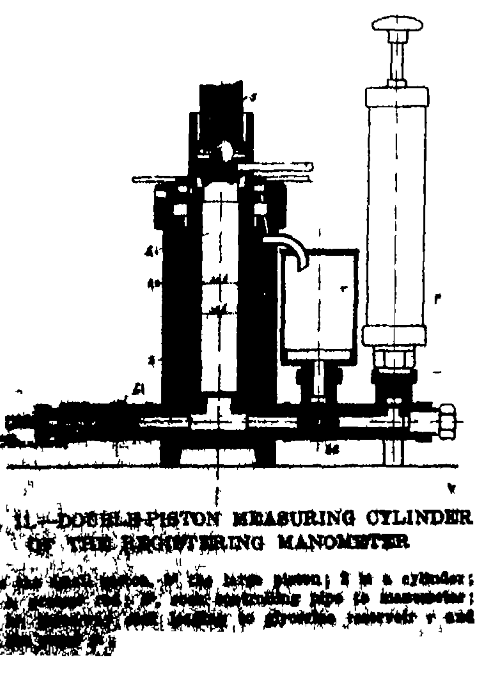

FIG. 11—DOUBLE-PISTON MEASURING CYLINDER OF THE REGISTERING MANOMETER

[illegible] the large piston; Z is a cylinder; [illegible] connecting pipe to manometer; [illegible] reservoir r and [illegible]

When now the lower gear is in action the annular toothed ring forming the upper gear is drawn up out of the way and fastened to the top of the casing, if on the other hand the exterior gear is brought into action, then this ring is fastened to its (Nabe) by a jaw clutch

In any case the horizontal shaft with its gears is displaced and united with the motor shaft by a suitable connection

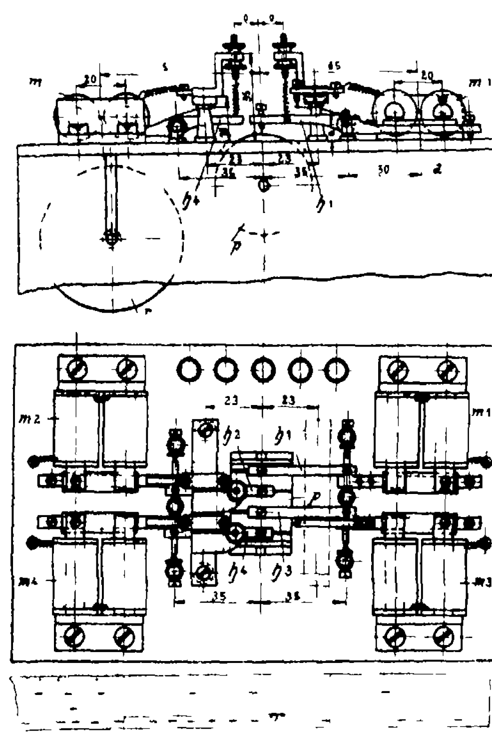
The cast aluminium casings are tightly closed so that the gears can run immersed in the lubricant The upper propeller shaft runs in ball bearings the thrust of the bevel gears being taken up by ball thrust bearings (Kugel stützlager) All other bearings are of bronze with large surfaces

The gears and their shafts are made of chrome nickel steel which accounts for the small dimensions possible in spite of the severe strain caused by the sudden shocks.

The parts just described serve another purpose i e they make possible the measurement of two things of importance namely the thrust and the turning moment necessary to drive them

This is best explained by the diagram On the trapezium formed base to which a frame is firmly fastened a parallelogram is movably carried by the propeller shaft If the screw gives an outward thrust the parallelogram has the tendency to tip toward the front in which movement it is hindered by the angle lever with the presser rod

The vertical pressure of this rod will therefore stand a definite relation to the propeller thrust The parallelogram which is of triangular cross section for the prevention of a side movement now carries on the propeller shaft the whole upper casing the verti



FIGS 12 AND 13 -CHRONOGRAPH

Side elevation and top plan view m_1 electromagnet for actuating the writing lever h of the second contact clock m with h^2 for the anemometer m^3 with h^3 for the car velocity m^4 with h^4 for the motor revolutions r paper drum p paper roll

cal shaft with its two universal joints permitting a marked oscillation of this casing

If now the propeller is driven the reaction of its torque retards its driving bevel wheel and causes the opposite wheel of the vetical shaft to roll off upon it

This motion vertical to the plane of the propeller shaft is transmitted through the bearing to the casing which would now shift outwardly if it were not held by a suitable rod

Through this simple arrangement the thrust and the torque can be estimated directly from the driving shaft without the necessity of allowing for lateral effects such as friction etc On this account also the suspension of the upper casing is so carefully carried out with many ball bearings while in general the upper shaft merely has one ball bearing

Even the bearings of the parallelogram used only when it tips, are provided with balls on account of the weight they carry The forward strut of the frame has an extension toward the front in order to distribute the propeller thrust well to the frame and thence to the under structure

The end flange of the upper shaft is furnished with a boss; every propeller to be tested must have a flange. In order to test with safety heavy or large air propellers without straining the bearings, there is provided a removable brace made of steel tubes with binding in pieces whose interiors move in two grooves in the direction of the length of the car in order to place a screw in each axle length

The essential position of the propeller shaft in this frame which can also be adjusted or displaced by different barrels of 25 to 70 diameter consists of a ball bearing which by means of two lateral pins can swing in turn in ball bearings

A movement forward relatively to the car occasioned by the thrust of the screw will therefore

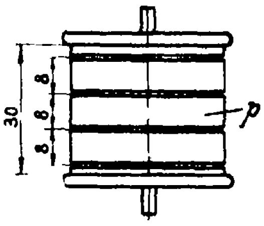


FIG 14—THE PAPER ROLL P

not be hindered except by the presser rod provided for that purpose

A rearward tipping of the parallelogram is avoided by a stop with an adjustable screw while a movement out of the upper casing toward the side opposite to the presser rod is prevented by the construction of a steel tube provided with a rubber buffer

The motor is provided with an ordinary leather friction clutch Moreover a claw clutch is built into the shaft in order to permit safe testing of the propeller with a running motor

Because the tests are made on straight tracks, and because the screws drive the car in only one direc-

FIG 16

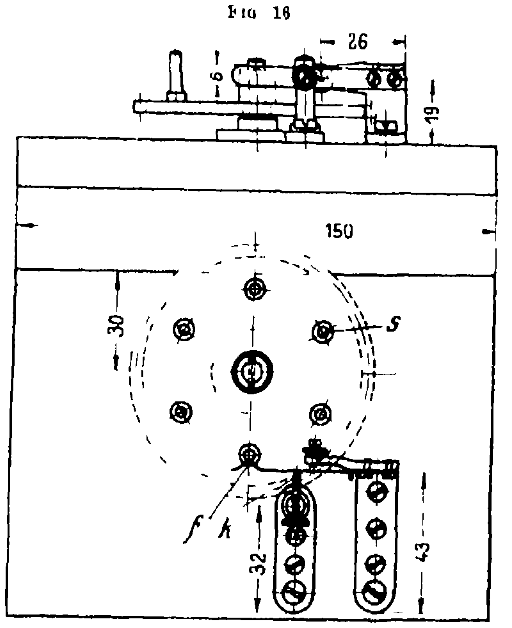

FIG 15

FIGS 15 AND 16—ELECTRICAL CONTACT APPARATUS FOR REGISTERING THE CAR SPEED AND THE MOTOR SPEED

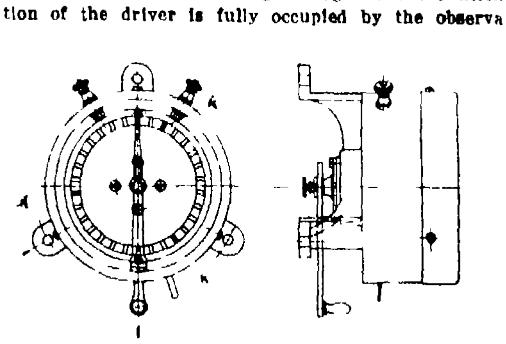
tion a special method of driving the motor must be provided for the return journey For this purpose a small bevel gear is placed on the intermediate shaft displaceably which by means of a larger and a smaller chain gear drives the rear axle directly after the whole propeller gear is thrown out by means of the chain clutch

Passing to the consideration of the measuring instruments it is obvious that the chief desideratum is that they should be self registering since the attention of the driver is fully occupied by the observa



FIGS 17 AND 18—SECOND-CONTACT CLOCK

Side elevation and top plan view k are the contacts for indicating the time at the recording manometer (Fig 7 a).

tion of the course and the attainment and maintenance of a certain uniformity of operation Therefore electric indicators are preferred except for the thrust and the revolutions

As we have seen the propeller thrust and the revolutions of the same are indicated by the pressure on a vertical rod For the automatic recording an hydraulic transmission was chosen and this connected with a double registering manometer

Under each recording lever is firmly fixed a measuring cylinder of chrome nickel steel in which are fitted two smoothly polished pistons These two pistons serve to give different ranges for small and large propellers The manometer registers up to 25 kilogrammes per square centimeter the small piston of 3 centimeters diameter suffices therefore for a rod pressure up to 170 kilogrammes while the larger of 6 centimeters diameter can absorb as high as 600 kilogrammes

When the small piston moves through the pumping in of a fluid (glycerine) the large piston must be forced up till it rests against the cover Consequently the small piston must vary from the large one by 1 to 2 centimeters

On the other hand if oil glycerine is allowed to flow out of the pump till the small piston rests upon the large then the whole cross section is thrown into operation

The connection with the presser rod is effected by a polished ball which lies between two ball pockets which are on the other hand loosely centered by a cover

Because of the different directions of revolution of the screw the measuring cylinder for the torque must be reversible tubing lies on either side (see diagram)

The pressure transmission leads the cylinders to two ordinary stop cocks whose purpose is to check chance shocks in the tube transmission and keep them from affecting the manometers

For this purpose the slits of the cock are soldered up the valve itself however can be pressed against the cone or withdrawn depending on the amount of the throttling

From this point the piping leads to two flat spring manometers with indicators which are gaged or standardized up to the double pressure of the registering manometer 30 kilogrammes per square centimeter

The control cocks lying behind these manometers are not opened until the indicator manometers show that the permissible pressure is not exceeded as for instance might happen by accidentally moving the small piston which might injure the delicate registering manometers

These instruments are placed behind the car since this is the place of least vibration a position not completely satisfactory because here the recording is difficult

The clockwork of the recording drum causes it to revolve once in 2 minutes if we reckon 10 seconds for the duration of the trip then there are a sufficient number of conditions united on one strip if it is put on and taken off at the right time

The second apparatus is the chronograph Clock work moves a strip of paper over a drum at a rate of about 13 meter-seconds beneath four writing levers operated by electromagnets Needles serve as stylo cutting a hole in the paper when the current is closed when the current is closed for a longer time a series of holes is made since the levers are provided with current interrupters as in the case of electric bells Thus tearing of the paper is avoided The indentations of the needles can be easily read on the reverse side of the paper

This chronograph is operated in the following manner On the intermediate shaft behind the motor a small worm is mounted meshing with a small worm wheel In this worm wheel two diametrically opposed pencils are carried which by means of a small spring close the current at every passing The worm has but one entrance the wheel has thirty teeth therefore with two pencils there is a contact after every fifteen revolutions of the motor this contact being indicated by the pencil as a point on the paper strip In a similar manner the revolutions of the front axle are recorded from which the speed of the car is found but here up to six pencils may have to be screwed in according to the expected speed so that a sufficient number of effective contacts may be obtained

Thirdly the relative speed of the propeller to the wind to be obtained For this purpose the car is lengthened at the front end by a mast five meters long to whose point is attached a wind vane with a Robinson's anemometer above it

The wind vane moves on two ball bearings and serves the purpose of reading during the journey from the scale the deviation caused by the side wind

The anemometer whose buckets lie at a distance of almost 16 inches from the screw on the lengthened propeller axle so that the suction may exert no influence on it (as experience has shown) is so arranged that it gives a contact after every twenty meters of its passage through the air making a dot on the paper (Fig 14)

Finally comes the important comparative instrument whose records determine the measure of time, the *second-contact-clock* (Figs 17 and 18) The revolving pointer makes and breaks the contacts as these are rather long a short row of dots is made instead of one dot

But the importance of the clock depends on another device (see diagram) Every tenth contact is separated from the others and leads the current in stead of to the chronograph, to an indicator of the registering manometer therefore there is a gap on the chronograph whenever a record is made on the manometer Consequently in synchronously arranged instruments the speed belonging to a given thrust and moment of revolution is unfailingly indicated when the diagram is superposed that the second marks of the manometer bulletin fill out the gap of the chronograph diagram

The meaning of the diagrams can be seen in Figs 9 and 14 which do not however belong together but merely serve as examples

First the strips of the chronograph In the upper row we see the regular time contacts of the clock after every nine dashes a gap for the tenth second Underneath the records of the anemometer the cam axle and the motor shaft For reckoning a vertical

FIG 19—END VIEW OF THE PROPELLER TESTING CAR

line is drawn every 10 seconds and merely the points lying between are counted (In case of irregularities a correspondingly greater time interval must be chosen) Then we find in our example a speed of the propeller against the air of 3 33 points in 10 seconds i e 0 333 in 1 second therefore 20 0 333 = 6 66 meter-seconds To this is added the anemometer correction which for this reading equals 1 004, so that the virtual speed reckoned at 6 69 meter seconds the speed of the car is reckoned according to the following formula The contact given on the car axle had three pencils with thirty teeth and a worm with one entrance therefore each contact signifies ten revolutions of the wheel which on the other hand with a 500 diameter = 15 28 meters 6 25 points in 10 seconds 0 625 in 1 second corresponding then to a car speed of 9 55 meter-seconds According to the foregoing the diagram gives finally 11 15 6 = 990 revolutions per minute for the motor from which can be estimated the revolutions of the propeller

Next the manometer bulletin The points *A* will therefore correspond constantly to a gap in the time marks on the chronograph and it is necessary to mark exactly on both only the beginning of the experiment The upper thrust curve is described when the large piston is working therefore every kilogramme-centimeter[2] of pressure corresponds to the cross section $\frac{6^2\pi}{4}$ = 28 3 kilogrammes in the designated case therefore = 9 1 28 3 = 257 kilogrammes.

But now by means of the angle lever, the thrusting of the propeller is transmitted to the rod in the relation 2 1, therefore a virtual thrust is found of $\frac{257}{2}$ = 128.5 kilogrammes. The moment of revolution transmits itself to the presser rod by a lever arm of [illegible] meter therefore corresponds to the pressure of (for example) 5 7 kilogramme-centimeters, in a cross section of the small piston of $\frac{3^2\pi}{4}$ = 7 07 centimeters,

5 7 7 07 0 05 = 20 15 meter-kilogrammes.

There are also two instruments of importance for the guiding of the car—a tachometer for its speed, and a frequency meter for the number of revolutions of the motor The first, a simple speed pendulum with a revolving indicator, is driven through belts by the forward axle and gives the speed of the car in second meters.

The frequency meter depends on the resonance principle the exciter being driven through belts by the motor shaft, and connected with the revolution indicator

These two devices and the indicating manometer are placed directly in front of the driver the other instruments also are fastened to the table in front (see diagram)

Further here are found at the left of the driver's seat the levers regulating the sparking and mixing for the motor, a foot lever operates the friction clutch a large lever forward is for use in handling the brake another to the right is used for the governing of the claw clutch, and finally somewhat to the rear lies the lever for reversing

The motor is turned forward by which the inertia of the car is quickly overcome Close by the motor is the seat for the observer who always goes along on the trip

The trial trips are conducted in the following manner After the clutch of the gear intended for the propeller is thrown in the meter transmissions and testing instruments are started the car is firmly braked the motor set going the gear with the claw clutch thrown in and the friction clutch on the motor slowly put in by means of the foot lever After the propeller (with the car not moving) has been brought to the right number of revolutions by the sparking and manipulating levers the brake is removed and the car comes very quickly to the required speed As soon as a certain uniformity is observed in the number of revolutions as well as in the indicating manometer by means of drawing cords, the measuring instruments are put in operation simultaneously Then the circuit is closed by a small governor in front of the driver's seat, while the driver tries to hold the speed constant by the regulation of the motor or use of the brake As soon as a record is made it is best seen by the striking of the time indicator on the registering manometer The instruments are then stopped and if the distance seems long enough another speed is taken and a second observation is made

PRELIMINARY RESULTS OF EXPERIMENTS WITH THE APPARATUS FOR TESTING AERIAL PROPELLERS

The tests of aerial propellers made with the apparatus constructed for the first international aeronautic exhibition are now completed The results will shortly be published in detail A brief summary of the results and the entries is given below

The long postponement of the final tests was caused through delay in the construction of the apparatus by an accident which necessitated extensive repairs and finally by the long practice which was required in order to secure perfectly harmonious action of the numerous instruments and the assistants in their operation

In January 1910 in a large hall in Frankfort, tests were made of the propellers which had been entered in competition for the prizes offered by the Prussian war department for propellers of German manufacture only

This competition was subject to the following conditions

1 Only propellers of uniform pitch were admitted

2 The tests were made at a fixed point the quantities measured being the tractive effort, the consumption of power and the number of revolutions per minute

3 The propellers were divided into two groups The first group included airship propellers not exceeding 5 meters (16.4 feet) in diameter, which were required to develop a tractive effort of 300 kilogrammes (661 pounds) at a fixed point The second group included propellers not exceeding 3 meters (9.8 feet) in diameter which were required to develop a tractive effort of 150 kilogrammes (330,7 pounds)

4. All propellers were excluded in which the product of the pitch multiplied by the number of revolutions per second required to develop the prescribed tractive effort, was less than 15 meters (49.2 feet) because the tractive effort of such propellers would vanish at a speed of 15 meters per second and the propellers would be unable to produce any useful tractive effort at the speeds required in practice.

5. A prize of 3,000 marks ($714) subject to deduction was offered in each group

6. Each propeller must be accompanied by a statement of its pitch and the maximum number of revolutions for which it was designed

7. The prizes were awarded for the smallest values of the product $N^3 r G$ in which N^3 denotes the number of horse-power consumed r the greatest radius and G the total weight of the propeller

The propellers originally entered for this competition numbered forty-eight, and eight others were subsequently sent as substitutes for propellers which had been broken making the total number fifty six. Two propellers of foreign make were excluded by the conditions of this national competition three were rejected because their weight or construction made it impossible to test them with the apparatus provided many failed to pass the test of strength applied by the centrifugal machine or broke during the final test before sufficient data had been obtained and finally the requirement of uniform pitch restricted the competition to nine propellers two of group I and seven of group II Details concerning the five propellers which made the best records are given in the following table, in which weights are expressed in kilograms and lengths in meters

Group	Required Tractive Effort	Radius r	Horse-power N	Weight G	Product $N^3 r G$	Prize	Name of Exhibitor
II	150	1 05	80 3	6 55	10 020	First	Reissner
II	150	1 18	88 5	12 5	20 900	Second	Gross

I	800	2 50	56 0	84 0	533 000	First	Ruthenberg
I	800	2 50	54 6	99 9	1 475 000	Second	Rettig

Translator's Note The third fourth and fifth members in the column marked Product appear to be about twice as large as they should be in order to correspond with the numbers in the preceding columns

FIG 20—GENERAL VIEW OF THE PROPELLER TESTING CAR

In the competition organized by the International Aeronautic Exhibition three qualities were recognized and two prizes were offered for excellence in each. These qualities were

1 Efficiency $\eta = \frac{P\,v}{M\,\omega}$

2 Economy of space $\zeta = \eta \left(\frac{1}{2} + \sqrt{\frac{1}{4} + \frac{\varphi}{2}}\right)$

where: $\varphi = \frac{P\,g}{\gamma\,\pi\,r^2\,v^2}$

3. Suitability for work at high speeds

$$\vartheta = \frac{P^3}{M^2\,\omega}\sqrt{\frac{r\,g}{\gamma}}$$

In these formulæ P denotes the thrust of the propeller, M the applied torque, r the radius of the propeller, v the velocity of the center of the propeller relatively to the velocity of the air current ω the angular velocity of the propeller γ the weight of a unit volume of air, and g the acceleration due to gravity. The values of η, ζ and ϑ calculated from the experiments were plotted as ordinates to the values of $\lambda = \frac{v}{r\omega}$ as abscissas, and curves were drawn through the points thus established. The prizes were given for the maximum ordinates of the curve or in case these maxima were not attained in the experiments for the highest measured points. The formulæ experimental results and curves will be discussed in a future article.

Of the 56 propellers four were rejected because they could not be tested with the apparatus three were withdrawn before the commencement of the experiments and seven were broken in testing The prize winners and the several groups are given in the following table

Exhibitor	Number of Blades	Radius r	Thrust P	Torque M	v	ω	η	ζ	ϑ	Prize

Rainfall and Parasites

THAT parasite diseases of stock are mainly due to wet and marshy pasture lands is very well brought out by M G Moussu a member of the French Agricultural Society He also shows how to remedy matters in such cases For the last few years the amount of rainfall has greatly exceeded the normal and if the year 1910 is to be counted as an exception in this regard the preceding years 1908 and 1909 had their share in preparing the economic disasters which we have felt recently The persistent dampness favors the development and spreading of spore maladies which affect vegetables and in stock raising the effect is none the less harmful The continual rains the freshets and inundations have greatly modified the aspect and the flora of meadow lands and transform the best pasturages into marshes Here the animal parasites find a very good ground for developing outside the organism and it is remarked that we find the great animal epidemics such as zootics of parasite origin to follow periods of inundation The year 1910 is one of the worst in this respect and sheep have especially suffered so that numerous flocks are disappearing for this reason In the two preceding years other parasite maladies prevailed such as affected the stomach and intestines but this year it is the parasite disease of the liver which causes the harm known as distomatose The embryos of the parasites are absorbed by the sheep as they go among marshy pastures or along overflowing streams and this is clear when we see that the malady only affects sheep which feed outside upon pasture land for most of the year Wherever the soil is dry on plateaus or arid summits the malady is not observed nor on the other hand when the animals are kept in the fold But in especially damp years such as 1910 we find it appearing in places where it is usually absent and the author explains this by the fact that the dampness favors an unusual development and spreading of parasite embryos. These the animals take into their system along with the food plants and they pass into the stomach and liver where they fix themselves and remain after the manner of parasites

In France it is the sheep which are most affected, but we find similar maladies among young animals of the bovine race in other countries, and there are regions where even wild animals such as hares or else rabbits and goats die from this cause This year the parasitic infection has been so strongly marked that the progress of the malady upon the animals is much more rapid than usual so that they succumb within a short time instead of becoming anemic and pining away Owing to the fact that such epidemics are seen only at comparatively rare intervals there has not been paid the proper attention to finding a remedy for this state of affairs But we already have the observations as to the manner in which the parasites act so that it is not hard to draw some practical conclusions Since it is the dampness which is at fault the first measure is to drain the pasturages or take other measures so as to keep them as dry as possible Such expense would soon be made up by suppressing the loss of animals The second point is to improve the quality of the pasturage by processes such as sulphating and the use of chemical fertilizer during the spring for the result appears not only in the modification of the flora but also in the disappearing of a great proportion of parasites which are likely to cause maladies But even this will not be effective in such unusual cases of dampness as we find in 1910 and here we must take special precautions

In the regions which under ordinary circumstances are only slightly affected by the distomatose malady but where the conditions change much for the worse by great dampness the author recommends that the flocks should not be taken upon the pasture lands which were inundated nor even upon lands which remain permanently in a wet state Although this may be contrary to custom it seems to be the only way to mend matters and preserve the flocks so that there should be no hesitation about adopting this measure With proper care and foresight the flocks can always be fed when in the stables even with a low grade of fodder which is well prepared It is to be noted that even fodder taken from the wet lands can be very well used provided it is well dried beforehand as in this case it is no longer dangerous

Crude Oil Fuel in the French Navy

THE French navy department is taking measures toward using petroleum residues more extensively in the future for heating marine boilers owing to the advantages which are now so well recognized as coming from the oil fuel This is one of the indications which show that the question of substituting oil for coal is occupying the attention of different countries Oil is likely to be largely used in the future either for burning under boilers or for operating the new Diesel and other crude oil engines which are now being made in units of increasing size As regards the use of oil residues in the French navy the Minister of the Marine *Admiral Boué de Lapeyrère* is quite in favor of it and is now engaged in promoting a number of plans which will lead to a more extensive use of this fuel It is now recognized that it will be of great use in the navy owing to the greater speed and ease in taking fuel on board the vessels and the greater radius of action which a boat will have owing to the greater amount of fuel represented as heat giving power which can be taken in the available given space

All the new torpedo destroyers of the navy are installed for firing the boilers with mazout or petroleum residues of European origin Up to the present the French seaports were not well equipped for handling and storing the oil so that the cost per ton was very high and much more than in other leading countries The admiral is now taking measures to organize more modern methods for handling the oil in the leading French ports so that this country will be one of the foremost in this field At the military ports such as Toulon Brest and Cherbourg are now being installed great oil reservoirs in which the petroleum residues will henceforth be stored up and besides this a very complete system is being organized as the navy has purchased a steamer to be used specially for oil transport It will ship on oil at the Roumanian port of Constanza in the Mediterranean region which is one of the leading shipping centers for this product and will then bring the mazout to the French ports and fill up the reservoirs directly without the extra handling which heretofore brought up the cost to $31 per (long) ton while it will be now reduced to $13 per ton The new steamer has been named the Rhone and it gages 7 000 tons It is also of interest to note that the 26 000-ton battleships Courbet and Jean Bart of the French fleet as well as the new units which are to be constructed will be fitted with the necessary appliances so that they can burn crude oil or residues at the same time as coal making thus a combination system.

The Cocoanut Palm

Its Products and Their Uses

By Randolph I Geare

SPEAKING on excellent authority it may be said that the almost universal demand at the present time for the cocoanut palm (*Cocos nucifera*) on account of the many and varied uses of its products is un precedented An American consul writes that the world is being sought for additional supplies of co-coanuts

One of the most valuable parts of the cocoanut is the dried kernel called copra and in Germany the very recent discovery of practical methods of converting the crude copra oil into a palatable but ter has given a wonderful impetus to the business in that country Oil of the first pressing is used which is bleached with boneblack or fuller s earth The raw material contains sixty to seventy per cent of fat It is white or very light yellow and has a sweet odor This odor has to be eliminated and it is done by expressing the oil with steam The im ports of copra into Germany last year principally from the Dutch Indies British India Ceylon Mal acca Samoa and the Philippines amounted to more than 112 000 metric tons Over 9 000 tons of the but ter were imported of which about 3 000 tons were afterward exported the remainder being consumed locally

Cocoanuts are imported into England chiefly in the form of copra for the extraction of the oil The only by product resulting from crushing is used for cattle feeding and is worth from $34 to $39 a ton The best quality of copra comes from Malabar and is worth about $136 a ton

In Barcelona Spain many thousands of tons o copra are imported yearly at an average of $117 ton The oil there is used wholly in making soap

In the Philippine Islands the prospect for the co coanut industry is brighter than ever before Last year 1 658 724 piculs (a picul = 133 1/3 pounds) of copra were produced making these islands the largest producer of this staple in the world and ex celling in product Java the Straits Settlements Cey lon and the South Sea Islands The price of co coanuts in the Philippine Islands has risen greatly in recent years The reasons for this are the extensive use of its products for commercial purposes for mak ing edible fats such as palmine and the rise in price of articles now being supplanted by copra prod ucts There is also a growing demand for cocoanut oil for which millions of cocoanuts are used every day The Consul at Hongkong writes The possi

FRUIT CLUSTERS OF MATURE COCOANUT PALM COSTA RICA

bilities of the use of this nut fat should receive more attention from American manufacturers

In India the exports of cocoanuts during 1909 and 1910 as reported from the Madras Presidency amounted to more than 200 000 Of copra over 900 000 hundredweight valued at more than $4 000 000 were exported while the exportation of cocoanut oil amounted to nearly 6 500 000 gallons worth about $2,500 000

The Consul at Carlsbad, Austria recently reported that owing to the fact that the oil from cocoanuts is now being converted into comestible fats its mar-ket price has increased enormously and the world is being sought for additional supplies of cocoanuts

COCOANUT PALM AT CAJABON ALTA VER APAZ GUATEMALA

COCOANUT PALM NEAR PALMIRA CAUCA VALLEY COLUMBIA

The butter is prepared in two forms soft and in firm cakes It is said to be excellent for cooking pur poses It retails at about fourteen cents a pound

The soil and climate of Trinidad and Tobago are very favorable to cocoanut growing especially along the coasts and in interior districts which come within the influence of the salty atmosphere At present the export price of the nuts averages about $16 per thousand of copra four to five cents a pound and of the oil ninety cents a gallon The largest producer grows 5 000 000 nuts a year The shells are used as fertilizer and for road making

In Brazil there are wild cocoanut groves over 200 miles long and millions of the nuts are shipped an nually from there to the United States and Europe Cocoanut palms are largely used in Brazil to adorn the public parks and gardens They often grow 80 to 90 feet high The leaves are from 15 to 20 feet long and at their base the nuts hang in clusters of three to fifteen each

The foregoing instances are cited as a few out of the many reports which have been made recently to demonstrate the enormous proportions which this in dustry is reaching

Concerning the origin of the cocoanut palm many opinions have been expressed Prof O F Cook in an excellent paper on the History of the Cocoanut Palm in America, published in Contributions from the National Herbarium affirms that it was already widely distributed in the new world before the ar-rival of the Europeans and he believes that biologi cal evidence of the American origin of the palm is complete and adequate while De Candolle and other writers believe that the cocoanut palm was intro-duced into South America and the West Indies by European settlers and that it existed in pre-Spanish America only on the Pacific coast of the Panama re-gion This writer also affirms that it had its origin in the old world whence it was disseminated by sea. One thing is sure however that wherever it origin ally came from it is now met with in all tropical regions

Prof Cook believes that hardy varieties of the palm might be successfully cultivated in southern California and Arizona, and perhaps in some parts of Texas where flowing artesian wells of warm water may make it possible to protect small areas from frost—an important essential indeed A cocoanut in-dustry has already been established in southern Florida and one planter is reported to have recently sold his crop for $15 000

The cocoanut palm has pinnate leaves, and male and female flowers on the same tree, the female flowers at the base of each spadix It grows to a height of 60 to 100 feet, and on the cylindrical stem appear rings marking the place of former leaves. At its summit is a crown of from 16 to 20 leaves. Of the three round, black scars at one end of the shell, the largest one through which an opening is com-monly made to get out the milk, is the destined out-let of the germinating embryo, which is situated there, the kernel consisting generally of the endo-sperm destined for its nourishment.

The oil of the cocoanut is obtained by pressure of the bruised kernel, or by boiling over a slow fire, and skimming off the oil as it floats to the surface. A quart may be obtained from seven or eight cocoa-nuts It is liquid at the ordinary temperature of tropical countries, but in colder climates becomes a white, solid butter-like oil It becomes liquid about 74 deg F It can be separated by compression into a liquid portion called olein" and a more solid art termed stearin" or cocoin" which is of complex constitution The cake resulting from the pressure of the endosperm for its oil is an important cattle food

The root of the cocoanut palm possesses narcotic properties and is sometimes chewed instead of the areca nut When the stem is young its central part is sweet and edible but when old it is a mass of hard fiber The terminal bud (palm cabbage) is esteemed a delicacy and trees are often cut down for the sake of it The saccharine sap of the flower spathes before they open is a source of 'toddy and palm wine and also by distillation of the liquor arrack In the East Indies the juice is often boiled down to yield sugar (jaggery)

The dried leaves of the cocoanut palm are much used for thatch and for many other purposes as the making of mats screens baskets, etc., by plaiting the leaflets

The midribs of the leaves supply the natives of the tropical coasts with oars The wood of the lower stem is very hard takes a beautiful polish and is employed for a great variety of purposes under the name of porcupine wood" The fibrous center of old stems is made into cordage By far the most important fibrous product of the cocoanut tree is that obtained from the husk of the somewhat im mature nut If the nuts are allowed to ripen the coir which is a fiber beaten out from the external

COCOANUT PALM AT BELIZE, BRITISH HON DURAS SHOWING THE WIDER FORM OF THE LEAVES UNDER SEA LEVEL CONDITIONS

husk, is coarse and brittle. The husk of the ripe nut is used for fuel and also, when cut across, for polish-ing furniture, scrubbing floors, etc The shell of the cocoanut is made into cups, goblets, ladles, etc., and is often finely polished and elaborately ornamented by carving.

From the particulars given above it will be seen that every part of the cocoanut palm has a special value.

Last year there were in all parts of the world nearly 3,150,000 acres cultivated for the cocoanut palm. The number of palms was about 280,000,000, which bore not less than 7 000 000 000 of nuts, the majority of which were consumed for food purposes where they were produced

Central and South America with the West Indies had 880,000 acres the export trade therefrom in all products of the cocoanut palm exceeding $3 000 000 in value Jamaica exports about 12,000 000 nuts a year, Trinidad, 9 000 000 while from the San Blas coast of Panama alone 6 000 000 nuts are shipped annually to the United States These sell for $33 to $45 per 1,000 in the New York market and are considered to be of the finest quality produced anywhere in the world.

Both coasts of Panama are already profiting by their proximity to the Panama Canal according to Dr Charles Melville Brown who has recently made a special tour of inspection through Panama and new plantations on a much larger scale are already being set out in anticipation of the opening of the canal Favored by abundant rainfall equable climate sea breezes from both oceans with an artery of transportation to feed all parts of the world passing directly through it, and with its already established reputation for the quality of the cocoanut which that region produces Panama presents in Mr Brown s opinion a fertile field for the development of the cocoanut industry within the next few years Its west coast he remarks does not suffer from the hurricanes that sweep over the West Indies its markets are up and down both coasts and it is favored

COCOANUT PALMS AT SALAMA GUATEMALA AT AN ALTITUDE OF NEARLY 3 000 FEET

with abundant water transportation which is an important factor in cocoanut cultivation

These facts might well be carefully digested by the vast army of young men seeking profitable employment.

In starting a cocoanut plantation the first step necessary after acquiring a suitable tract of land is the selection of proper seed nuts from which the young palms are to be grown After they are six months old, clearing and transplanting takes place though some planters prefer to transplant them to a second seed bed setting them out about three feet apart and leaving them in this second bed for 12 to 18 months longer Ultimately the palms are set out at a distance of from 18 to 30 feet apart Under very favorable conditions they begin to bear fruit between the fifth and sixth years after planting and often continues to bear for 70 to 80 years The production should gradualy increase to 250 nuts a year

In the West Indies and Central America the cocoanut palm is liable to attacks of fungi as well as to a disease caused by bacteria and known as bud rot.' This disease is generally caused by the deposition of some insect's eggs in a wound in the tender stalks of the undeveloped leaves Dr Edwin Smith, of the United States Department of Agriculture, has published an exhaustive report of the subject.

The first remedial act is to destroy all diseased palms, whether they are only just beginning to be attacked or are in a dying conditions The roots should be dug out, and, with the stem leaves, burned up Lime, preferably quicklime, should be well dug into the affected spot, and the ground frequently dug over, so as to break up and aerate the soil. If necessary, the soil should be drained, the weeds on the ground should be destroyed and heavy manuring resorted to No palms should be planted in the infected spot for a year after the removal of the diseased trees.

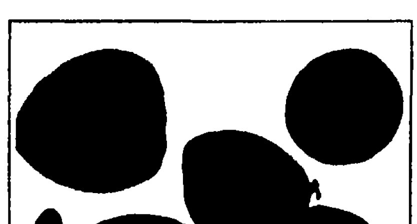
Horned beetles devour the leaves of the cocoanut palm in Samoa and other localities and the best safeguard against the ravages of insects is to plant the trees directly along the seashore within the influ

INFLORESCENCE OF THE COCOANUT PALM WITH STAMINATE AND PISTILLATE FLOWERS

ence of the salt spray The cocoanut palm is attracted by sunshine and will bend in any direction to reach it

Rats too and porcupines attack the nuts and stems of this palm respectively while wild pigs eat the tips of the young leaves

The illustrations accompanying this article have been kindly lent to me for this occasion by the Bureau of Plant Industry United States Department of Agriculture They include not only cocoanut palms but also their relative the peach palm (*Guilielma speciosa*) of Costo Rica with its fruit and seed The peach palm bears a fruit almost as large as an apricot and of a reddish yellow color It forms an important article of diet among the natives of a vast region along the eastern slopes of the Andes from Brazil and Peru through Ecuador



PEACH PALM FRUIT AND SEED

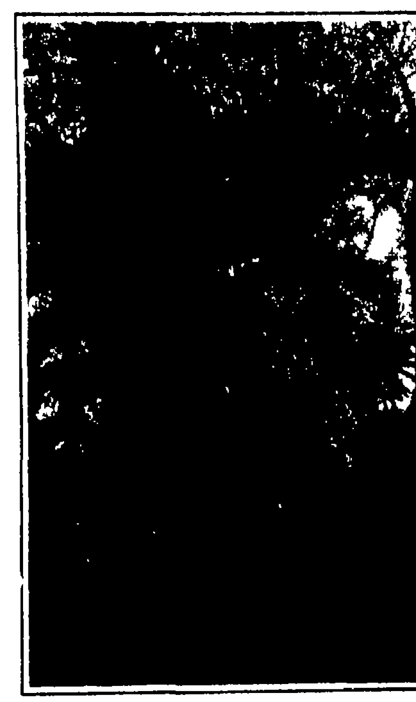
Venezuela and Colombia and beyond the Isthmus of Panama in Costa Rica

Heat from the Earth

CERTAIN scientific men now believe that the enormous internal heat of the earth may be utilized for some practical purpose Among the most distinguished scientists that hold this view may be mentioned Prof Hallock of Columbia University who is of the opinion that the plan is distinctly feasible

It is not merely a question of getting steam It is a question of the quantity of steam that can be had Near Boise Idaho hot water is now drawn from a well and used to heat a dwelling The Pittsburg and Wheeling wells are capable of heating the water left in them over night but even if their depth were sufficient to turn the water to steam it would require so many hours waiting as to rob the process of all commercial value In other words there would not be the slightest difficulty in obtaining steam from the interior of the earth because that involves only a little extra labor in boring into the hot area and it is almost as easy to bore ten thousand feet as six thousand but in order to give the steam commercial value a method must be provided for dropping the water to the hot area allowing it to heat and yet having it returned to the surface as steam without interrupting the flow

Two holes might be bored into the earth twelve thousand feet deep and perhaps fifty feet apart There would be a temperature far above the boiling point of water Then if very heavy charges of dynamite or other explosive were lowered to the bottom of each hole and exploded simultaneously a sufficient connection might be established between the two holes The rock would be cracked and fissured in all directions and shattering it thus around the base of the holes would turn the surrounding area into an immense water heater The water poured into one hole would be heated and turned into steam which would pass through the second hole to the earth s surface The pressure of such a column of steam would be enormous for aside from its initial vel



THE PEACH PALM (GUILIELMA SPECIOSA) IN COSTA RICA A RELATIVE OF THE COCOANUT

ocity the descending column of cold water would exert a pressure of at least five thousand pounds to the square inch which would drive everything movable through the second hole The problem is therefore a mechanical one concerned chiefly with connecting the two holes This accomplished the water heater would operate itself and establish a source of power that would surpass anything now in use

Disappearance of Lakes

WHETHER the globe on which we dwell is gradually drying up or not is a question that has been much debated Recent discoveries in Central Asia have been regarded by some as favoring an affirmative answer but others have replied that the observed phenomena are simply periodic changes Dr Walse of Zurich champions the affirmative view on the ground that a great number of European lakes have certainly disappeared within the last two hundred and fifty years The canton of Zurich for example had one hundred and forty nine lakes a quarter of a century ago and only seventy six to day He believes that a similar tendency to disappearance has affected the lakes of Germany and Russia

Wood stain for Canes—(a) Prepare solutions of logwood decoction 1 part of logwood in 1 part of water a solution of 0 1° part of caustic potash in 1 part of water The object is first immersed in the hot logwood decoction dried and then painted with the dilute caustic potash solution Finally place in chromate of potash (hot) (b) 250 parts of bleached shellac 400 parts of benzole and 80 parts of Venice turpentine (prime quality) dissolved in 2 000 parts of rectified alcohol and the precipitate filtered out.

Radiant Energy and Matter—III*

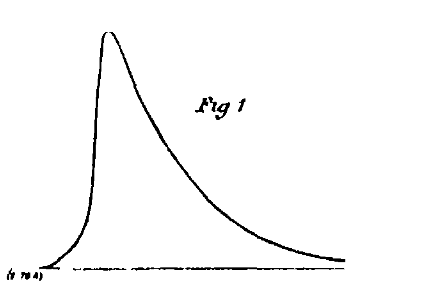
Sir J J Thomson's Royal Institution Lectures

Continued from Supplement No. 1850, page 371

In opening his third lecture at the Royal Institution Sir J J Thomson F R S said that on the last occasion he had explained that the radiometer effect constituted a very great difficulty in demonstrating the existence of a pressure due to light When light fell on a delicate vane the vane was warmed and when its temperature thus became different from that of the walls enclosing it effects were obtained due to the communication of heat from the warmed vane to molecules of the gas inside the bulb These in their turn gave up this heat to the walls of the enclosure and flying back were reheated again at the vanes and the result was that a torque was established between the system of vanes and the bulb containing them On the last occasion he had described how Prof Poynting had eliminated this effect by fixing the vanes rigidly to their mica enclosure the whole system being suspended from a quartz fibre and deflected as a whole by the light pressure falling on one of the vanes Sir James Dewar had arranged for him an experiment in which this radiometer effect was got rid of in another way Evidently since this effect arose from the presence of gas in the vessel if this gas were entirely removed the radiometer effect would disappear To make the effect negligible it was however necessary to remove practically the whole of the residual gas which was by no means an easy matter to accomplish Sir James Dewar had however prepared for him a radiometer in which the vacuum was so good that the radiometer effect was absent This was done by forming the radiometer bulb with a small narrow branch containing charcoal and immersing this stem in liquid air

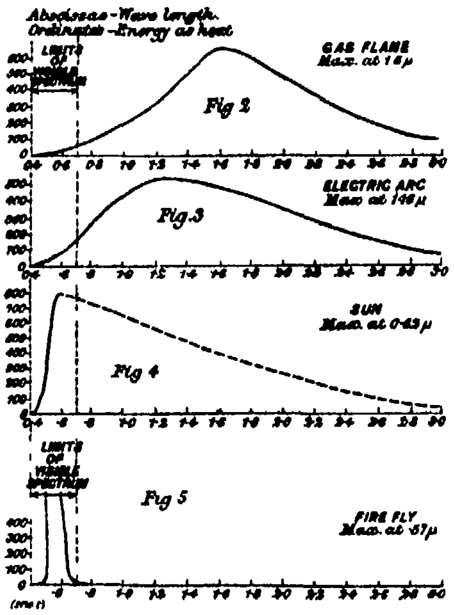
The lecturer then showed that on exposing this radiometer and an ordinary one to the same source of light the vanes in the former remained stationary while the latter spun round rapidly On next removing the vessel of liquid air from the stem already mentioned and thus allowing the charcoal to warm up the mercury vapor then liberated inside the bulb was sufficient to set the vanes in rotation while on replacing the liquid air they again came to rest as the vacuum became perfected by the condensation of the mercury vapor in the pores of the cooled charcoal A vapor pressure of less than $\frac{1}{100\,000\,000}$ of an atmosphere was the lecturer said sufficient to produce rotation of the vanes

Taking account of the existence of this light pressure it was possible he continued to prove as he had shown last week that the total amount of energy radiated from a black body must vary as θ^4 where θ denoted the absolute temperature This law he proceeded told us everything about the quantity of the radiation but nothing as to the influence of temperature on the quality of the radiation Here however the effect was even more marked than it was on the quantity By quality of radiation was meant he proceeded the character of the spectrum of the radiant energy If such energy were allowed to pass through a rock salt prism which was transparent to most kinds of radiation a spectrum was produced If the radiation proceeded from a very hot body such as the



Curve Showing the Distribution of Energy in a Spectrum Wave Lengths are Plotted as Abscissæ From Left to Right Energy Vertically Upward as Ordinates Note the Very Abrupt Falling off For the Short Wave Lengths

lime in the lime light a certain amount of the spectrum would be visible to the eye which could see a certain distance towards the red end of the spectrum and also for a certain distance towards the violet In the case taken however this visible portion was a very minute fraction of the whole radiation In fact the visible spectrum covered only about one octave the longest wave-lengths visible being 0 7 μ and the shortest about 0 4 μ where μ represented $\frac{1}{1000}$ millimeter On the other hand Rubens and Woods had recently demonstrated the existence of waves having a length equal to 108 μ—that was to say comparable with $\frac{1}{10}$ millimetre—and there was no reason to believe that this was a limiting value Probably indeed a hot body sent out radiations the wave-lengths of which extended to infinity in both directions It was interesting he said, to determine the distribution of energy in such a spectrum This could be done by moving



Curves Showing Energy Distribution in Light From Different Sources Only Radiation to the Left of the Dotted Line is Visible Note That *all* the Radiation From the Fire Fly is Visible But Only a Very Small Proportion of the Light From All Other Sources

a very fine platinum wire from point to point of the spectrum and then measuring electrically the temperature it acquired at each point This procedure gave an indication of the energy distribution and if the results were plotted against wave lengths as abscissæ a curve such as that indicated in Fig 1 was obtained in which the verticals were proportional to the energy of the *radiation of corresponding* wave length This reached a maximum at a particular value of the wave length and as would be seen the curve tumbled down from this maximum extremely rapidly on the side of the shorter wave lengths Curves such as the foregoing drawn for a number of radiating bodies were all similar in character but the position of the maximum ordinate moved very rapidly toward the side of shorter wave-length as the temperature rose The wave-length of maximum energy the speaker continued was connected with the temperature of the radiating body by the following equation

$$\lambda max\ \theta = 2940$$

where λmax denoted the wave length in μ and θ *the absolute temperature in Centigrade degrees*

Thus for the sun which had an absolute temperature of about 6 000 deg the wave-length of maximum energy was about ½ μ which lay in the yellowish green part of the spectrum At 16 deg C or 289 deg absolute the equation gave λmax = 10 μ nearly which was far beyond the visible portion of the spectrum the limit of which on the red side was about 0 75 μ corresponding to a dull crimson Hence increasing the absolute temperature from that of the lecture room to that of the sun shifted the wave-length of maximum energy from 10 μ to ½ μ

The relative amount of energy in different parts of the spectrum Sir Joseph continued varied more rapidly with change of temperature than did the total energy *If* the temperature of a body were raised from 300 deg absolute to 600 deg absolute (which was just below the limit of visibility) the total radiation would be multiplied by 16 but it by no means followed that the energy of each constituent of the spectrum was increased in the same ratio In fact by such a rise of temperature the energy in certain of the very short wave-lengths was multiplied by millions and in brief the multiplier was extraordinarily different in different parts of the spectrum

It was interesting the speaker continued, to note the abrupt fashion in which the energy curve tumbled down on the side of the shorter wave-lengths, and to exhibit this more strikingly he had prepared the following table showing the proportion of the total energy which lay to the left of the spectrum, having 1 8 μ as the wave-length of maximum energy

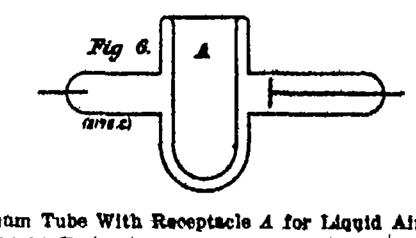
Wave-Length λ.	Energy in Waves Shorter than λ.
$\lambda_{max} = 1\ 8\ \mu$	$\frac{1}{4}$
$\frac{1}{2}\ \lambda_{max.}$	$\frac{1}{100}$
$\frac{1}{4}\ \lambda_{max}$	$\frac{1}{5000}$
$\frac{1}{10}\ \lambda_{max}$	$\frac{1}{1\,000\,000}$

Referring again to Fig 1 it would, the speaker continued be seen that by far the larger proportion of the energy lay on the side of the larger wave-lengths At higher temperatures however, the proportion of energy in the visible spectrum and on the ultra-violet side increased as was shown by the following figures

Absolute Temperature deg Cent	Proportionate Energy Lying Beyond λ = 0.7 μ	Proportionate Energy Lying Beyond λ = 0.5 μ
1500	$\frac{1}{15\,000}$	$\frac{1}{3\,000\,000}$
2000	$\frac{1}{100}$	$\frac{1}{125\,000}$
2500	$\frac{1}{37}$	$\frac{1}{163}$
3000	$\frac{1}{11}$	$\frac{1}{31}$
4000	$\frac{1}{3}$	$\frac{1}{13}$

It followed therefore that, in using an incandescent lamp with a filament at 1 500 only about $\frac{1}{15\,000}$ part of the total energy supplied was utilized as light the remainder being spent in heating up the bulb of the lamp If the filament were raised to 2 000 deg absolute then the energy lying on the short-wave side of the extreme red was 1 in 100 and 1 part in 13 000 lay beyond the yellowish green to which the eye was most sensitive With a temperature of 3 000 deg absolute one part in eleven of the total energy lay in the visible spectrum and when the temperature was 4 000 deg absolute nearly one-third of the energy lay to the left of the red extremity of the visible spectrum and one-thirteenth in the portion most useful for vision Thus with low temperature sources of radiation only about $\frac{1}{10\,000}$ of the energy was usefully applied with the carbon arc on the other hand having a temperature of about 4 000 deg nearly one-third was utilized It was on account of the higher temperature at which they could be run that metallic filament lamps were so much more efficient than the carbon filament lamps With the latter having a temperature of about 2 000 deg absolute only about 1 per cent of the energy served to produce light

To illustrate the small correlation between the total amount of energy radiated and amount utilizable for purposes of vision the lecturer next placed a thermopile between a limelight and a red hot ball each source heating an opposite face of the instrument He showed that in the conditions of the experiment the thermopile indicated that it received equal heat from the two sources when about midway between them Substituting then a photometer for the thermopile he showed that it was impossible under any condition to get a balance between the light from the ball and that from the limelight No matter how close the photometer was moved to the ball the side exposed to the limelight was always much the brightest showing that as a light producer the limelight was enormously the more efficient of the two radiators.



Vacuum Tube With Receptacle *A* for Liquid Air The Light Emitted is in no way Diminished by This Intense Cooling.

The temperature at which radiation first affected the eye was he said a matter of considerable interest No matter how carefully one might prepare the eye by previous sojourn in a dark room it was impossible to perceive by it any radiation from a body at the temperature of boiling water If the temperature were gradually raised, however, there came a stage pretty much the same for all bodies, and within narrow limits for all individuals, at which light was perceived All agreed that this first perception was not red though the sensation was differently described by different people. His own view was that this first

* Report taken from *Engineering*

perceivable radiation was not a color sensation at all in the sense in which we got colors at higher temperatures If the experiment were tried it would be noticed that the light was best seen when the source was looked at not directly but out of the corner of the eye. This circumstance he thought, gave a clue to what the nature of the first impression really was. In the retina there were two sets of structures—viz rods and cones—the latter being concerned in the sensation of color The rods apparently were affected by radiation slightly before the cones Hence the first effect of radiation as the temperature rose was on the rods only the impulse being insufficient to affect the cones. This explained why this first perception of light was best seen out of the corner of the eye In normal conditions the eye naturally focussed for the 'yellow spot which was the part most sensitive to color and consisted almost wholly of cones Thus if the rods were first affected the eye ought to perceive the radiation with the rods and not with the cones and the image should therefore be formed on the retina at a point where the rods were more plentiful and not on the yellow spot Evidently it would follow that animals which saw in the dark should cultivate rods rather than cones, and his zoologist friends informed him that the eye of the owl was remarkable for the extremely great proportion of rods as compared with cones Probably the owl might not in a faint light see any distinct color but it saw something good enough for its own purposes where ordinary mortals would see nothing

The sensitiveness of the eye to different colors the lecturer proceeded varied in a most extraordinary way Langley had made an estimate of the energy required to excite various color sensations Taking as unity the energy required to excite the sensation of a dull crimson red then $\frac{1}{100000}$ of this amount would suffice for the yellowish green It was remarkable that the sensitiveness of the eye to light was greatest for the wave length of maximum energy in the solar spectrum It would he said be interesting were it possible, to investigate whether the eyes of such animals as had remained unaltered for long geological periods had a maximum of sensitiveness to the light of the same color as we had If the sun s temperature had changed within the geological period covered by the life-history of such organisms it was possible that the latter would prove to have a maximum of sensitiveness for some color other than the yellowish green From the table already given above it would he continued be seen that the energy radiated from most incandescent bodies lay nearly all in the non luminous portion of the spectrum In the case of the arc light nine tenths of the energy supplied and paid for was wasted The ideal to aim at in illumination was the production of radiation confined to the color to which the eye was most sensitive Engineers had not yet succeeded in doing this but there were certain lowly animals which had solved the problem for themselves the firefly for example producing light most efficiently

The spectrum of the firefly had first been investigated by Langley whose results were very remarkable He had given the diagrams Figs 2 to 5 showing the amounts of total and of useful energy radiated from different sources Of these Fig 2 represented the energy distribution in the spectrum from a gas flame the useful portion of the energy lying to the left of the dotted vertical In the case of the firefly it would be seen that every bit of the energy radiated lay in the proper place nothing being wasted either in the production of heat or of ultra violet rays It seemed therefore that the future of lighting might lie in the finding of some substance capable when suitably excited of producing light like the glow worms without the expenditure of energy in long waves

That heat was not a necessary concomitant of light could he continued be shown by the following experiment The apparatus (Fig 6) used was a vacuum tube having a receptacle for liquid air formed in it at A On exciting this tube Prof Thomson showed that filling the cup A with liquid air in no way affected the production of the light There was no dark space formed near the walls of the cup though the temperature there must have been very little above that of the liquid air

The sensitiveness of the eye to small amounts of energy was the lecturer continued exceedingly remarkable In the greenish yellow the expenditure of $\frac{1}{100000000}$ of an erg could be distinguished by the eye If vision were due in the first place to chemical changes produced by the light it could be shown if these changes were of the same order as those to which we were accustomed in the laboratory that the amount of matter decomposed by this amount of energy could not exceed a few thousand individual molecules The eye must therefore be extraordinarily efficient in detecting chemical changes if this were actually what it did do in the act of seeing On the other hand others held that chemical actions were not involved but that in the eye there were systems capable of taking up any kind of vibration and being set into resonance by it If the action were primarily chemical the fact that the changes were produced only by light of short wave length constituted a difficulty There was however one view of light on which this difficulty would not arise and this was coming into favor with many physicists who held that radiation was built up of a number of different units of energy somewhat resembling the particles in the old corpuscular theory The energy of the light was concentrated into these individual units the amount in each unit being more the shorter the wave-length of the light If this were so it would be easy to understand how it was that chemical action was excited by light of short wave length only If the change in question required more energy than an individual unit contained it would not be effected and as the units corresponding to the shorter wave lengths contained the most energy it was with these that chemical activity should be associated

(To be continued)

A New System of Perforating Metal

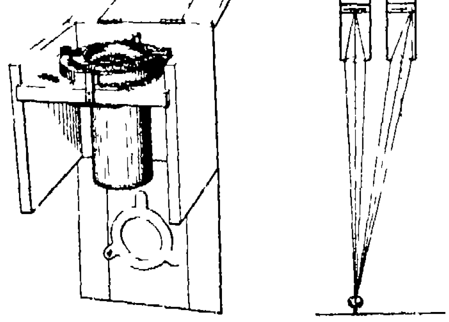
Andrew Smith's Improvement

A FEW years ago Andrew Smith a mechanical engineer of San Mateo California had under his supervision the construction of a number of water wells It was found by him in common with all engineers that the difficulty of using the ordinary well casing was almost insurmountable A number of attempts to improve the methods of making perforated casing were made by him the object being directed to get a definite water area through the use of inner and outer slotted tubes These attempts were governed to the well-established rule that sheet metal cannot be punched with a punch narrower than the thickness of the metal These tubes were so placed as to provide openings sufficiently small to prevent the ingress of fine sand and silt While this was a distinct advance in the art of constructing water well casings the results were not fully satisfactory to the experimenter for he felt that the same result should be obtained with a single tube casing

Further experimentation proved that an entirely new process of perforating metal had been developed and that by this process sheet steel one-half an inch thick could be perforated with slots one thousandth of an inch wide by any desired length or that a slot of any desired width could be made While developing the new process of perforating metal most of the leading metal perforating establishments in the United States were consulted Some went so far as to say that the feat was impossible others that it was impracticable while still others stated that the inquirer was wasting time in trying to solve the problem

The invention in common with many other important discoveries is very simple when it is known how it is done The old way of cracking the metal with a sharp chisel to make slots narrower than the thickness of the metal left rough jagged openings and bulged the metal outwardly This outwardly bulged metal was exposed to corrosions and made the casings difficult to drive because of the great resistance of the projections The first attempt made by Mr Smith to obtain a casing with slots of the required width resulted in a clean-cut shear by depressing one edge of the metal a little more than its thickness thereof, thus producing a smooth opening not at all like the old cracked perforation This style of perforated metal can be used, for example in shallow water wells, drain tiling or irrigating pipes

The step having been taken and the sheet actually sheared to produce the given slots, the next step was to make a clean-cut shear by depressing the sheet metal in opposite directions on each side of the slot to be produced thus reducing the distortion of a given portion of the metal sheet After being so sheared the projecting lips can be cut again or upset to make an opening of any desired size whereupon the projecting lips may be rolled back into the plane of the sheet leaving it perfectly smooth It is also possible to produce openings by making a clean



A COMPASS FOR BALLOONS

cut shear first and then rolling the projecting portions back into the plane of the sheet the uncut portions between series of slots being rolled enough to stretch the metal to make the openings This latter process is the most ingenious part of the new invention for the reason that the perforating can be done by having suitable dies in rolls or in a gang punch ing machine As soon as the plate has been passed through the rolls or gang punch the sheet may be passed through another set of rolls which rolls the lips back into place and stretches the metal the proper amount

This process does away with the use of fine saws fine milling or fine punches such as were required by the old processes and results in saving considerable money for tools alone since each tool used is very strong and withstands an enormous amount of wear

Two of the most important uses for this perforated metal lie in the water and oil well casing fields The first requires a very fine casing to prevent sand from passing into the well and the latter requires a very strong and heavy casing to prevent injury thereto each of which conditions may be adequately met by this process

Another form of the casing is produced by depressing the casing with a sufficiently large punch to form a clean cut shear after which one edge of the depressed lip is cut at an angle to the first cut so that when the metal is returned to the general plane of the plate a V shaped slot is formed The advantage of such fine V shaped perforations cannot be over-estimated Where the oil or water sands are struck the gas oil or water enters the perforations at once and therefore equalizes the pressure and prevents the sands from heaving up in the casing When the casing has been put down the required depth the well casing itself acts as a strainer and it retains at the narrowest portion of the V shaped slots all fine material any material passing into the casing not being retained by said slots since the narrowest portion is at the outer circumference thereof Such a casing has more than ten times the capacity of the old cracked casing and it is much stronger for the reason that the metal is not broken transversely to the slots formed

A Compass for Balloons

DR. BESTELMEYER has invented a compass by which the direction and velocity of a balloon s flight can be determined in a very convenient and practical manner A transparent compass card with its needle is attached between two glass plates to the top of a wide aluminium tube which is swung on gimbals in the usual manner The lower end of the tube carries a lens by which an inverted image of the landscape is thrown on the compass card When the balloon is moving in any given horizontal direction the image of every point of the landscape moves across the compass card in the same direction as is shown in the diagram The pilot selects a point of the landscape which passes exactly under the center of the card and notes the point of the compass at which it leaves the circumference This observation gives the direction of the balloon s course The horizontal velocity of the balloon is determined by measuring with a stop-watch the time occupied by a point of the landscape in moving from the center of the compass card to the circumference of a circle of one centimeter radius which is inscribed on the card From this interval in combination with the height of the balloon obtained by other observations the velocity of the balloon is obtained by reference to a table

Romanized Typewriter Type

By Jacob Backes

It is part of every business education imparted with thoroughness on modern lines to learn how to produce or at any rate how are produced through the agency of several imitative processes facsimile and form letters which when filled in with names and addresses on a real typewriting machine with matching ribbon and skillful manipulation may serve the purpose of giving to each of the unsuspecting recipients of the letters the idea that the communication was directed to him only

On the other hand the ability to quickly discern the really and individually typewritten letter in the morning mail is also a very useful part of that same kind of modern education

A well executed form letter is in a way a flower of applied knowledge The grammar spelling diction and general politesse of the average form" letters are distinctly better than those of the average individually written letter No form letter coming to the notice of the writer ever contained offense in the lines or between them

The increase in the fac-simile expert s ability to create simulative favors and the antagonistic development in the mail clerk of those apprehending faculties by the exercise of which such productions may be immediately recognized are comparable to the increasing size and projective force of modern missiles of destruction which step by step bear a certain and unmistakable relation to the improvement in the processes or appliances by which munizers are created or defensive armor is thickened and toughened

Recent developments in typewriter technique and performance threaten still further complications The army which makes use of the machine has literally become millioned and astute manufacturers have found that among this array of users are many typists unable to summon enthusiasm for the conventional pattern and apparence of typewriter characters These particularists existing and vociferous from the very advent of the machine have become numerous enough to be regarded by powerful typewriter organizations as worthy of special catering Result an output and increasing sale of machines equipped with types -variantly trade known as Imperial Clarendon Printype so fairly simulating customary printers typographical outlines and shadings that recipients oftentimes—so experience has proved have without perusal thrown away letters typed with such characters under the impression that they were common printed circulars

It certainly is food for thought that the better the wording arrangement and layout of a letter is and the more correctly and smoothly it is typed the more likely is it to look like a form letter and to

outside of their employment, and they have se
invented in the typewriter line. I have figure
clined to think that I would not come up to yc
calue I was given to understand that the Fil
typewriter to compete in the general field of t
it up, if they secured the right machine. They

SAMPLE SHOWING HOW THE TYPEWRITER CAN IMITATE PRINTED CHARACTERS THE LATEST ADVANCE

luminative citations from a circular

Messrs Ambitious Printers

The work of typewriters using large type is closely imitated by using our 12 point new model ——— ——— No 3 There are hundreds of job presses running constantly on this typewriter work in the large cities The rapid increase in the mail order business and use of follow up systems has created an enormous demand for this work and no hustling printer can afford to overlook this source of profit

This is our new model ——— ——— No 3 printed through silk All our typewriter faces are made from dies furnished by the makers of the typewriter and duplicate the typewritten work If you wish to match the work of any typewriter not mentioned here send us a sample and we can undoubtedly furnish the type you want

If the addresses are to be filled in on a typewriter have the strenographer write a sample letter Use this as a color sheet and have the pressman work to it You can vary the depth of color on the press and not on the typewriter Hence the pressman must work to the typewritten sheet When addresses are not inserted this typewritten color sheet is not necessary etc

A few specimens are herewith shown of what has been and is being accomplished by peculiar typewriting contrivances It is seen that so well do printers imitate typewriting and so well can typewriting be done to imitate printing that any distinction which may have formerly existed between printers characters and epistolary type has been submerged in the rising tide of imitation

Incorrect notions are abroad of the versatility with which the genius of the manufacturer has endowed and will further continue to endow typewriter mechanisms In times past with the scarcer population and relatively little appreciation or understanding of mechanographical latencies it was enough to make machines of limited range of performance and severe typographical restrictions At present there is a universal market for them and a legion of critical yet appreciative users which legion is divided and subdivided and yet again into sections requiring special things to be done and in a special way and to these purchasing divisions each larger than the integer of not many years ago the keen-sighted inventor finds it profitable to turn observant eyes

Elephant Domestication in Africa

While elephants are trained and commonly used for various purposes in Asia it appears that in Africa there is as yet but little attention paid to this question Some points about elephants in Africa and the great need of employing them so as to obtain a valuable aid have been brought out by Capt. Devedeix, a French cavalry officer, commanding the native troops of the Chari Tchad region. With forty-two of the cavalry he made a brilliant raid in the Ouadai region not long since and is well able to speak about the present subject. How to supply the French troops of the Lake Tchad and Ouadai regions is becoming a very important question, and he proposes to use the African elephants for this purpose so as to replace the native carriers Such work is very trying for the natives and often shortens their life, so that humane reasons are one of the points in favor of this.

Besides this reason there are somewhat numerous advantages to be gained by training elephants for domestic work It is estimated that at present the number of elephants in Africa is 300 000 or 400,000, but it must not be forgotten that we are exterminating 50,000 every year so that before many years the elephant will become extinct, like the American bison for in the case of the elephant, its reproduction is far from keeping pace with the great slaughter of these animals which is now going on It is likely that different regulations will be made in the future to try to stop this rapid killing off of the African elephant and in fact some such decrees have already been issued in this country showing that attention is being awakened to conditions. Special societies are even formed for preserving the elephant. Capt. Devedeix thinks that the example of Asia should be followed and there is no reason why the elephants should not be trained so as to give a very good means of transport especially as this is very much needed in the Congo region which is the part of Africa under consideration at present In this country the imported pack animals die off rapidly from marsh fever or lack of proper care But the elephant is well adapted to replace pack horses or mules, by reason of its being accustomed to the climate and besides its very long life of over a hundred years Its force is ten times as great as the strongest of the other animals and the remarkable intelligence of the elephant is proverbial Not only can it be used for carrying loads but at the same time it opens up routes through the dense forests

In the Belgian part of Congo steps have been already made toward training elephants and the first work of the kind is carried out at the recently opened elephant farm at Appi where there are fifty or more elephants now and many more are to be added before long The idea is due to a French officer in the first place but it was the Belgian government which took the first steps to laying out an elephant farm on a large scale in the Congo under Com Laplume At present the fifty elephants are well domesticated and are used for cultivating the

A PRINTED APPEARANCE IS PRODUCED BY USING A SPECIAL NARROW SPACING BETWEEN WORDS

soil drawing wagons or carrying loads. Not long ago the first long trip across the country was made by one of the teams belonging to the farm, composed of eight animals and they covered more than 400 miles, returning home in very good condition. In order to proceed with training a greater number of animals, it was decided to send experts to India and Ceylon so as to observe the methods of capture and domestication which are used there. After this it is intended to begin, not only with young elephants, but also with adults as well The elephant is still abundant in the Congo region and in the neighborhood of Lake Tchad, and owing to the increasing needs of transportation it is desirable that some more be made toward establishing elephant farms in many places and on a large scale, as there [illegible]

[illegible] African region should be deprived of the [illegible] services rendered by these animals such as [illegible] so strikingly in India.

This condition of things is especially true in the regions where there are no railroads and such could only be built at an enormous cost and even pack animals are lacking. Native porters are all that is to be seen in such regions for carrying loads and supplying the troops Besides should elephants be used the natives would be free to take up agricul ture for which there is need of labor at present Again the natives themselves would soon be led to domesticate the animals stimulated by the high prices which wo ild be offered For instance an elephant when killed does not bring more than $60 or $80 while as in India the value of a trained animal is no less than $800 to $1 000 After this it remains to domesticate other African animals especially the zebu and also the hippopotamus which is now em ployed on rice plantations in other countries as well as the ostrich and the antelope

The Morane Monoplane

Scale Drawings of the Machine that Won the Paris-Madrid Race

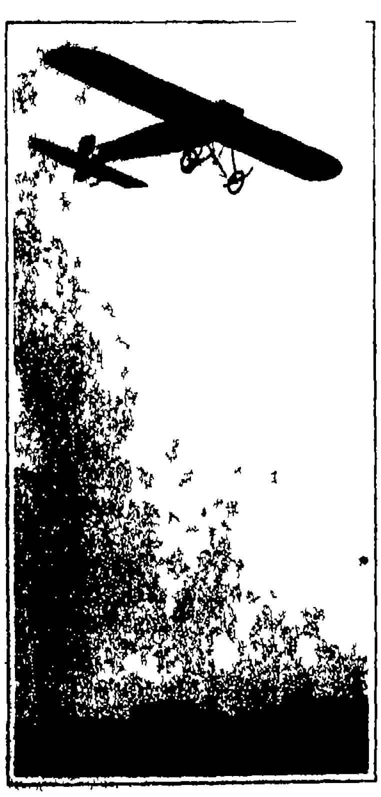
By John Jay Ide

One of the most successful aeroplanes which have made their appearance recently is the Morane mono plane This machine was designed by Leon Morane in collaboration with Ralph Saulnier formerly as sociated with Louis Blériot Morane first appeared

VEDRINES THE WINNER OF THE PARIS MADRID RACE AT 60 MILES AN HOUR

in the public eye last summer at Reims where he broke the world s records for five ten and twenty kilometers with the 100 horse power Blériot XI bis *type de course* He also drove one of the Blé iot XI bis two-seaters which made their debut a few weeks previously He used this same achine at Bourne mouth and it was with a similar model equipped with a 100 horse power motor that he and his brother made their disastrous attempt last October to win the Paris-Puy de Dôme prize Thus ended Morai e s ex perience with the Blériot machine

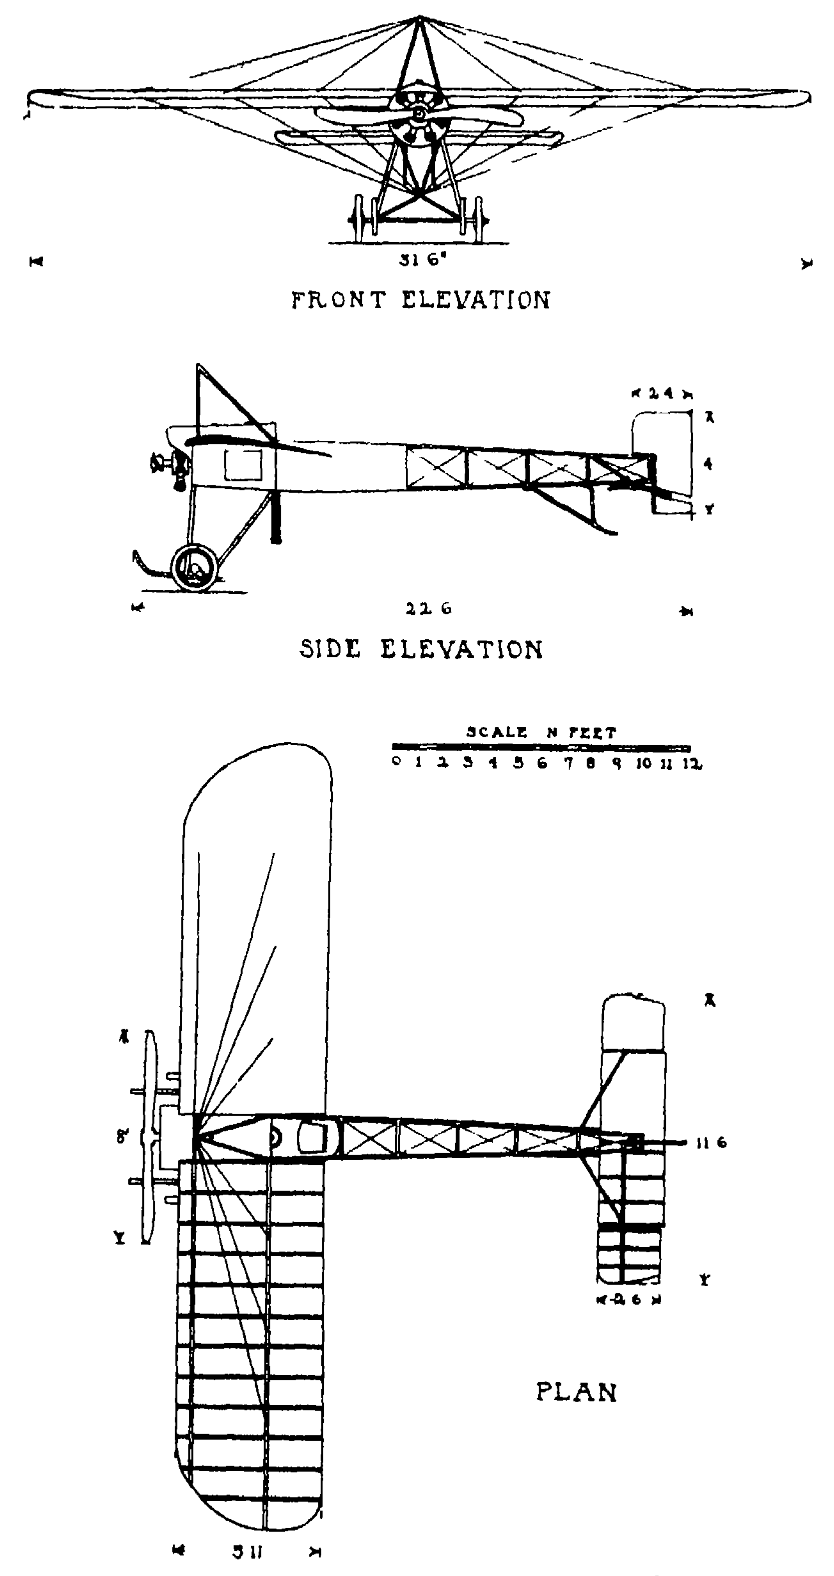
While prevented from flying as a result of his acci



VEDRINES IN FLIGHT

dent, Morane with the aid of M Saulnier designed a monoplane which although broadly resembling the Blériot, has several original features One of the essential points of difference between the two machines is the landing chassis In the Morane the chassis consists of two very short skids curved up in front so as to protect the tractor screw and joined solidly to the fuselage by four main struts. By means of rubber rings the skids are joined to the axle, which carries the two wheels placed five feet three inches apart The total weight of the undercarriage is only forty two pounds and yet its strength may be realized by the fact that it has repeatedly withstood the shock of landing on l ad ground at speeds of over eighty miles an hour with the wind

A further difference between the Blériot and he Morane is in the entire suppression of the dihedral angle between the wings of the latter This has been done with a view to obtaining increased speed For the same purpose the wings have been made very flat on the underside and the point of maximum camber is very near the leading edge It will also be noticed that the shape of the extremities of the wings has been radically altered. The mast carrying the upper wing stays is pyramidal and so arranged that t e support at he front is more at right angles to the wings and so bet er protects the spars from over stress The rudder is divided into two sections by t e stabilizing tail j s forward of which is he light double skid



SCALE DRAWINGS OF THE MORANE MONOPLANE

With a view to re lucing wind resistance part of t e fuselage which is quadrangular in section has been covered in with fabric The pilot sits behind a long bonnet inclosing the tanks and extending over the engine By this means he is protected from the spray of oil incidental to the employment of a re volving motor which in this case is a 50 horse power Gnome driving a Chauvière Intégrale tractor screw eight feet in diameter and five feet eleven inches in pitch At 1 100 revolutions per minute this

combination has driven the machine at a speed of seventy miles an hour officially timed on a closed circuit

The leading dimensions are as follows Span 31 feet 6 inches length 22 feet 6 inches The total carrying surface is 188 square feet of which 151 are accounted for by the wings the remaining 37 being in the stabilizing tail The machine weighs 440 pounds empty which shows with what great care the question of lightness has been studied moreover this result has not been reached at the expense of strength and from the point of view of solidity the Morane monoplane can compare with any

When the Morane was first brought out Aubrun was taken over from Blériot and became the chief pilot When he left to join the Deperdussin firm Pierre Védrines was selected to fill the position Védrines had been chief mechanic to Mr Robert Loraine the actor aviator and later had distinguished himself by some fine cross country flights on a Goupy biplane On becoming chief pilot of the Morane Védrines promptly did some more cross country work flying from Pau to Toulouse Carcassone and other places in the south of France where hitherto little or no flying had been seen Late in March he set out to fly from Paris to Pau but got lost in a fog On the 30th of the month he did the famous Poitiers Paris trip of 210 miles in two hours and twelve minutes at a speed of over ninety miles per hour with a twenty-mile wind It was this feat which first brought the Morane to the attention of the American public On April 22nd Védrines made another attempt on the Paris Pau prize and this time he succeeded in winning it He covered the course of 500 miles in three stages His actual flying time was six hours and fifty five minutes which gives a speed of 72 28 miles an hour

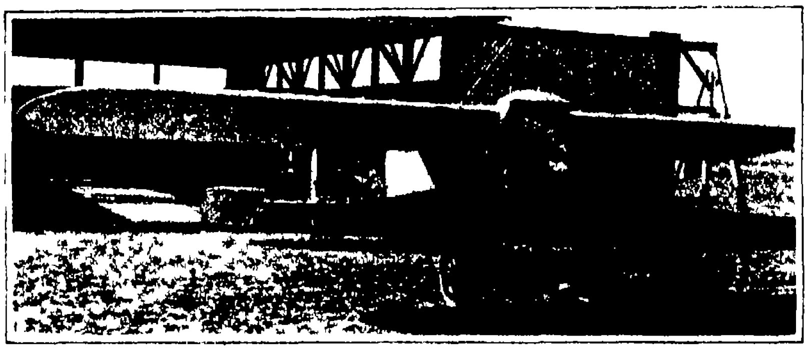
The above flights were however completely over shadowed by the wonderful performance of the Morane in the Paris Madrid race which started on May 21st under such tragic circumstances Védrines who left Paris the day after the start won the first stage Paris Angoulême the second stage Angoulême San Sebastian and was the only entrant to reach Madrid thus winning the prize of $20 000 offered by Le Petit Parisien

In the Paris Rome Turin race three Morane monoplanes were entered Two of them one driven by Vedrines and the other by Caget quit the race Andre Frey however continued He started from the aerodrome at Buc on May 28th and arrived at Dijon (16_ miles) the reporting station at 7 11 o clock in the evening He resumed his course at 4 16 A M toward Lyons arriving there at 7 43 A M covering the distance of 108½ miles in 3 hours 27 minutes At 8 45 he started again for Avignon (127 miles south) which place he reached at 12 05 o clock P M on the 29th He left Avignon at 5 35 A M arriving at Genoa shortly after 6 o clock on the 30th—requiring 12 hours 45 minutes time

On May 31st Frey left Genoa with high hopes of overtaking the leaders But in this he was not successful At Pisa he mistook a racecourse decorated with flags for the San Rossare aerodrome and he landed so heavily that the machine turned complete somersaults and was so badly damaged that Frey had to send for a new one from Paris Frey arrived in Rome on June 7th

On Tuesday June 13th the German aviator set out to complete the last leg of the journey He was warned against the attempt but paid no heed to warning and started out in spite of the fact that other competitors who had intended to start also withdrew on account of a threatening sky When but a short distance from Rome he encountered heavy fog that confused him and soon lost his way sailing into a terrific storm of rain wind and hail He endeavored to ascend above the clouds but his machine refused to rise and suddenly and unexpectedly it swooped downward all control of it being lost by Frey He was in the mountainous country between Viterbo and Rome when his aeroplane fell into a ravine, burying him under the debris. The fact that he wore a heavy helmet saved him from a gruesome, instantaneous death and the fact that he landed on soft marshy ground His arms and left leg were broken and his face badly cut

A number of searching parties set out to find him including the Passionist monks from the monastery on Monte Fogliana who know every foot of the mountainous country Also a number of reporters at the Camorra trial formed a party in search for him He was found by the Red Cross searchers in an unconscious condition under the debris of his machine



FRONT VIEW OF MORANE MONOPLANE FITTED WITH A GNOME MOTOR

Cold Storage

By H E Barnard

The preservation of food stuffs so that the surplus created during seasons of plenty could be distributed throughout the year and the fresh products of one country shipped to another was at one time impossible The use of chemical preservatives which arrested decomposition served in a measure to supply the need but this doubtful method of retarding the natural spoilage of foodstuffs has given way almost entirely with the development of methods of refrigeration which make it possible for foods of every character to be placed in cold storage and there held for considerable periods without apparent change in composition or structure Cold storage is simply the placing of foodstuffs in rooms kept at a sufficiently low temperature to hold the goods in normal condition until such time as these are needed for consumption This temperature varies from a point several degrees above freezing to zero and below Certain goods such as fruits which can not well be frozen can be kept without any spoilage for months at a temperature of about 34 deg F while butter and meats are stored at a temperature ranging from below zero to freezing Poultry is usually stored at a temperature varying from 0—25 degrees Cheese supposed by manufacturers to cure or ripen in storage is usually held at a temperature slightly above freezing Cold storage at suitable temperatures undoubtedly improves certain foodstuffs up to a certain point This is especially true in the case of fresh meats poultry and fruits Other products do not improve in storage and after a time begin to deteriorate even when kept at temperatures which inhibit to a large extent the ordinary processes of fermentation and decay

The investigations of the United States Department of Agriculture on the effect of cold storage on eggs poultry and game have been carefully worked out and have developed much data which throw a new light upon the results of storage at low temperatures In general the results of the studies show that cold storage when properly used is a very valuable improvement in the methods of the conservation and distribution of the food supply and that the term cold storage as applied to foods is in no sense a mark of inferiority or low grade

It is true that time limits are well established beyond which goods should not be kept in storage and that if such foods as eggs fish or poultry are held for a longer period deterioration at first slight and later marked takes place But such time limits are sufficiently long to carry the products until the natural season of scarcity is past and in fact carrying charges insurance and interest on the money invested does not except under most unusual conditions make it profitable for the warehouse men to hold goods longer

Food prices have been advancing rapidly and in part at least this has been attributed to the increasing practice of holding foodstuffs in storage and because of this fact as well as because of the impression that they are of poor quality cold storage foods are viewed with disfavor by the consumer This feeling coupled with the constantly increasing tendency to throw additional safeguards around the food supply has prompted the introduction of cold-storage bills in many of the State legislatures In one State at least, namely Indiana, such a bill has been enacted into law The bills up for consideration in the various States vary widely in character and on the whole show a great lack of information as to the purpose and practices of cold storage. In some measures the time limit placed upon the storage of foodstuffs is so short that the passage of such a law would demoralize the produce business and instead of reducing prices on food stuffs would bing a return of former conditions of plenty during the season and scarcity throughout the rest of the year

The Indiana statute is entitled "An Act for the protection of the public health and the prevention of fraud and deception by regulating cold storage and refrigerating warehouses, the holding of food products stored therein and the sale of such products.' It requires that foodstuffs which are entered into cold storage shall be marked with the date of entry and that when withdrawn for sale they shall show the date of removal. All foods products placed in cold storage shall be withdrawn at the end of nine months. It is provided however that such goods shall be subject to inspection as to their sanitary condition and that if the goods are found unfit for food they shall be destroyed The authorities are furthermore instructed to condemn and close any warehouse which is not kept in a sanitary conditions This measure does not discriminate against cold storage goods in favor of goods which have been so kept but it does provide that the purchaser of eggs poultry or meat may know how long the goods have been in storage Another section providing that the warehouse records shall be subject to inspection and so making it possible to determine the amount of goods held in storage will have a tendency to regulate the too frequent practice of speculation in the food supply

During the past year foodstuffs notably eggs and meat have commanded very high prices although there was in cold storage an adequate supply of both products. The fact that the owners of much of these goods were obliged to sell at a loss and in many instances were driven into bankruptcy at the close of the season does in no way compensate the consumer, who during most of the months of the year paid high prices for foodstuffs although following the break in prices they for a short time were sold below their actual value

Cold storage is necessary to the conservation of food products It is to be hoped that the public will learn to appreciate more than now its value It should be regulated by practical laws which do not have for their purpose the destruction of the business but which are intended rather to put a stop to the practice of storing foods which are not suitable for refrigeration but which have even before entry into storage deteriorated or become unfit for food and to assure the withdrawal of all goods before they have been held sufficiently long to undergo partial spoilage Such legislation will also be of decided benefit to the cold storage industry as all products will be subject to inspection and to this extent at least the quality of cold storage foods will be guaranteed to the consumer

Snow's Radioactivity

Some interesting data have been gathered in France as a result of the study of the radioactivity of snow that fell at Boulogne during the past winter

It has been known for some time that newly fallen snow is radioactive but until the French scientists looked into the matter the subject was not examined closely

The investigators announce that snow quickly gathered after its descent to the earth is highly radioactive Radioactivity disappears almost entirely after the lapse of two hours however Snow which has fallen on the soil appears to retain its radioactivity a little longer than that which has come to rest upon the roofs of buildings

French Lithographic Pencils—Take of talcum 100 parts soap 83 parts, shellac 70 parts mastic 10 parts, lamp black 10 parts The making up of this mass is effected in the same manner as described for the English pencils
